

WORKING GROUP I CONTRIBUTION TO THE IPCC FIFTH ASSESSMENT REPORT CLIMATE CHANGE 2013: THE PHYSICAL SCIENCE BASIS

Final Draft Underlying Scientific-Technical Assessment

A report accepted by Working Group I of the IPCC but not approved in detail.

Note:

The final draft Report, dated 7 June 2013, of the **Working Group I contribution to the IPCC 5th Assessment Report "Climate Change 2013: The Physical Science Basis"** was accepted but not approved in detail by the **12th Session of Working Group I and the 36th Session of the IPCC on 26 September 2013 in Stockholm, Sweden**. It consists of the full scientific and technical assessment undertaken by Working Group I.

The Report has to be read in conjunction with the document entitled "Climate Change 2013: The Physical Science Basis. Working Group I Contribution to the IPCC 5th Assessment Report - Changes to the underlying Scientific/Technical Assessment" to ensure consistency with the approved Summary for Policymakers (IPCC-XXVII/Doc.4) and presented to the Panel at its 36th Session. This document lists the changes necessary to ensure consistency between the full Report and the Summary for Policymakers, which was approved line-by-line by Working Group I and accepted by the Panel at the above-mentioned Sessions.

Before publication the Report will undergo final copyediting as well as any error correction as necessary, consistent with the IPCC Protocol for Addressing Possible Errors. Publication of the Report is foreseen in January 2014.

Disclaimer:

The designations employed and the presentation of material on maps do not imply the expression of any opinion whatsoever on the part of the Intergovernmental Panel on Climate Change concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries.

WGI-12 only and should not be cited, quoted, or distributed**

CORRIGENDA

The caption to Figure 3.16 in lines 3-4 should read:

%; the Sea of Japan (Park et al., 2006) ...+

Section 13.6.1 in paragraph 3, lines 2-3 should read:

% a sea level rise of $5.4 \pm 0.3 \text{ mm yr}^{-1}$ in the Sea of Japan from 1993 to 2001 is nearly two times the GMSL trend $\delta +$

DISCLAIMER TO BE INCLUDED IN THE FRONT MATTER OF THE REPORT:

The designations employed and the presentation of material on maps do not imply the expression of any opinion whatsoever on the part of the Intergovernmental Panel on Climate Change concerning the legal status of any country, territory, city or area or of its authorities, or concerning the delimitation of its frontiers or boundaries.

NOTE:

The Final Draft Underlying Scientific-Technical Assessment is submitted to the Twelfth Session of Working Group I for acceptance. The IPCC at its Thirty-sixth Session (Stockholm, 26 September 2013) will be informed of the actions of the Twelfth Session of Working Group I in this regard.

TS.1 Introduction

"*Climate Change 2013: The Physical Science Basis*" is the contribution of Working Group I to the Fifth Assessment Report of the Intergovernmental Panel on Climate Change. This comprehensive assessment of the physical aspects of climate change puts a focus on those elements that are relevant to understand past, document current, and project future climate change. The assessment builds on the IPCC Fourth Assessment Report (AR4)¹ and the recent Special Report on Managing the Risk of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX)² and is presented in 14 Chapters and 6 Annexes. The chapters cover direct and proxy observations of changes in all components of the climate system, they assess the current knowledge of various processes within, and interactions among, climate system components, which determine the sensitivity and response of the system to changes in forcing, and they quantify the link between the changes in atmospheric constituents, and hence radiative forcing³, and the consequent detection and attribution of climate change. Projections of changes in all climate system components are based on model simulations forced by a new set of scenarios. The report also provides a comprehensive assessment of past and future sea level change in a dedicated chapter. Regional climate change information is presented in the form of an Atlas of Global and Regional Climate Projections (Annex I). This is complemented by Annex II: Climate System Scenario Tables and Annex III: Glossary.

The primary purpose of this Technical Summary is to provide the link between the complete assessment of the multiple lines of independent evidence presented in the 14 chapters of the main report and the highly condensed summary prepared as the WGI Summary for Policymakers. The Technical Summary thus serves as a starting point for those readers who seek the full information on more specific topics covered by this assessment. This purpose is facilitated by including pointers to the chapters and sections where the full assessment can be found. Policy-relevant topics, which cut across many chapters and involve many interlinked processes in the climate system, are presented here as Thematic Focus Elements, allowing rapid access of this information.

An integral element of this report is the use of uncertainty language that permits a traceable account of the assessment (see Box TS.1). The degree of certainty in key findings in this assessment is based on the author teams' evaluations of underlying scientific understanding and is expressed as a level of confidence that results from the type, amount, quality, and consistency of evidence and the degree of agreement in the scientific studies considered⁴. Confidence is expressed qualitatively. Quantified measures of uncertainty in a finding are expressed probabilistically and are based on a combination of statistical analyses of observations or model results, or both, and expert judgment. Where appropriate, findings are also formulated as statements of fact without using uncertainty qualifiers (See Chapter 1 and Box TS.1 for more details).

[START BOX TS.1 HERE]

Box TS.1: Treatment of Uncertainty

Based on the Guidance Note for Lead Authors of the IPCC Fifth Assessment Report on Consistent Treatment of Uncertainties, this WGI Technical Summary and the WGI Summary for Policymakers rely on two metrics for communicating the degree of certainty in key findings, which is based on author teams' evaluations of underlying scientific understanding:

¹ IPCC, 2007: *Climate Change 2007: The Physical Science Basis*. Contribution of Working Group I to the Fourth Assessment Report of the Intergovernmental Panel on Climate Change [Solomon, S., D. Qin, M. Manning, Z. Chen, M. Marquis, K.B. Averyt, M. Tignor and H.L. Miller (eds.)]. Cambridge University Press, Cambridge, United Kingdom and New York, NY, USA, 996 pp.

² IPCC, 2012: *Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation*. A Special Report of Working Groups I and II of the Intergovernmental Panel on Climate Change [Field, C.B., V. Barros, T.F. Stocker, D. Qin, D.J. Dokken, K.L. Ebi, M.D. Mastrandrea, K.J. Mach, G.-K. Plattner, S.K. Allen, M. Tignor, and P.M. Midgley (eds.)]. Cambridge University Press, Cambridge, UK, and New York, NY, USA, 582 pp.

³ Radiative forcing (RF) is a measure of the net change in the energy balance of the Earth system in response to some external perturbation. It is expressed in Watts per square meter ($W m^{-2}$), see Box TS.2.

⁴ Mastrandrea, M.D., C.B. Field, T.F. Stocker, O. Edenhofer, K.L. Ebi, D.J. Frame, H. Held, E. Kriegler, K.J. Mach, P.R. Matschoss, G.-K. Plattner, G.W. Yohe, and F.W. Zwiers, 2010: *Guidance Note for Lead Authors of the IPCC Fifth Assessment Report on Consistent Treatment of Uncertainties*. Intergovernmental Panel on Climate Change (IPCC).

- Confidence in the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and the degree of agreement. Confidence is expressed qualitatively.
- Quantified measures of uncertainty in a finding expressed probabilistically (based on statistical analysis of observations or model results, or expert judgment).

The AR5 Guidance Note refines the guidance provided to support the IPCC Third and Fourth Assessment Reports. Direct comparisons between assessment of uncertainties in findings in this report and those in the IPCC Fourth Assessment Report and the IPCC Special Report on Managing the Risk of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX) are difficult, because of the application of the revised guidance note on uncertainties, as well as the availability of new information, improved scientific understanding, continued analyses of data and models, and specific differences in methodologies applied in the assessed studies. For some climate variables, different aspects have been assessed and therefore a direct comparison would be inappropriate.

Each key finding is based on an author team's evaluation of associated evidence and agreement. The confidence metric provides a qualitative synthesis of an author team's judgment about the validity of a finding, as determined through evaluation of evidence and agreement. If uncertainties can be quantified probabilistically, an author team can characterize a finding using the calibrated likelihood language or a more precise presentation of probability. Unless otherwise indicated, high or very high confidence is associated with findings for which an author team has assigned a likelihood term.

The following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers very low, low, medium, high, and very high. Box TS.1, Figure 1 depicts summary statements for evidence and agreement and their relationship to confidence. There is flexibility in this relationship; for a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence.

[INSERT BOX TS.1, FIGURE 1 HERE]

Box TS.1, Figure 1: A depiction of evidence and agreement statements and their relationship to confidence. Confidence increases toward the top-right corner as suggested by the increasing strength of shading. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality. {Figure 1.11}

The following terms have been used to indicate the assessed likelihood:

Term*	Likelihood of the outcome
<i>Virtually certain</i>	99–100% probability
<i>Very likely</i>	90–100% probability
<i>Likely</i>	66–100% probability
<i>About as likely as not</i>	33–66% probability
<i>Unlikely</i>	0–33% probability
<i>Very unlikely</i>	0–10% probability
<i>Exceptionally unlikely</i>	0–1% probability

* Additional terms (*extremely likely*: 95–100% probability, *more likely than not*: >50–100% probability, and *extremely unlikely*: 0–5% probability) may also be used when appropriate.

[END BOX TS.1 HERE]

The Technical Summary is structured into four main sections presenting the assessment results following the storyline of the WGI contribution to AR5: Section TS.2 covers the assessment of observations of changes in the climate system; Section TS.3 summarizes the information on the different drivers, natural and anthropogenic, expressed in terms of radiative forcing; Section TS.4 presents the assessment of the quantitative understanding of observed climate change; and Section TS.5 summarizes the assessment results

for projections of future climate change over the 21st century and beyond from regional to global scale. Section TS.6 combines and lists key uncertainties from the WGI assessment from Sections TS.2–TS.5. The overall nine Thematic Focus Elements (TFEs), cutting across the various components of the WGI AR5, are dispersed throughout the four main TS sections, are visually distinct from the main text, and should allow stand-alone reading.

The basis for substantive paragraphs in this Technical Summary can be found in the chapter sections of the underlying report. These references are given in curly brackets.

TS.2 Observation of Changes in the Climate System

TS.2.1 Introduction

Observations of the climate system are based on direct physical and biogeochemical measurements, remote sensing from ground stations and satellites; information derived from paleoclimate archives provides a long-term context. Global-scale observations from the instrumental era began in the mid-19th century, and paleoclimate reconstructions extend the record of some quantities back hundreds to millions of years. Together, they provide a comprehensive view of the variability and long-term changes in the atmosphere, the ocean, the cryosphere, and the land surface.

The assessment of observational evidence for climate change is summarized in this section. Substantial advancements in the availability, acquisition, quality and analysis of observational data sets in atmosphere, land surface, ocean, and cryosphere have occurred since the AR4. Many aspects of the climate system are showing evidence of a changing climate.

TS.2.2 Changes in Temperature

TS.2.2.1 Surface

It is certain that Global Mean Surface Temperature (GMST) has increased since the late 19th century (Figure TS.1). Each of the past three decades has been warmer than all the previous decades in the instrumental record, and the decade of the 2000's has been the warmest. The global combined land and ocean temperature data show an increase of about 0.89°C [0.69–1.08]⁵ over the period 1901–2012 and about 0.72°C [0.49–0.89] over the period 1951–2012 when described by a linear trend⁶. The warming from 1850–1900 (early-industrial) to 1986–2005 (reference period for the modelling chapters and the Atlas in Annex 1) is 0.61°C [0.55 to 0.67], when calculated using HadCRUT4 and its uncertainty estimates. It is also *virtually certain* that maximum and minimum temperatures over land have increased on a global scale since 1950. {2.4.1, 2.4.3, Supplementary Material 2.SM.3}

Despite the robust multi-decadal timescale warming, there exists substantial interannual to decadal variability in the rate of warming, with several periods exhibiting weaker trends (including the warming hiatus since 1998) (Figure TS.1). Although the trend uncertainty is large for short records, the rate of warming over the past 15 years (1998–2012; 0.05°C per decade [–0.05 to +0.15]) is smaller than the trend since 1951 (1951–2012; 0.12°C per decade [0.08 to 0.14])⁶. Several independently analysed data records of global and regional land surface air temperature obtained from station observations are in broad agreement that land surface air temperature s have increased. Sea surface temperatures have also increased. Intercomparisons of new sea surface temperature data records obtained by different measurement methods, including satellite data, have resulted in better understanding of errors and biases in the records. {2.4.1, 2.4.2, 2.4.3; Box 9.2}

⁵ In the WGI contribution to the AR5, uncertainty is quantified using 90% uncertainty intervals unless otherwise stated. The 90% uncertainty interval, reported in square brackets, is expected to have a 90% likelihood of covering the value that is being estimated. The upper endpoint of the uncertainty interval has a 95% likelihood of exceeding the value that is being estimated and the lower endpoint has a 95% likelihood of being less than that value. A best estimate of that value is also given where available. Uncertainty intervals are not necessarily symmetric about the corresponding best estimate.

⁶ The warming is reported as an unweighted average based upon linear trend estimates calculated from HadCRUT4, MLOST and GISS datasets (see Figure TS.2; Section 2.4.3)

[INSERT FIGURE TS.1 HERE]

Figure TS.1: Multiple complementary indicators of a changing global climate. Each line represents an independently-derived estimate of change in the climate element. The time series presented are assessed in chapters 2, 3, and 4. In each panel all datasets have been normalized to a common period of record. A full detailing of which source datasets go into which panel is given in Chapter 2, Supplementary Material 2.SM.5 and in the respective chapters (See also FAQ 2.1, Figure 1). {2.4, 2.5, 3.2, 3.7, 4.5.2, 4.5.3}

[INSERT FIGURE TS.2 HERE]

Figure TS.2: Change in surface temperature over 1901-2012 as determined by linear trend for three data sets. White areas indicate incomplete or missing data. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). Differences in coverage primarily reflect the degree of interpolation to account for data void regions undertaken by the dataset providers ranging from none beyond grid box averaging (HadCRUT4) to substantial (GISS). {Figure 2.21}

It is *unlikely* that any uncorrected urban heat-island effects and land use change effects have raised the estimated centennial globally averaged land surface air temperature trends by more than 10% of the reported trend. This is an average value; in some regions that have rapidly developed urban heat island and land use change impacts on regional trends may be substantially larger. {2.4.1}

There is *high confidence* that annual mean surface warming since the 20th century has reversed long-term cooling trends of the past 5,000 years in mid-to-high latitudes of the Northern Hemisphere. For average annual Northern Hemisphere temperatures, the period 1983–2012 was *very likely* the warmest 30-year period of the last 800 years (*high confidence*) and *likely* the warmest 30-year period of the last 1400 years (*medium confidence*). This is supported by comparison of instrumental temperatures with multiple reconstructions from a variety of proxy data and statistical methods, and is consistent with AR4. Continental-scale surface temperature reconstructions show, with *high confidence*, multidecadal intervals during the Medieval Climate Anomaly (950 to 1250) that were in some regions as warm as in the mid-20th century and in others as warm as in the late 20th century. With *high confidence*, these intervals were not as synchronous across seasons and regions as the warming since the mid-20th century. Based on the comparison between reconstructions and simulations, there is *high confidence* that not only external orbital, solar and volcanic forcing, but also internal variability, contributed substantially to the spatial pattern and timing of surface-temperature changes between the Medieval Climate Anomaly and the Little Ice Age (1450 to 1850). {5.3.5, 5.5.1}

TS.2.2.2 Troposphere and Stratosphere

Based upon multiple independent analyses of measurements from radiosondes and satellite sensors, it is *virtually certain* that globally the troposphere has warmed and the stratosphere has cooled since the mid-20th century (Figure TS.1). Despite unanimous agreement on the sign of the trends, substantial disagreement exists between available estimates as to the rate of temperature changes, particularly outside the Northern Hemisphere extra-tropical troposphere, which has been well sampled by radiosondes. Hence there is only *medium confidence* in the rate of change and its vertical structure in the Northern Hemisphere extra-tropical troposphere and *low confidence* elsewhere. {2.4.4}

TS.2.2.3 Ocean

It is *virtually certain* that the upper ocean (above 700 m) has warmed from 1971 to 2010, and *likely* that it has warmed from the 1870s to 1971 (Figure TS.1). There is less certainty in changes prior to 1971 because of relatively sparse sampling in earlier time periods. Instrumental biases in historical upper ocean temperature measurements have been identified and mitigated since AR4, reducing artificial decadal variation in temperature and upper ocean heat content, most prominent during the 1970s and 1980s. {3.2.1, 3.2.2, 3.2.3, 3.5.3}

It is *likely* that the ocean warmed between 700 and 2000 m from 1957 to 2010, based on five-year averages. It is *likely* that the ocean warmed from 3000 m to the bottom from 1992 to 2005, when sufficient observations became available for a global assessment. No significant trends in global average temperature

were observed between 2000 and 3000 m depth for either overlapping time period. The largest changes in deep ocean temperature have been observed close to the sources of deep and bottom water in the northern North Atlantic and especially in the Southern Ocean with anomaly amplitudes lessening along the routes through which these waters spread. {3.2.4, 3.5.1}

TS.2.3 Changes in Energy Budget and Heat Content

Earth has been in radiative imbalance, with more energy from the sun entering than exiting the top of the atmosphere, since at least circa 1970. It is *virtually certain* that Earth has gained substantial energy from 1971–2010. The estimated increase in energy inventory between 1971 and 2010 is $274 [196 \text{ to } 351] \times 10^{21}$ J, with a heating rate of 213×10^{12} W from a linear fit to the annual values over that time period (see also TFE.4).

Ocean warming dominates that total heating rate, with full ocean depth warming accounting for about 93% (and warming of the upper (0–700 m) ocean accounting for about 64%). Melting ice (including Arctic sea ice, ice sheets, and glaciers) and warming of the continents each account for 3 of the total. Warming of the atmosphere makes up the remaining 1%. The 1971–2010 estimated rate of ocean energy gain is 199×10^{12} W from a linear fit to data over that time period, equivalent to 0.42 W m^{-2} heating applied continuously over Earth's entire surface, and 0.55 W m^{-2} for the portion owing to ocean warming applied over the ocean's entire surface area. Earth's estimated energy increase from 1993–2010 is $163 [127 \text{ to } 201] \times 10^{21}$ J with a trend estimate of 275×10^{15} W. The ocean portion of the trend for 1993–2010 is 257×10^{12} W, equivalent to a mean heat flux into the ocean of 0.71 W m^{-2} . {3.2.3, 3.2.4; Box 3.1}

The rate of ocean warming in some of the 0–700 m estimates was lower from 2003 to 2010 than in the previous decade (Figure TS.1); however, warming in the subsurface layer between 700 and 2000 m *likely* continued unabated during this period. {3.2.3, 3.2.4; Box 9.2}

TS.2.4 Changes in Circulation and Modes of Variability

Large variability on interannual to decadal time scales hampers robust conclusions on long-term changes in atmospheric circulation in many instances. *Confidence* is *high* that the increase of the northern mid-latitude westerly winds and the NAO index from the 1950s to the 1990s, and the weakening of the Pacific Walker circulation from the late 19th century to the 1990s, have been largely offset by recent changes. With *high confidence*, decadal and multi-decadal changes in the winter North Atlantic Oscillation index (NAO) observed since the 20th century are not unprecedented in the context of the past 500 years. {2.7.2, 2.7.5, 2.7.8, 5.4; Box 2.5; Tables 2.12}

It is *likely* that circulation features have moved poleward since the 1970s, involving a widening of the tropical belt, a poleward shift of storm tracks and jet streams, and a contraction of the northern polar vortex. Evidence is more robust for the Northern Hemisphere. It is *likely* that the Southern Annular Mode has become more positive since the 1950s. The increase in the strength of the observed summer Southern Annular Mode since 1950 has been anomalous, with *medium confidence*, in the context of the past 400 years. {2.7.5, 2.7.6, 2.7.8, 5.4; Box 2.5; Tables 2.2–2.12}

New results from high-resolution coral records document with *high confidence* that the El Niño-Southern Oscillation (ENSO) system has remained highly variable throughout the past 7,000 years, showing no discernible evidence for an orbital modulation of ENSO. {5.4}

Recent observations have strengthened evidence for variability in major ocean circulation systems on time scales from years to decades. It is *very likely* that the subtropical gyres in the North Pacific and South Pacific have expanded and strengthened since 1993. Based on measurements of the full Atlantic Meridional Overturning Circulation (AMOC) and its individual components at various latitudes and different time periods, there is no evidence of a long-term trend. There is also no evidence for trends in the transports of the Indonesian Throughflow, the Antarctic Circumpolar Current (ACC), or in the transports between the Atlantic Ocean and Nordic Seas. However, a southward shift of the ACC by about 1° of latitude is observed in data spanning the time period 1950 to 2010 with *medium confidence*. {3.6}

TS.2.5 Changes in the Water Cycle and Cryosphere

TS.2.5.1 Atmosphere

Confidence in precipitation change averaged over global land areas is *low* prior to 1950 and *medium* afterwards because of insufficient data, particularly in the earlier part of the record (for an overview of observed and projected changes in the global water cycle see TFE.1). Available globally incomplete records show mixed and non-significant long-term trends in reported global mean changes. Further, when virtually all the land area is filled in using a reconstruction method, the resulting time series shows little change in land-based precipitation since 1900. Northern hemisphere mid-latitude land areas do show a *likely* overall increase in precipitation (*medium confidence* prior to 1950, but *high confidence* afterwards). {2.5.1}

It is *very likely* that global near surface and tropospheric air specific humidity have increased since the 1970s. However, during recent years the near-surface moistening trend over land has abated (*medium confidence*) (Figure TS.1). As a result, fairly widespread decreases in relative humidity near the surface are observed over the land in recent years. {2.4.4, 2.5.5, 2.5.6}

While trends of cloud cover are consistent between independent data sets in certain regions, substantial ambiguity and therefore *low confidence* remains in the observations of global-scale cloud variability and trends. {2.5.7}

TS.2.5.2 Ocean and Surface Fluxes

It is *very likely* that regional trends have enhanced the mean geographical contrasts in sea surface salinity since the 1950s: saline surface waters in the evaporation-dominated mid-latitudes have become more saline, while relatively fresh surface waters in rainfall-dominated tropical and polar regions have become fresher. The mean contrast between high and low salinity regions increased by 0.13 [0.08 to 0.17] from 1950 to 2008. It is *very likely* that the inter-basin contrast in freshwater content has increased: the Atlantic has become saltier and the Pacific and Southern Oceans have freshened. While similar conclusions were reached in AR4, recent studies based on expanded data sets and new analysis approaches provide *high confidence* in this assessment. {3.3.2, 3.3.3, 3.9; FAQ 3.3}

The spatial patterns of the salinity trends, mean salinity and the mean distribution of evaporation minus precipitation are all similar (see also TFE.1, Figure 1). These similarities provide indirect evidence that the pattern of evaporation minus precipitation over the oceans has been enhanced since the 1950s (*medium confidence*). Uncertainties in currently available surface fluxes prevent the flux products from being reliably used to identify trends in the regional or global distribution of evaporation or precipitation over the oceans on the timescale of the observed salinity changes since the 1950s. {3.3.2, 3.3.3, 3.3.4, 3.4.2, 3.4.3, 3.9; FAQ 3.3}

TS.2.5.3 Sea Ice

Continuing the trends reported in AR4, there is *very high confidence* that the Arctic sea ice extent (annual, multiyear and perennial) decreased over the period 1979–2012 (Figure TS.1). The rate of the annual decrease was *very likely* between 3.5 and 4.1% per decade. The average decrease in decadal extent of annual Arctic sea ice has been most rapid in summer and autumn (*high confidence*), but the extent has decreased in every season, and in every successive decade since 1979 (*high confidence*). The extent of Arctic perennial and multiyear ice decreased between 1979 and 2012 (*very high confidence*). The rates are *very likely* 11.5 [9.4 to 13.6] % per decade for the perennial sea ice area at summer minimum and *very likely* 13.5 [11 to 16] % per decade for multiyear ice. There is *medium confidence* from reconstructions that the 1980–2012 summer sea-ice retreat and increase in sea-surface temperatures in the Arctic are anomalous in the last 2,000 years. {4.2.2, 5.5.2}

It is *likely* that the annual period of surface melt on Arctic perennial sea ice lengthened by 5.7 [4.8 to 6.6] days per decade over the period 1979–2012. Over this period, in the region between the East Siberian Sea and the western Beaufort Sea, the duration of ice-free conditions increased by nearly 2 months. {4.2.2}

There is *high confidence* that the average winter sea ice thickness within the Arctic Basin decreased between 1980 and 2008. The average decrease was *likely* between 1.3 m and 2.3 m. *High confidence* in this assessment is based on observations from multiple sources: submarine, electromagnetic probes, and satellite altimetry; and is consistent with the decline in multiyear and perennial ice extent. Satellite measurements made in the period 2010–2012 show a decrease in sea ice volume compared to those made over the period 2003–2008 (*medium confidence*). There is *high confidence* that in the Arctic, where the sea ice thickness has decreased, the sea ice drift speed has increased. {4.2.2}

It is *very likely* that the annual Antarctic sea ice extent increased at a rate of between 1.2 and 1.8% per decade between 1979 and 2012. There was a greater increase in sea ice area, due to a decrease in the percentage of open water within the ice pack. There is *high confidence* that there are strong regional differences in this annual rate, with some regions increasing in extent/area and some decreasing. {4.2.3}

TS.2.5.4 Glaciers and Ice Sheets

There is *very high confidence*—with a very few regional exceptions—that, since AR4, overall glaciers world-wide have continued to shrink as revealed by the time series of measured changes in glacier length, area, volume and mass (Figure TS.1, Figure TS.3). Measurements of glacier change have increased substantially in number since AR4. Most of the new datasets, along with a globally complete glacier inventory, have been derived from satellite remote sensing {4.3.1, 4.3.3}

There is *very high confidence* that, during the last decade, most ice was lost from glaciers in Alaska, the Canadian Arctic, the periphery of the Greenland ice sheet, the Southern Andes and the Asian mountains. Together these areas account for more than 80% of the total ice loss. Total mass loss from all glaciers in the world, excluding those on the periphery of the ice sheets, was *very likely* 226 [91 to 361] Gt yr⁻¹ (sea-level equivalent, 0.62 [0.25 to 0.99] mm yr⁻¹) in the period 1971–2009, 275 [140 to 410] Gt yr⁻¹ (0.76 [0.39 to 1.13] mm yr⁻¹) in the period 1993–2009, and 301 [166 to 436] Gt yr⁻¹ (0.83 [0.46 to 1.20] mm yr⁻¹) between 2005 and 2009⁷. {4.3.3; Tables 4.4, 4.5}

There is *high confidence* that current glacier extents are out of balance with current climatic conditions, indicating that glaciers will continue to shrink in the future even without further temperature increase. {4.3.3}

There is *very high confidence* that the Greenland Ice Sheet has lost ice during the last two decades. Combinations of satellite and airborne remote sensing together with field data indicate with *high confidence* that the ice loss has occurred in several sectors and that large rates of mass loss have spread to wider regions than reported in AR4 (Figure TS.3). There is *high confidence* that the mass loss of the Greenland Ice Sheet has accelerated since 1992: the average rate has *very likely* increased from 34 [–6 to 74] Gt yr⁻¹ over the period 1992–2001 (sea-level equivalent, 0.09 [–0.02 to 0.20] mm yr⁻¹), to 215 [157 to 274] Gt yr⁻¹ over the period 2002–2011 (0.59 [0.43 to 0.76] mm yr⁻¹). There is *high confidence* that ice loss from Greenland resulted from increased surface melt and runoff, and increased outlet glacier discharge, and these occurred in similar amounts. There is *high confidence* that the area subject to summer melt has increased over the last two decades. {4.4.2, 4.4.3}

[INSERT FIGURE TS.3 HERE]

Figure TS.3: Upper panels: distribution of ice loss determined from GRACE time-variable gravity for (a) Antarctica and (b) Greenland, shown in centimetres of water per year (cm of water yr⁻¹) for the period 2003 to 2012. Lower panel: the assessment of the total loss of ice from glaciers and ice sheets in terms of sea level equivalent (in mm). The contribution from glaciers excludes those on the periphery of the ice sheets. {4.3.4; Figures 4.12, 4.13, 4.14, 4.16, 4.17}

There is *high confidence* that the Antarctic Ice Sheet has been losing ice during the last two decades (Figure TS.3). There is *very high confidence* that these losses are mainly from the northern Antarctic Peninsula and the Amundsen Sea sector of West Antarctica, and *high confidence* that they result from the acceleration of outlet glaciers. The average rate of ice loss from Antarctica *likely* increased from 30 [–37 to 97] Gt yr⁻¹ (sea

⁷ 100 Gt yr⁻¹ of ice loss corresponds to about 0.28 mm yr⁻¹ of sea level equivalent.

level equivalent, 0.08 [−0.10 to 0.27] mm yr^{−1}) over the period 1992–2001, to 147 [72 to 221] Gt yr^{−1} over the period 2002–2011 (0.40 [0.20 to 0.61] mm yr^{−1}). {4.4.2, 4.4.3}

There is *high confidence* that in parts of Antarctica floating ice shelves are undergoing substantial changes. There is *medium confidence* that ice shelves are thinning in the Amundsen Sea region of West Antarctica, and *low confidence* that this is due to high ocean heat flux. There is *high confidence* that ice shelves around the Antarctic Peninsula continue a long-term trend of retreat and partial collapse that began decades ago. {4.4.2, 4.4.5}

TS.2.5.5 Snow Cover, Freshwater Ice and Frozen Ground

There is *very high confidence* that snow cover extent has decreased in the Northern Hemisphere, especially in spring (Figure TS.1). Satellite records indicate that over the period 1967–2012, snow cover extent *very likely* decreased; the largest change, −53% [−40% to −66%], occurred in June. No month had statistically significant increases. Over the longer period, 1922–2012, data are only available for March and April, but these show *very likely* a 7% [4.5% to 9.5%] decline and a negative correlation (−0.76) with March to April 40°N–60°N land temperature. In the Southern Hemisphere, evidence is too limited to conclude whether changes have occurred. {4.5.2, 4.5.3}

Permafrost temperatures have increased in most regions around the world since the early 1980s (*high confidence*). These increases were in response to increased air temperature, and changes in the timing and thickness of snow cover (*high confidence*). The temperature increase for colder permafrost was generally greater than for warmer permafrost (*high confidence*). {4.7.2, Table 4.8}

TFE.1: Water Cycle Change

The water cycle describes the continuous movement of water through the climate system in its liquid, solid and vapour forms, and storage in the reservoirs of ocean, cryosphere, land surface and atmosphere. In the atmosphere, water occurs primarily as a gas, water vapour, but it also occurs as ice and liquid water in clouds. The ocean is primarily liquid water, but the ocean is partly covered by ice in Polar Regions. Terrestrial water in liquid form appears as surface water (lakes, rivers), soil moisture and groundwater. Solid terrestrial water occurs in ice sheets, glaciers, snow and ice on the surface and permafrost. The movement of water in the climate system is essential to life on land, since much of the water that falls on land as precipitation and supplies the soil moisture and river flow has been evaporated from the ocean and transported to land by the atmosphere. Water that falls as snow in winter can provide soil moisture in springtime and river flow in summer and is essential to both natural and human systems. The movement of fresh water between the atmosphere and the ocean can also influence oceanic salinity, which is an important driver of the density and circulation of the ocean. The latent heat contained in water vapour in the atmosphere is critical to driving the circulation of the atmosphere on scales ranging from individual thunderstorms to the global circulation of the atmosphere. {12.4.5; FAQ 3.3, FAQ 12.2}

Observations of Water Cycle Change

Because the saturation vapour pressure of air increases with temperature, it is expected that the amount of water vapour suspended in air will increase with a warming climate. Observations from surface stations, radiosondes, global positioning systems, and satellite measurements indicate increases in tropospheric water vapour at large spatial scales (TFE.1, Figure 1). It is *very likely* that tropospheric specific humidity has increased since the 1970s. The magnitude of the observed global change in water vapour of about 3.5% in the past 40 years is consistent with the observed temperature change of about 0.5°C during the same period, and the relative humidity has stayed approximately constant. The water vapour change can be attributed to human influence with *medium confidence*. {2.5.4, 10.3.2}

Changes in precipitation are harder to measure with the existing records, both because of the greater difficulty in sampling precipitation and also because it is expected that precipitation will have a smaller fractional change than the water vapour content of air as the climate warms. When virtually all the land area

is filled in using a reconstruction method, the resulting time series shows little change in land-based precipitation since 1900. At present there is *medium confidence* that there has been a significant human influence on global scale changes in precipitation patterns, including increases in northern hemisphere mid to high latitudes. Changes in the extremes of precipitation, and other climate extremes related to the water cycle are comprehensively discussed in TFE.9. {2.5.1, 10.3.2}

Although direct trends in precipitation and evaporation are difficult to measure with the available records, the observed oceanic surface salinity, which is strongly dependent on the difference between evaporation and precipitation, shows significant trends (TFE.1, Figure 1). The spatial patterns of the salinity trends since 1950, the mean salinity and the mean distribution of evaporation–precipitation are similar to each other: regions of high salinity where evaporation dominates have become more saline, while regions of low salinity where rainfall dominates have become fresher (TFE.1, Figure 1). This provides indirect evidence that the pattern of evaporation-precipitation over the oceans has been enhanced since the 1950s (*medium confidence*). The inferred changes in evaporation minus precipitation are consistent with the observed increased water vapour content of the warmer air. It is *very likely* that observed changes in surface and subsurface salinity are due in part to anthropogenic increases in forcings. {2.5, 3.3.2, 3.3.3, 3.3.4, 3.4, 3.9, 10.4.2; FAQ 3.3}

[INSERT TFE.1, FIGURE 1 HERE]

TFE.1, Figure 1: Changes in sea surface salinity are related to the atmospheric patterns of Evaporation minus Precipitation (E-P) and trends in total precipitable water: (a) Linear trend (1988 to 2010) in total precipitable water (water vapor integrated from Earth’s surface up through the entire atmosphere) (kg m^{-2} per decade) from satellite observations. (b) The 1979–2005 climatological mean net evaporation minus precipitation (cm yr^{-1}) from meteorological reanalysis data. (c) Trend (1950 to 2000) in surface salinity (PSS78 per 50years). (d) The climatological-mean surface salinity (PSS78) (blues <35; yellows-reds >35). (e) Global difference between salinity averaged over regions where the sea surface salinity is greater than the global mean sea surface salinity (“High Salinity”) and salinity averaged over regions values below the global mean (“Low Salinity”). Details of data sources: see Figure 3.21 and FAQ 3.3, Figure 1. {3.9}

In most regions analyzed, it is *likely* that decreasing numbers of snowfall events are occurring where increased winter temperatures have been observed. Both satellite and in-situ observations show significant reductions in the Northern Hemisphere snow cover extent over the past 90 years, with most of the reduction occurring in the 1980s. Snow cover decreased most in spring when the average extent decreased by around 8% (7 million km^2) over the period 1970–2010 compared with the period 1922–1970. Because of earlier spring snowmelt, the duration of the Northern Hemisphere snow season has declined by 5.3 days per decade since the 1972/1973 winter. It is *likely* that there has been an anthropogenic component to these observed reductions in snow cover since the 1970s. {4.5.2, 10.5.1, 10.5.3}

The most recent and most comprehensive analyses of river runoff do not support the AR4 conclusion that global runoff has increased during the 20th century. New results also indicate that the AR4 conclusions regarding global increasing trends in droughts since the 1970s are no longer supported. {2.5.2, 2.6.2}

Projections of Future Changes

Changes in the water cycle are projected to occur in a warming climate (TFE.1, Figure 2, see also TS 4.6, TS 5.6, Annex I). Global-scale precipitation is projected to gradually increase in the 21st century. It is *virtually certain*, that precipitation increase will be much smaller, approximately $2\% \text{ K}^{-1}$, than the rate of lower tropospheric water vapour increase ($\sim 7\% \text{ K}^{-1}$), due to global energetic constraints. It is *virtually certain* that changes of average precipitation in a much warmer world will not be uniform, with some regions experiencing increases, and others with decreases or not much change at all. The high latitudes are *likely* to experience greater amounts of precipitation due to the additional water carrying capacity of the warmer troposphere. Many mid-latitude arid and semi-arid regions will *likely* experience less precipitation. The largest precipitation changes over northern Eurasia and North America are projected to occur during the winter. {12.4.5, Annex I}

[INSERT TFE.1, FIGURE 2 HERE]

TFE.1, Figure 2: Annual mean changes in precipitation (P), evaporation (E), relative humidity, E-P, runoff and soil moisture, for 2081–2100 relative to 1986–2005 under the RCP8.5 scenario (see Box TS.6). The number of CMIP5

models to calculate the multi-model mean is indicated in the upper right corner of each panel. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). {Figures 12.25–12.27}

Regional to global-scale projections of soil moisture and drought remain relatively uncertain compared to other aspects of the water cycle. Nonetheless, drying in the Mediterranean, southwestern U.S. and south African regions are consistent with projected changes in Hadley circulation, so drying in these regions as global temperatures increase is *likely* for several degrees of warming under the RCP8.5 scenario. Decreases in runoff are *likely* in southern Europe and the Middle East. The high northern latitude runoff increases are likely and consistent with the projected precipitation increases. {12.4.5}

TS.2.6 Changes in Sea Level

The primary contributions to changes in the volume of water in the ocean are the expansion of the ocean water as it warms and the transfer to the ocean of water currently stored on land, particularly from glaciers and ice sheets. Water impoundment in reservoirs and ground water depletion (and its subsequent run-off to the ocean) also affects sea level. Change in sea level relative to the land (relative sea level) can be significantly different from the global mean sea level (GMSL) change because of changes in the distribution of water in the ocean and vertical movement of the land. For an overview on the scientific understanding and uncertainties associated with recent (and projected) sea level change see TFE.2. {3.7.3, 13.1}

During the warm intervals of the middle Pliocene (3.3 to 3.0 million years ago), when there is *medium confidence* that global mean surface temperatures were 2°C to 3.5°C warmer than for pre-industrial climate and CO₂ levels were between 250 and 450 ppm, sedimentary records suggest periodic deglaciation of West Antarctica and parts of the East Antarctica. Ice-sheet models suggest near-complete deglaciation of the Greenland, West Antarctica and partial deglaciation of East Antarctica. Together, the evidence suggests that GMSL was above present levels at that time, but did not exceed 20 m above present (*high confidence*). {5.6.1, 13.2}

During the Last Interglacial Period (about 129,000 to 116,000 years ago) when peak global warmth was not more than 2°C above pre-industrial temperatures, and peak global annual sea surface temperatures were 0.7 [0.1 to 1.3] °C warmer (*medium confidence*), maximum GMSL was at least 5 m higher than at present (*very high confidence*), but did not exceed 10 m (*high confidence*). Based on ice-sheet model simulations consistent with elevation changes derived from a new Greenland ice core, the Greenland ice sheet *very likely* contributed between 1.4 m and 4.3 m sea level equivalent, implying with *medium confidence* a contribution from the Antarctic ice sheet to the global mean sea level during the last interglacial period. {5.6.2, 13.2}

Based on proxy data, the magnitude of centennial-scale global mean sea level variations did not exceed 0.25 m over the past few millennia (*medium confidence*). The current rate of global mean sea level change, starting in the late 19th-early 20th century, is, with *medium confidence*, unusually high in the context of centennial-scale variations of the last two millennia. Tide gauge data also indicate a *likely* acceleration during the last two centuries. Based on proxy and instrumental data, it is *virtually certain* that the rate of global mean sea level rise has accelerated during the last two centuries, marking the transition from relatively low rates of change during the late Holocene (order tenths of mm yr⁻¹) to modern rates (order mm yr⁻¹). {3.7, 5.6.3, 13.2}

Global mean sea level has risen by 0.19 [0.17 to 0.21] m, estimated from a linear trend over the period 1901–2010, based on tide gauge records and additionally on satellite data since 1993. It is *very likely* that the mean rate of sea level rise was 1.7 [1.5 to 1.9] mm yr⁻¹ between 1901 and 2010. Between 1993 and 2010, the rate was *very likely* higher at 3.2 [2.8 to 3.6] mm yr⁻¹; similarly high rates *likely* occurred between 1930 and 1950. The rate of global mean sea level rise has *likely* increased since the early 1900 with estimates ranging from 0.000 to 0.013 [–0.002 to 0.019] mm yr⁻². {3.7, 5.6.3, 13.2}

TFE.2: Sea Level Change: Scientific Understanding and Uncertainties

After the Last Glacial Maximum, global mean sea levels reached close to present-day values several thousand years ago. Since then, it is *virtually certain* that the rate of global mean sea level rise has increased from low rates of sea level change during the late Holocene (order tenths of mm yr^{-1}) to 20th century rates (order mm yr^{-1} , Figure TS1). {3.7, 5.6, 13.2}

Ocean thermal expansion and glacier mass loss are *very likely* the dominant contributors to global mean sea level rise during the 20th century. It is *very likely* that warming of the ocean has contributed 0.8 [0.5 to 1.1] mm yr^{-1} of sea level change during 1971–2010, with the majority of the contribution coming from the upper 700 m. The model-mean rate of ocean thermal expansion for 1971–2010 is close to observations. {3.7, 13.3}

Observations, combined with improved methods of analysis, indicate that the global glacier contribution (excluding the peripheral glaciers around Greenland and Antarctica) to sea level was 0.25 to 1.00 mm yr^{-1} sea level equivalent during 1971–2010. *Medium confidence* in global glacier mass balance models used for projections of global changes arises from the ability of the models of the well-observed glaciers to reproduce time series of historical changes of those glaciers using observed climate input. A simulation using observed climate data shows a larger rate of glacier mass loss during the 1930s than the simulations using AOGCM input, possibly a result of an episode of warming in Greenland associated with unforced regional climate variability. {4.3, 13.3}

Observations indicate that the Greenland Ice Sheet has *very likely* experienced a net loss of mass due to both increased surface melting and run off, and increased ice discharge over the last two decades (Figure TS.3). Regional climate models indicate that Greenland ice-sheet surface mass balance showed no significant trend from the 1960s to the 1980s, but melting and consequent runoff has increased since the early 1990s. This tendency is related to pronounced regional warming, which may be attributed to a combination of anomalous regional variability in recent years and anthropogenic climate change. *High confidence* in projections of future warming in Greenland and increased surface melting is based on the qualitative agreements of models in projecting amplified warming at high northern latitudes for well-understood physical reasons. {4.4, 13.3}

There is *high confidence* that the Antarctic Ice Sheet is in a state of net mass loss and its contribution to sea level is also *likely* to have increased in the last two decades. Acceleration in ice outflow has been observed since the 1990s, especially in the Amundsen Sea sector of West Antarctica. Interannual variability in accumulation is large and as a result no significant trend is present in accumulation since 1979 in either models or observations. Surface melting is currently negligible in Antarctica. {4.4, 13.3}

Model-based estimates of climate-related changes in water storage on land (as snow cover, surface water, soil moisture and ground water) do not show significant long-term contributions to sea level change for recent decades. However, human-induced changes (reservoir impoundment and groundwater depletion) have each contributed at least several tenths of mm yr^{-1} to sea level change. Reservoir impoundment exceeded groundwater depletion for the majority of the 20th century but the rate of groundwater depletion has increased and now exceeds the rate of impoundment. Their combined net contribution for the 20th century is estimated to be small. {13.3}

[INSERT TFE.2, FIGURE 1 HERE]

TFE.2, Figure 1: Comparison of the observed global mean sea level rise from the sum of the modelled contributions from ocean thermal expansion, glaciers (excluding glaciers peripheral to the Antarctic ice sheet, PGs) and changes in land-water storage. In panels (a)-(d): the grey lines are results for individual CMIP5 AOGCMs; the black line is the model mean plus a correction for the omission of volcanic forcing in the AOGCM control experiments; the adjusted model mean (dashed black line) is the sum of the corrected model mean thermal expansion, the change in land-water storage, the glacier estimate using observed (rather than modelled) climate, and an illustrative long-term ice-sheet contribution (of 0.1 mm yr^{-1}); the adjusted model mean including the observed ice sheet contribution (dotted black line) begins in 1993 and includes the ice-sheet contributions, but excludes the glaciers peripheral to both the Greenland Ice Sheet and the Antarctic Ice Sheet, to avoid double counting because the observational ice-sheet estimates include the peripheral glaciers; three estimates of global mean sea level, with the shading indicating the uncertainty estimates (two standard deviations) are shown; the satellite altimeter data since 1993 are shown in red. The modelled sea level is given (a) for the period 1900 to 2010, (b) the rates of sea level change for the same period, with the satellite altimeter data shown as a red dot for the rate, (c) for 1961 to 2010 and (d) for 1990 to 2010. Panel (e) compares the sum of the observed contributions (orange) and the observed sea level from the satellite altimeter data (red). {13.3; Figure 13.7}

The observed global mean sea level (GMSL) rise for 1993–2010 is consistent with the sum of the observationally estimated contributions (TFE.2, Figure 1e). The closure of the observational budget for recent periods within uncertainties represents a significant advance since the AR4 in physical understanding of the causes of past GMSL change, and provides an improved basis for critical evaluation of models of these contributions in order to assess their reliability for making projections. {13.3}

The sum of modelled ocean thermal expansion and glacier contributions and the estimated change in land water storage (which is relatively small) accounts for about 65% of the observed GMSL rise for 1901–1990, and 90% for 1971–2010 and 1993–2010 (TFE.2, Figure 1). After inclusion of small long-term contributions from ice sheets and the possible greater mass loss from glaciers during the 1930s due to unforced climate variability, the sum of the modelled contribution is close to the observed rise. The addition of the observed ice sheet contribution since 1993 improves the agreement further between the observed and modelled sea level rise (TFE.2, Figure 1). The evidence now available gives a clearer account than in previous IPCC assessments of 20th century sea level change. {13.3}

When calibrated appropriately, recently improved dynamical ice-sheet models can reproduce the observed rapid changes in ice-sheet outflow for individual glacier systems (e.g., Pine Island Glacier in Antarctica; *medium confidence*). However, models of ice sheet response to global warming and particularly ice sheet-ocean interactions are incomplete and the omission of ice-sheet models, especially of dynamics, from the model budget of the past means that they have not been as critically evaluated as other contributions. {13.3, 13.4}

Global mean sea level rise for 2081–2100 (relative to 1986–2005) for the RCPs will *likely* be in the 5–95% ranges derived from CMIP5 climate projections in combination with process-based models (*medium confidence*), i.e., 0.26–0.54 m (RCP2.6), 0.32–0.62 m (RCP4.5), 0.33–0.62 m (RCP6.0), 0.45–0.81 (RCP8.5) m (see Table TS.1 and Figure TS.15 for RCP forcing). For RCP8.5 the range at 2100 is 0.53–0.97 m. Confidence in the projected *likely* ranges comes from the consistency of process-based models with observations and physical understanding. It is assessed that there is currently insufficient evidence to evaluate the probability of specific levels above the *likely* range. Based on current understanding, only the collapse of marine-based sectors of the Antarctic ice sheet, if initiated, could cause GMSL to rise substantially above the *likely* range during the 21st century. There is a lack of consensus on the probability for such a collapse, and the potential additional contribution to GMSL rise cannot be precisely quantified, but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise during the 21st century. It is *virtually certain* that global mean sea level rise will continue beyond 2100. {13.5.1, 13.5.3}

Many semi-empirical models projections of global mean sea level rise are higher than process-based model projections, but there is low agreement in semi-empirical model projections, and no consensus about their reliability. {13.5.2, 13.5.3}

TFE.2, Figure 2 combines the paleo, tide-gauge, and altimeter observations of sea level rise from 1700 with the projected global mean sea level change to 2100. {13.5, 13.7, 13.8}

[INSERT TFE.2, FIGURE 2 HERE]

TFE.2, Figure 2: Compilation of paleo sea level data (purple), tide gauge data (blue, red and green), altimeter data (light blue), and central estimates and likely ranges for projections of global-mean sea level rise from the combination of CMIP5 and process-based models for RCP2.6 (blue) and RCP8.5 (red) scenarios, all relative to pre-industrial values. {Figures 13.3, 13.11, 13.27}

TS.2.7 Changes in Extremes

TS.2.7.1 Atmosphere

Recent analyses of extreme events generally support the AR4 and SREX conclusions (see TFE.9 and in particular TFE.9, Table 1, for a synthesis). It is *very likely* that the number of cold days and nights has decreased and the number of warm days and nights has increased on the global scale between 1951 and

2010. Globally, there is *medium confidence* that the length and frequency of warm spells, including heat waves, has increased since the middle of the 20th century mostly due to lack of data or studies in Africa and South America. However it is *likely* that heat wave frequency has increased over this period in large parts of Europe, Asia, and Australia. {2.6.1; Table 2.12, 2.13}

It is *likely* that since 1950 the number of heavy precipitation events over land has increased in more regions than it has decreased. Regional trends vary but confidence is *high* for North America with *very likely* trends towards heavier precipitation events. {2.6.2; Table 2.13}

There is *low confidence* in a global-scale observed trend in drought or dryness (lack of rainfall), due to lack of direct observations, dependencies of inferred trends on the index choice and geographical inconsistencies in the trends. However this masks important regional changes and, for example, the frequency and intensity of drought has *likely* increased in the Mediterranean and West Africa and *likely* decreased in Central North America and North-West Australia since 1950. {2.6.2; Table 2.13}

During the last millennium, there is *high confidence* for the occurrence of droughts of greater magnitude and longer duration than observed since 1900 in many regions. There is *medium confidence* that more megadroughts occurred in monsoon Asia and wetter conditions prevailed in arid Central Asia and the South American monsoon region during the Little Ice Age (1450–1850) compared to the Medieval Climate Anomaly (950–1250). {5.5.4, 5.5.5}

Confidence remains *low* for long-term (centennial) changes in tropical cyclone activity, after accounting for past changes in observing capabilities. However since the 1970s, it is *virtually certain* that the frequency and intensity of storms in the North Atlantic has increased although the reasons for this increase are debated (see TFE.9). There is *low confidence* of large-scale trends in storminess over the last century and there is still insufficient evidence to determine whether robust trends exist in small-scale severe weather events such as hail or thunder storms. {2.6.2, 2.6.3, 2.6.4}

With *high confidence*, past floods larger than recorded since the 20th century occurred during the past five centuries in northern and central Europe, the western Mediterranean region, and eastern Asia. There is *medium confidence* that in the Near East, India, central North America, modern large floods are comparable or surpass historical floods in magnitude and/or frequency. {5.5.5}

TS.2.7.2 Oceans

It is *likely* that the magnitude of extreme high sea level events has increased since 1970 (see TFE.9, Table 1). Most of the increase in extreme sea level can be explained by the mean sea level rise: changes in extreme high sea levels are reduced to less than 5 mm yr⁻¹ at 94% of tide gauges once the rise in mean sea level is accounted for. There is *medium confidence* based on reanalysis forced model hindcasts and ship observations that mean significant wave height has increased since the 1950s over much of the North Atlantic north of 45°N, with typical winter season trends of up to 20 cm per decade. {3.4.5, 3.7.5}

TS.2.8 Changes in Carbon and Other Biogeochemical Cycles

Concentrations of the atmospheric greenhouse gases carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O) in 2011, exceed the range of concentrations recorded in ice cores during the past 800,000 years. Past changes in atmospheric greenhouse-gas concentrations are determined with *very high confidence* from polar ice cores. Since AR4 these records have been extended from 650,000 years to 800,000 years ago. {5.2.2}

With *very high confidence*, the current rates of CO₂, CH₄ and N₂O rise in atmospheric concentrations and the associated increases in radiative forcing are unprecedented with respect to the “highest resolution” ice core records of the last 22,000 years. There is *medium confidence* that the rate of change of the observed greenhouse gas rise is also unprecedented compared with the lower resolution records of the past 800,000 years. {2.2.1, 5.2.2}

In several periods characterized by high atmospheric CO₂ concentrations, there is *medium confidence* that global mean temperature was significantly above pre-industrial level. During the mid-Pliocene (3.3 to 3.0 million years ago), atmospheric CO₂ concentration between 350 ppm and 450 ppm (*medium confidence*) occurred when global mean surface temperature was approximately 2°C to 3.5°C warmer (*medium confidence*) than for pre-industrial climate. During the Early Eocene (52 to 48 million years ago), atmospheric CO₂ concentration exceeded ~1000 ppm when global mean surface temperature was 9°C to 14°C higher (*medium confidence*) than for pre-industrial conditions. {5.3.1}

TS.2.8.1 CO₂

Between 1750 and 2011, CO₂ emissions from fossil fuel combustion and cement production are estimated from energy and fuel use statistics to have released 365 [335 to 395] PgC⁸. In 2000–2009, average fossil fuel and cement manufacturing emissions were 7.8 [7.2 to 8.4] PgC yr⁻¹, with an average growth rate of 3.2% yr⁻¹ (Figure TS.4). This rate of increase of fossil fuel emissions is higher than during the 1990's (1.0% yr⁻¹). In 2011, fossil fuel emissions were 9.5 [8.7 to 10.3] PgC. {2.2.1, 6.3.1; Table 6.1}

[INSERT FIGURE TS.4 HERE]

Figure TS.4: Annual anthropogenic CO₂ emissions and their partitioning among the atmosphere, land and ocean (PgC yr⁻¹) from 1750 to 2011. (Top) Fossil fuel and cement CO₂ emissions by category, estimated by the Carbon Dioxide Information Analysis Center (CDIAC). (Bottom) Fossil fuel and cement CO₂ emissions as above. CO₂ emissions from net land use change, mainly deforestation, are based on land cover change data (see Table 6.2). The atmospheric CO₂ growth rate prior to 1959 is based on a spline fit to ice core observations and a synthesis of atmospheric measurements from 1959. The fit to ice core observations does not capture the large interannual variability in atmospheric CO₂ and is represented with a dashed line. The ocean CO₂ sink is from a combination of models and observations. The residual terrestrial sink (term in green in the figure) is computed from the residual of the other terms. The emissions and their partitioning only include the fluxes that have changed since 1750, and not the natural CO₂ fluxes (e.g., atmospheric CO₂ uptake from weathering, outgassing of CO₂ from lakes and rivers, and outgassing of CO₂ by the ocean from carbon delivered by rivers; see Figure 6.1) between the atmosphere, land and ocean reservoirs that existed before that time and still exist today. The uncertainties in the various terms are discussed in chapter 6 and reported in Table 6.1 for decadal mean values. {Figure 6.8}

Between 1750 and 2011, land use change (mainly deforestation), derived from land cover data and modelling, is estimated to have released 180 [100 to 260] PgC. Land use change emissions between 2000 and 2009 are dominated by tropical deforestation, and are estimated at 1.1 [0.3 to 1.9] PgC yr⁻¹, with possibly a small decrease from the 1990s due to lower reported forest loss during this decade. This estimate includes gross deforestation emissions of around 3 PgC yr⁻¹ compensated by around 2 PgC yr⁻¹ of forest regrowth in some regions, mainly abandoned agricultural land. {6.3.2; Table 6.2}

Of the 545 [460 to 630] PgC released to the atmosphere from fossil fuel and land use emissions from 1750 to 2011, 240 [230 to 250] PgC accumulated in the atmosphere, as estimated with very high accuracy from the observed increase of atmospheric CO₂ concentration from 278 [275 to 281] ppm⁹ in 1750 to 390.5 ppm in 2011. The amount CO₂ in the atmosphere grew by 4.0 [3.8 to 4.2] PgC yr⁻¹ in the first decade of the 21st century. The distribution of observed atmospheric CO₂ increases with latitude clearly shows that the increases are driven by anthropogenic emissions which primarily occur in the industrialized countries north of the equator. Based on annual average concentrations, stations in the Northern Hemisphere show slightly higher concentrations than stations in the Southern Hemisphere. An independent line of evidence for the anthropogenic origin of the observed atmospheric CO₂ increase comes from the observed consistent decrease in atmospheric O₂ content and a decrease in the stable isotopic ratio of CO₂ (¹³C/¹²C) in the atmosphere (Figure TS.5). {2.2.1, 6.1.3}

The remaining amount of carbon released by fossil fuel and land-use emissions has been re-absorbed by the ocean and terrestrial ecosystems. Based on high agreement between independent estimates using different methods and data sets (e.g., oceanic carbon, oxygen, and transient tracer data), it is *very likely* that the global

⁸ 1 Petagram of carbon = 1 PgC = 10¹⁵ grams of carbon = 1 Gigatonne of carbon = 1 GtC. This corresponds to 3.67 GtCO₂.

⁹ ppm (parts per million) or ppb (parts per billion, 1 billion = 1,000 million) is the ratio of the number of greenhouse gas molecules to the total number of molecules of dry air. For example, 300 ppm means 300 molecules of a greenhouse gas per million molecules of dry air.

ocean inventory of anthropogenic carbon increased from 1994 to 2010. In 2011, it is estimated to be 155 [125 to 185] PgC. The annual global oceanic uptake rates calculated from independent data sets (from oceanic C_{ant} inventory changes, from atmospheric O_2/N_2 measurements or from pCO_2 data) and for different time periods agree with each other within their uncertainties, and *very likely* are in the range of 1.0–3.2 PgC yr^{-1} . Regional observations of the storage rate of anthropogenic carbon in the ocean are in broad agreement with the expected rate resulting from the increase in atmospheric CO_2 concentrations, but with significant spatial and temporal variations. {3.8.1, 6.3}

[INSERT FIGURE TS.5 HERE]

Figure TS.5: Atmospheric concentration of CO_2 , oxygen, $^{13}C/^{12}C$ stable isotope ratio in CO_2 , as well as CH_4 and N_2O atmospheric concentrations and oceanic surface observations of pCO_2 and pH, recorded at representative time series stations in the Northern and the Southern Hemispheres. MLO: Mauna Loa Observatory, Hawaii; SPO: South Pole; HOT: Hawaii Ocean Time-Series station; MHD: Mace Head, Ireland; CGO: Cape Grim, Tasmania; ALT: Alert, Northwest Territories, Canada. {Figure 6.3, FAQ 3.2, Figure 1}

Natural terrestrial ecosystems (those not affected by land use change) are estimated by difference from changes in other reservoirs to have accumulated 150 [60 to 240] PgC between 1750 and 2010. The gain of carbon by natural terrestrial ecosystems is estimated to take place mainly through the uptake of CO_2 by enhanced photosynthesis at higher CO_2 levels and nitrogen deposition, longer growing seasons in mid and high latitudes. Natural carbon sinks vary regionally due to physical, biological and chemical processes acting on different time scales. An excess of atmospheric CO_2 absorbed by land ecosystems gets stored as organic matter in diverse carbon pools, from short lived (leaves, fine roots) to long-lived (stems, soil carbon). {6.3; Table 6.1}

TS.2.8.2 Carbon and Ocean Acidification

It is *very likely* that oceanic uptake of anthropogenic CO_2 results in gradual acidification of the ocean. The pH^{10} of seawater has decreased by 0.1 since the beginning of the industrial era, corresponding to a 26% increase in hydrogen ion concentration. The observed pH trends range between -0.0014 and -0.0024 per year in surface waters. In the ocean interior, natural physical and biological processes, as well as uptake of anthropogenic CO_2 can cause changes in pH over decadal and longer time scales. {3.8.2; Box 3.2; Table 3.2; FAQ 3.2}

TS.2.8.3 CH_4

The concentration of CH_4 has increased by a factor of 2.5 since preindustrial times, from 720 [695 to 745] ppb in 1750 to 1803 [1799 to 1807] ppb in 2011 (Figure TS.5). There is *very high confidence* that the atmospheric CH_4 increase during the Industrial Era is caused by anthropogenic activities. The massive increase in the number of ruminants, the emissions from fossil fuel extraction and use, the expansion of rice paddy agriculture and the emissions from landfills and waste, are the dominant anthropogenic CH_4 sources. Anthropogenic emissions account for 50% to 65% of total emissions. By including natural geological CH_4 emissions that were not accounted for in previous budgets, the fossil component of the total CH_4 emissions (i.e., anthropogenic emissions related to leaks in the fossil fuel industry and natural geological leaks) is now estimated to amount to about 30% of the total CH_4 emissions (*medium confidence*). {2.2.1, 6.1, 6.3.3}

In recent decades, CH_4 growth in the atmosphere has been variable. CH_4 concentrations were relatively stable for about a decade in the 1990s, but then started growing again starting in 2007. The exact drivers of this renewed growth are still debated. Climate driven fluctuations of CH_4 emissions from natural wetlands (177 to 284×10^{12} g (CH_4) yr^{-1} for 2000–2009 based on bottom-up estimates) are the main drivers of the global inter-annual variability of CH_4 emissions (*high confidence*), with a smaller contribution from biomass burning emissions during high fire years {2.2.1, 6.3.3; Table 6.8}.

TS.2.8.4 Nitrogen

¹⁰ pH is a measure of acidity : a decrease in pH value means an increase in acidity, i.e., acidification.

Since preindustrial times, the concentration of N₂O in the atmosphere has increased by a factor of 1.2 (Figure TS.5). Changes in the nitrogen cycle, in addition to interactions with CO₂ sources and sinks, affect emissions of N₂O both on land and from the ocean. {2.2.1, 6.4.6}

TS.2.8.5 Oceanic Oxygen

High agreement among analyses provides *medium confidence* that oxygen concentrations have decreased in the open ocean thermocline in many ocean regions since the 1960s. The general decline is consistent with the expectation that warming-induced stratification leads to a decrease in the supply of oxygen to the thermocline from near surface waters, that warmer waters can hold less oxygen, and that changes in wind-driven circulation affect oxygen concentrations. It is *likely* that the tropical oxygen minimum zones have expanded in recent decades. {3.8.3}

TS.3 Drivers of Climate Change

TS.3.1 Introduction

Human activities have changed and continue to change the Earth's surface and atmospheric composition. Some of these changes have a direct or indirect impact on the energy balance of the Earth and are thus drivers of climate change. Radiative forcing (RF) is a measure of the net change in the energy balance of the Earth system in response to some external perturbation (see Box TS.2), with positive RF leading to a warming and negative RF to a cooling. The RF concept is valuable for comparing the influence on global mean temperature of most individual agents affecting Earth's radiation balance. The quantitative values provided in AR5 are consistent with those in previous IPCC reports, though there have been some important revisions (Figure TS.6). Effective radiative forcing (ERF) is now used to quantify the impact of some forcing agents that involve rapid adjustments of components of the atmosphere and surface that are assumed constant in the RF concept (see Box TS.2). RF and ERF are estimated from the change between 1750 and 2011, referred to as "industrial era", if other time periods are not explicitly stated. Uncertainties are given associated with the best estimates of RF and ERF, with values representing the 5–95% (90%) confidence range. {8.1, 7.1}

In addition to the global mean RF or ERF, the spatial distribution and temporal evolution of forcing, as well as climate feedbacks, play a role in determining the eventual impact of various drivers on climate. Land surface changes may also impact the local and regional climate through processes that are not radiative in nature {8.1, 8.3.5, 8.6}.

[START BOX TS.2 HERE]

Box TS.2: Radiative Forcing and Effective Radiative Forcing

Radiative Forcing (RF) and Effective Radiative Forcing (ERF) are used to quantify the change in Earth's energy balance that occurs as a result of an externally imposed change. They are expressed in Watts per square meter (W m^{-2}). RF is defined in AR5, as in previous IPCC assessments, as the change in net downward flux (shortwave + longwave) at the tropopause after allowing for stratospheric temperatures to readjust to radiative equilibrium, while holding other state variables such as tropospheric temperatures, water vapor and cloud cover fixed at the unperturbed values (see Glossary). {8.1.1}

Although the RF concept has proved very valuable, improved understanding has shown that including rapid adjustments of the Earth's surface and troposphere can provide a better metric of climate response. These rapid adjustments occur over a variety of timescales, but are relatively distinct from responses to global mean surface temperature change. Aerosols in particular impact the atmosphere temperature profile and cloud properties on a time scale much shorter than adjustments of the ocean (even the upper layer) to forcings. The ERF concept defined in AR5 allows rapid adjustments to perturbations, for all variables except for global mean surface temperature or ocean temperature and sea ice cover. The ERF and RF values are significantly different for the anthropogenic aerosols, due to their influence on clouds and on snow or ice cover. For other components that drive the Earth energy balance, such as greenhouse gases, ERF and RF are fairly similar, and RF may have comparable utility given that it requires fewer computational resources to

calculate and is not affected by meteorological variability and hence can better isolate small forcings. In cases where RF and ERF differ substantially, ERF has been shown to be a better indicator of the global mean temperature response and is therefore emphasized in AR5. {7.1.3, 8.1; Box 8.1}

[END BOX TS.2 HERE]

TS.3.2 Radiative Forcing from Greenhouse Gases

Human activity leads to change in the atmospheric composition either directly (via emissions of gases or particles) or indirectly (via atmospheric chemistry). Anthropogenic emissions have driven the changes in well-mixed greenhouse gas (WMGHG) concentrations during the industrial era (see Section TS.2.8 and TFE.7). As historical WMGHG concentrations since the preindustrial are well known based on direct measurements and ice core records, and WMGHG radiative properties are also well known, the computation of RF due to concentration changes provides tightly constrained values (Figure TS.6). There has not been significant change in our understanding of WMGHG radiative impact, so that the changes in RF estimates relative to AR4 are due essentially to concentration increases. The best estimate for WMGHG ERF is the same as RF, but the uncertainty range is twice as large due to the poorly constrained cloud responses. Due to high-quality observations, it is certain that increasing atmospheric burdens of most WMGHGs, especially CO₂, resulted in a further increase in their radiative forcing from 2005 to 2011. Based on concentration changes, the RF of all WMGHG in 2011 is 2.83 [2.54 to 3.12] W m⁻² (*very high confidence*). This is an increase since AR4 of 0.20 [0.18 to 0.22] W m⁻², with nearly all of the increase due to the increase in the abundance of CO₂ since 2005. The industrial era RF for CO₂ alone is 1.82 [1.63 to 2.01] W m⁻². Over the last 15 years, CO₂ has been the dominant contributor to the increase in RF from the WMGHGs, with RF of CO₂ having an average growth rate slightly less than 0.3 W m⁻² per decade. The uncertainty in the WMGHG RF is due in part to its radiative properties but mostly to the full accounting of atmospheric radiative transfer including clouds. {2.2.1, 5.2, 6.3, 8.3, 8.3.2; Table 6.1}

[INSERT FIGURE TS.6 HERE]

Figure TS.6: Radiative Forcing (RF) and Effective Radiative Forcing (ERF) of climate change during the industrial era. Top: Forcing by concentration change between 1750 and 2011 with associated uncertainty range (solid bars are ERF, hatched bars are RF, green diamonds and associated uncertainties are for RF assessed in AR4). Bottom: Probability Density Functions for the ERF, for the aerosol, well-mixed greenhouse gas (WMGHG) and total. The green lines show the AR4 RF 90% confidence intervals and can be compared with the red, blue and black lines which show the AR5 ERF 90% confidence intervals (although RF and ERF differ, especially for aerosols). The ERF from surface albedo changes and combined contrails and contrail induced cirrus is included in the total anthropogenic forcing, but not shown as a separate probability density function. For some forcing mechanisms (ozone, land use, solar) the RF is assumed to be representative of the ERF but an additional uncertainty of 17% is added in quadrature to the RF uncertainty. {Figures 8.15, 8.16}

After a decade of near stability, the recent increase of CH₄ concentration led to an enhanced RF compared to AR4 by 2% to 0.48 [0.43 to 0.53] W m⁻². It is *very likely* that the RF from methane is now larger than that of all halocarbons combined. {2.2.1, 8.3}

Atmospheric N₂O has increased by 6% since AR4 causing a RF of 0.17 [0.15 to 0.19] W m⁻². N₂O concentrations continue to rise while those of CFC-12, the third largest WMGHG contributor to RF for several decades, are decreasing due to phase-out of emissions of this chemical under the Montreal Protocol. N₂O is now *likely* the third largest WMGHG contributor to RF. The RF from halocarbons is very similar to the value in AR4, with a reduced RF from CFCs but increases in many of their replacements. Four of the halocarbons (CFC-11, CFC-12, CFC-113, and HCFC-22) account for 85% of the total halocarbon RF. The former three compounds have declining RF over the last five years but are more than compensated for by the increased RF from HCFC-22. There is *high confidence* that the growth rate in RF from all WMGHG is weaker over the last decade than in the 1970s and 1980s owing to a slower increase in the non-CO₂ RF. {2.2.1, 8.3}

The short-lived GHGs ozone (O₃) and stratospheric water vapour also contribute to anthropogenic forcing. Observations indicate that O₃ *likely* increased at many undisturbed (background) locations through the 1990s. These increases have continued mainly over Asia (though observations cover a limited area) and flattened over Europe during the last decade. The total RF due to changes in ozone is 0.35 [0.15 to 0.55] W

m^{-2} (*high confidence*) (Figure TS.6), with RF due to tropospheric ozone of 0.40 [0.20 to 0.60] W m^{-2} (*high confidence*) and due to stratospheric ozone of -0.05 [-0.15 to $+0.05$] W m^{-2} (*high confidence*). Ozone is not emitted directly into the atmosphere; instead it is formed by photochemical reactions. In the troposphere these reactions involve precursor compounds that are emitted into the atmosphere from a variety of natural and anthropogenic sources. Tropospheric ozone RF is largely attributed to increases in emissions of methane, carbon monoxide, volatile organics and nitrogen oxides, while stratospheric RF results primarily from ozone depletion by anthropogenic halocarbons. However, there is now strong evidence for substantial links between the changes in tropospheric and stratospheric ozone and a total ozone RF of 0.50 [0.30 to 0.70] W m^{-2} is attributed to tropospheric ozone precursor emissions and -0.15 [-0.30 to 0.00] W m^{-2} to ozone-depletion by halocarbons. There is strong evidence that tropospheric ozone also has a detrimental impact on vegetation physiology, and therefore on its CO_2 uptake. This reduced uptake leads to an indirect increase in the atmospheric CO_2 concentration. Thus a fraction of the CO_2 RF should be attributed to ozone or its precursors rather than direct emission of CO_2 , but there is a *low confidence* on the quantitative estimates. RF for stratospheric water vapour produced from CH_4 oxidation is 0.07 [0.02 to 0.12] W m^{-2} . Other changes in stratospheric water vapour, and all changes in water vapour in the troposphere, are regarded as a feedback rather than a forcing. {2.2.2, 8.1, 8.2, 8.3; FAQ 8.1}

TS.3.3 Radiative Forcing from Anthropogenic Aerosols

Anthropogenic aerosols are responsible for a radiative forcing of climate through multiple processes which can be loosely grouped into two types: aerosol-radiation interactions (ari) and aerosol-cloud interactions (aci) (Figure TS.6). There has been progress since AR4 on observing and modeling climate-relevant aerosol properties (including their size distribution, hygroscopicity, chemical composition, mixing state, optical and cloud nucleation properties) and their atmospheric distribution. Nevertheless, substantial uncertainties remain in assessments of long-term trends of global aerosol optical depth and other global properties of aerosols due to difficulties in measurement and lack of observations of some relevant parameters, high spatial and temporal variability and the relatively short observational records that exist. The anthropogenic RF_{ari} is given a best estimate of -0.35 [-0.85 to $+0.15$] W m^{-2} (*high confidence*) using evidence from aerosol models and some constraints from observations. The RF_{ari} is caused by multiple aerosol types (see Section TS3.6). The rapid adjustment to RF_{ari} leads to further negative forcing, in particular through cloud adjustments. As a consequence, the ERF_{ari} is more negative than the RF_{ari} (*low confidence*) and given a best estimate of -0.45 [-0.95 to $+0.05$] W m^{-2} . The assessment for RF_{ari} is less negative than reported in AR4 because of a re-evaluation of aerosol absorption. The uncertainty estimate is wider but more robust. {2.2.3, 7.3, 7.5.2}

Improved understanding of aerosol-cloud interactions has led to a reduction in the estimated magnitude of many global aerosol-cloud forcings estimates. The total effective radiative forcing due to aerosols ($\text{ERF}_{\text{ari+aci}}$, excluding the effect of absorbing aerosol on snow and ice) is assessed to be -0.9 [-1.9 to -0.1] W m^{-2} (*medium confidence*). This estimate encompasses all rapid adjustments, including changes to the cloud lifetime and aerosol microphysical effects on mixed-phase, ice and convective clouds. This range was obtained by giving equal weight to satellite-based studies and estimates from climate models and inverse studies grouped together. It is consistent with multiple lines of evidence suggesting less negative estimates for aerosol-cloud interactions than those discussed in AR4. {7.4, 7.5}

The RF from black carbon (BC) on snow and ice is assessed to be 0.04 [0.02 to 0.09] W m^{-2} (*low confidence*). Unlike in the previous IPCC assessment, this estimate includes the effects on sea-ice, accounts for more physical processes, and incorporates evidence from both models and observations. This RF causes a 2–4 times larger global mean surface temperature change per unit forcing than CO_2 primarily because all of the forcing energy is deposited directly into the cryosphere, whose evolution drives a positive albedo feedback on climate. This effect thus can represent a significant forcing mechanism in the Arctic and other snow or ice covered regions. {7.3, 7.5}

Despite the large uncertainty ranges on aerosol forcing, there is a *high confidence* that aerosols have offset a substantial portion of GHG forcing. Aerosol-cloud interactions can influence the character of individual storms, but evidence for a systematic aerosol effect on storm or precipitation intensity is more limited and ambiguous. {7.4, 7.6}

TS.3.4 Radiative Forcing from Land Surface Changes and Contrails

There is robust evidence that anthropogenic land use changes such as deforestation have increased the land surface albedo, which leads to a RF of -0.15 [-0.25 to -0.05] W m^{-2} (Figure TS.6). There is still a large spread of quantitative estimates due to different assumptions for the albedo of natural and managed surfaces (e.g., croplands, pastures). In addition, the time evolution of the land use change, and in particular how much was already completed in the reference year 1750, are still debated. Furthermore, land use change causes other modifications that are not radiative but impact the surface temperature, including modifications in the surface roughness, latent heat flux, river runoff, and irrigation. These are more uncertain and they are difficult to quantify, but they tend to offset the impact of albedo changes at the global scale. As a consequence, there is low agreement on the sign of the net change in global mean temperature as a result of land use change. Land use change, and in particular deforestation, also has significant impacts on WMGHG concentrations. It contributes to the corresponding RF associated with CO_2 emissions or concentration changes. {8.3}

Persistent contrails from aviation contribute a positive RF of 0.01 [0.005 to 0.03] W m^{-2} (*medium confidence*) for year 2011, and the combined contrail and contrail-cirrus ERF from aviation is assessed to be 0.05 [0.02 to 0.15] W m^{-2} (*low confidence*). This forcing can be much larger regionally but there is now *medium confidence* that it does not produce observable regional effects on either the mean or diurnal range of surface temperature. {7.2.7}

TS.3.5 Radiative Forcing from Natural Drivers of Climate Change

Solar and volcanic forcings are the two dominant natural contributors to global climate change during the industrial era. Satellite observations of total solar irradiance (TSI) changes since 1978 show quasi-periodic cyclical variation with a period of roughly 11 years. Longer-term forcing is typically estimated by comparison of solar minima (during which variability is least). This gives a RF change of -0.04 [-0.08 to 0.00] W m^{-2} between the most recent (2008) minimum and the 1986 minimum. There is some diversity in the estimated trends of the composites of various satellite data, however. Secular trends of TSI before the start of satellite observations rely on a number of indirect proxies. The best estimate of RF from TSI changes over the industrial era is 0.05 [0.00 to 0.10] W m^{-2} (*medium confidence*), which includes greater RF up to around 1980 and then a small downward trend. This RF estimate is substantially smaller than the AR4 estimate due to the addition of the latest solar cycle and inconsistencies in how solar RF was estimated in earlier IPCC assessments. The recent solar minimum appears to have been unusually low and long-lasting and several projections indicate lower TSI for the forthcoming decades. However, current abilities to project solar irradiance are extremely limited so that there is *very low confidence* concerning future solar forcing. Nonetheless, there is a *high confidence* that 21st century solar forcing will be much smaller than the projected increased forcing due to GHGs. {5.2.1, 8.4; FAQ 5.1}

Changes in solar activity affect the cosmic ray flux impinging upon the Earth's atmosphere, which has been hypothesized to affect climate through changes in cloudiness. Cosmic rays enhance aerosol nucleation and thus may affect cloud condensation nuclei production in the free troposphere, but the effect is too weak to have any climatic influence during a solar cycle or over the last century (*medium evidence, high agreement*). No robust association between changes in cosmic rays and cloudiness has been identified. In the event that such an association exists, it is *very unlikely* to be due to cosmic ray-induced nucleation of new aerosol particles. {7.3, 7.4.6}

The RF of stratospheric volcanic aerosols is now well understood and there is a large RF for a few years after major volcanic eruptions (Box TS.5, Figure 1). While volcanic eruptions inject both mineral particles and sulphate aerosol precursors into the atmosphere, it is the latter, because of their small size and long lifetimes, which are responsible for radiative forcing important for climate. The emissions of CO_2 from volcanic eruptions are at least 100 times smaller than anthropogenic emissions, and inconsequential for climate on century time scales. Large tropical volcanic eruptions have played an important role in driving annual to decadal scale climate change during the industrial era due to their sometimes very large negative RF. There has not been any major volcanic eruption since Mt. Pinatubo in 1991, which caused a one-year RF of about -3.7 W m^{-2} , but several smaller eruptions have caused a RF for the years 2008–2011 of -0.10 [-0.13 to -0.07] W m^{-2} (*high confidence*), twice as strong in magnitude compared to 1999–2002. The smaller

eruptions have led to better understanding of the dependence of radiative forcing on the amount of material from and time of the year of high-latitude injections. {5.2.1, 5.3.5, 8.4; Annex II}

TS.3.6 Synthesis of Forcings; Spatial and Temporal Evolution

A synthesis of the industrial era forcing finds that among the forcing agents, there is a *very high confidence* only for the WMGHG RF. Relative to AR4, the confidence level has been elevated for seven forcing agents due to improved evidence and understanding. {8.5; Figure 8.14}

The time evolution of the total anthropogenic RF shows a nearly continuous increase from 1750, primarily since about 1860. There is *very high confidence* that the total anthropogenic RF increase rate since 1960 has been much greater than during earlier industrial-era periods, driven primarily by the continuous increase in most WMGHG concentrations. There is still low agreement on the time evolution of the total aerosol ERF, which is the primary factor for the uncertainty in the total anthropogenic forcing. The fractional uncertainty in the total anthropogenic forcing decreases gradually after 1950 due to the smaller offset of positive WMGHG forcing by negative aerosol forcing. There is robust evidence and high agreement that natural forcing is a small fraction of the WMGHG forcing. Natural forcing changes over the last 15 years have *likely* offset a substantial fraction (10–95%) of the anthropogenic forcing increase during this period (Box TS.3). Forcing by CO₂ is the largest single contributor to the total forcing during the industrial era and during 1980 to 2011. Compared to the entire industrial era the dominance of CO₂ forcing is larger for 1980 to 2011 with respect to other WMGHG, and there is *high confidence* that the offset from aerosol forcing to WMGHG forcing during this period was much smaller than over the 1950–1980 period. {8.5.2}

Forcing can also be attributed to emissions rather than to the resulting concentration changes (Figure TS.7). Carbon dioxide is the largest single contributor to historical RF from either the perspective of changes in the atmospheric concentration of CO₂ or the impact of changes in net emissions of CO₂. The relative importance of other forcing agents can vary markedly with the perspective chosen, however. In particular, methane emissions have a much larger forcing (~1.0 W m⁻² over the industrial era) than methane concentration increases (~0.5 W m⁻²) due to several indirect effects through atmospheric chemistry. In addition, carbon monoxide emissions have a clear positive forcing, while emissions of reactive nitrogen oxides *likely* cause a net negative forcing but uncertainties are large. Emissions of ozone-depleting halocarbons *very likely* cause a net positive forcing as their direct radiative effect is larger than the impact of the stratospheric ozone depletion that they induce. Emissions of SO₂, organic carbon and ammonia cause a negative forcing, while emissions of black carbon lead to positive forcing via aerosol-radiation interactions. Note that mineral dust forcing may include a natural component or a climate feedback effect. {7.3, 7.5.2, 8.5.1}

[INSERT FIGURE TS.7 HERE]

Figure TS.7: Radiative forcing of climate change during the industrial era shown by emitted components from 1750 to 2011. The horizontal bars indicate the overall uncertainty, while the vertical bars are for the individual components (vertical bar lengths proportional to the relative uncertainty, with a total length equal to the bar width for a ±50% uncertainty). Best estimates for the totals and individual components (from left to right) of the response are given in the right column. Values are RF except for the ERF of aerosol-cloud interactions (ERF_{aci}). An additional rapid adjustment to aerosol-radiation interactions of -0.1 [-0.3 to +0.1] W m⁻² is attributable primarily to black carbon (ERF_{ari}-RF_{ari} in Figure TS.6). CFCs= Chlorofluorocarbons, HCFCs= Hydrochlorofluorocarbons, HFCs=Hydrofluorocarbons, PFCs= Perfluorocarbons, NMVOC= Non-Methane Volatile Organic Compounds, BC= Black Carbon. {Figure 8.17}

Although the WMGHG show a spatially fairly homogeneous forcing, other agents such as aerosols, ozone and land-use changes are highly heterogeneous spatially. RF_{ari} showed maximum negative values over eastern North America and Europe during the early 20th century, with large negative values extending to East and Southeast Asia, South America and central Africa by 1980. Since then, however, the magnitude has decreased over eastern North America and Europe due to pollution control and the peak negative forcing has shifted to South and East Asia primarily as a result of economic growth and the resulting increase in emissions in those areas. Total aerosol ERF shows similar behaviour for locations with maximum negative forcing, but also shows substantial positive forcing over some deserts and the Arctic. In contrast, the global mean whole atmosphere ozone forcing increased throughout the 20th century, and has peak positive amplitudes around 15°N–30°N but negative values over Antarctica. Negative land-use forcing by albedo changes has been strongest in industrialized and biomass burning regions. The inhomogeneous nature of

these forcings can cause them to have a substantially larger influence on the hydrologic cycle than an equivalent global mean homogeneous forcing. {8.3, 8.6}

Over the 21st century, there is *very high confidence* that the anthropogenic radiative forcing will increase. Simple model estimates of the RF resulting from the Representative Concentration Pathways (RCPs, see Box TS.6), which include WMGHG emissions spanning a broad range of possible futures, show anthropogenic RF relative to 1750 increasing to 3.0–4.8 W m⁻² in 2050, and 2.7–8.4 W m⁻² at 2100. In the near-term, the RCPs are quite similar to one another (and emissions of near-term climate forcers do not span the literature range of possible futures), with RF at 2030 ranging only from 2.9 to 3.3 W m⁻² (additional 2010 to 2030 RF of 0.7–1.1 W m⁻²), but they show highly diverging values for the second half of the 21st century driven largely by CO₂. Results based on the RCP scenarios suggest only small changes in aerosol ERF between 2000 and 2030, followed by a strong reduction in the aerosols and a substantial weakening of the negative total aerosol ERF. Nitrate aerosols are an exception to this reduction with a substantially increased negative forcing which is a robust feature among the few available models. The divergence across the RCPs indicates that, although a certain amount of future climate change is already ‘in the system’ due to the current radiative imbalance caused by historical emissions and the long lifetime of some atmospheric forcing agents, societal choices can still have a very large effect on future radiative forcing, and hence on climate change. {8.2, 8.5, 8.6, 12.3}

TS.3.7 Climate Feedbacks

Feedbacks will also play an important role in determining future climate change. Indeed, climate change may induce modification in the carbon, water and geochemical cycles which may reinforce (positive feedback) or dampen (negative feedback) the expected temperature increase. Snow and ice albedo feedbacks are known to be positive. The combined water vapor and lapse rate feedback is *extremely likely* and now fairly well quantified, while cloud feedbacks have larger uncertainties (see TFE.6). In addition, the new Coupled Model Intercomparison Project Phase 5 (CMIP5) models consistently estimate a positive carbon-cycle feedback, i.e. reduced natural sinks or increased natural CO₂ sources in response to future climate change. In particular, carbon-cycle feedbacks in the oceans are positive in the models. Carbon sinks in tropical land ecosystems are less consistent, and may be susceptible to climate change via processes such as drought and fire that are sometimes not yet fully represented. A key update since AR4 is the introduction of nutrient dynamics in some of the CMIP5 land carbon models, in particular the limitations on plant growth imposed by nitrogen availability. The net effect of accounting for the nitrogen cycle is a smaller projected land sink for a given trajectory of anthropogenic CO₂ emissions (see TFE.7). {6.3, 6.4; Box 6.1, 7.2}

Models and ecosystem warming experiments show high agreement that wetland CH₄ emissions will increase per unit area in a warmer climate, but wetland areal extent may increase or decrease depending on regional changes in temperature and precipitation affecting wetland hydrology, so that there is low confidence in quantitative projections of wetland CH₄ emissions. Reservoirs of carbon in hydrates and permafrost are very large, and thus could potentially act as very powerful feedbacks. Although poorly constrained, the 21st century global release of CH₄ from hydrates to the atmosphere is *likely* to be low due to the under-saturated state of the ocean, long-ventilation time of the ocean, and slow propagation of warming through the seafloor. Release of carbon from thawing permafrost is *very likely* to provide a positive feedback, but there is limited confidence in quantitative projections of its strength. {6.4}

Aerosol-climate feedbacks occur mainly through changes in the source strength of natural aerosols or changes in the sink efficiency of natural and anthropogenic aerosols; a limited number of modeling studies have assessed the magnitude of this feedback to be small with a *low confidence*. There is *medium confidence* for a weak feedback (of uncertain sign) involving dimethyl sulphide, cloud condensation nuclei, and cloud albedo due to a weak sensitivity of cloud condensation nuclei population to changes in dimethyl sulphide emissions. {7.3.5}

TS.3.8 Emission Metrics

Different metrics can be used to quantify and communicate the relative and absolute contributions to climate change of emissions of different substances, and of emissions from regions/countries or sources/sectors. Up to AR4, the most common metric has been the Global Warming Potential (GWP) that integrates RF out to a

particular time horizon. This metric thus accounts for the radiative efficiencies of the various substances, and their lifetimes in the atmosphere, and gives values relative to those for the reference gas CO₂. There is now increasing focus on the Global Temperature change Potential (GTP), which is based on the change in global mean surface temperature at a chosen point in time, again relative to that caused by the reference gas CO₂, and thus accounts for climate response along with radiative efficiencies and atmospheric lifetimes. Both the GWP and the GTP use a time horizon (Figure TS.8 top), the choice of which is subjective and context-dependent. In general, GWPs for near-term climate forcers are higher than GTPs due to the equal time-weighting in the integrated forcing used in the GWP. Hence the choice of metric can greatly affect the relative importance of near-term climate forcers and WMGHGs, as can the choice of time horizon. Analysis of the impact of current emissions (one-year pulse of emissions) shows that near-term climate forcers, such as black carbon, sulfur dioxide or methane, can have contributions comparable to CO₂'s for short time horizons (of either the same or opposite sign), but their impacts become progressively less for longer time horizons over which emissions of CO₂ dominate (Figure TS.8 top). {8.7}

[INSERT FIGURE TS.8 HERE]

Figure TS.8: (Upper Panel) Global anthropogenic present-day emissions weighted by the Global Warming Potential (GWP) and the Global Temperature change Potential (GTP) for the chosen time horizons. Year 2008 (single-year pulse) emissions weighted by GWP, which is the global mean radiative forcing per unit mass emitted integrated over the indicated number of years relative to the forcing from CO₂ emissions, and GTP which estimates the impact on global mean temperature based on the temporal evolution of both radiative forcing and climate response per unit mass emitted relative to the impact of CO₂ emissions. The units are “CO₂ equivalents” which reflects equivalence only in the impact parameter of the chosen metric (integrated RF over the chosen time horizon for GWP; temperature change at the chosen point in time for GTP), given as Pg(CO₂)eq (left axis) and PgCeq (right axis) (see footnote 5). (Bottom Panel) The Absolute GTP (AGTP) as a function of time multiplied by the present-day emissions of all compounds from the indicated sectors is used to estimate global mean temperature response (AGTP is the same as GTP, except is not normalized by the impact of CO₂ emissions). There is little change in the relative values for the sectors over the 60–100 year time horizon. The effects of aerosol-cloud interactions and aviation-induced cirrus are not included in the upper panel. {Figures 8.32, 8.33}

A large number of other metrics may be defined down the driver-response-impact chain. No single metric can accurately compare all consequences (i.e., responses in climate parameters over time) of different emissions, and a metric that establishes equivalence with regard to one effect will not give equivalence with regard to other effects. The choice of metric therefore depends strongly on the particular consequence one wants to evaluate. It is important to note that the metrics do not define policies or goals, but facilitate analysis and implementation of multi-component policies to meet particular goals. All choices of metric contain implicit value-related judgments such as type of effect considered and weighting of effects over time. While GWP integrates the effects up to a chosen time horizon (i.e. giving equal weight to all times up to the horizon and zero weight thereafter), the GTP gives the temperature just for one chosen year with no weight on years before or after. {8.7}

The GWP and GTP have limitations and suffer from inconsistencies related to the treatment of indirect effects and feedbacks, for instance if climate-carbon feedbacks are included for the reference gas CO₂ but not for the non-CO₂ gases. The uncertainty in the GWP increases with time horizon and for the 100-year GWP of WMGHGs the uncertainty can be as large as $\pm 40\%$. Several studies also point out that this metric is not well suited for policies with a maximum temperature target. Uncertainties in GTP also increase with time as they arise from the same factors contributing to GWP uncertainties along with additional contributions from it being further down the driver-response-impact chain and including climate response. The GTP metric is better suited to target-based policies, but is again not appropriate for every goal. Updated metric values accounting for changes in knowledge of lifetimes and radiative efficiencies and for climate-carbon feedbacks are now available. {8.7}

With these emission metrics, the climate impact of past or current emissions attributable to various activities can be assessed. Such activity-based accounting can provide additional policy-relevant information since these activities are more directly affected by particular societal choices than overall emissions. A single-year's worth of emissions (a pulse) is often used to quantify the impact on future climate. From this perspective and with the absolute GTP metric used to illustrate the results, energy and industry have the largest contributions to warming over the next 50–100 years (Figure TS.8 bottom). Household fossil and biofuel, biomass burning and on-road transportation are also relatively large contributors to warming over

these timescales, while current emissions from sectors that emit large amounts of methane (animal husbandry, waste/landfills and agriculture) are also important over shorter time horizons (up to ~20 years). Another useful perspective is to examine the effect of sustained current emissions. Since emitted substances are removed according to their residence time, short-lived species remain at nearly constant values while long-lived gases accumulate in this analysis. In both cases, the sectors that have the greatest long-term warming impacts (energy and industry) lead to cooling in the near-term (primarily due to SO₂ emissions), and thus emissions from those sectors can lead to opposite global mean temperature responses at short and long timescales. The relative importance of the other sectors depends upon the time and perspective chosen. As with RF or ERF, uncertainties in aerosol impacts are large, and in particular attribution of aerosol-cloud interactions to individual components is poorly constrained. {8.7}

TS.4 Understanding the Climate System and its Recent Changes

TS.4.1 Introduction

Understanding of the climate system results from combining observations, theoretical studies of feedback processes, and model simulations. Compared to AR4, more detailed observations and improved climate models (see Box TS.4) now enable the attribution of detected changes to human influences in more climate system components. The consistency of observed and modeled changes across the climate system, including regional temperatures, the water cycle, global energy budget, cryosphere and oceans (including ocean acidification), point to global climate change resulting primarily from anthropogenic increases in greenhouse gas concentrations. {10}

TS.4.2 Surface Temperature

Several advances since the AR4 have allowed a more robust quantification of human influence on surface temperature changes. Observational uncertainty has been explored much more thoroughly than previously and the assessment now considers observations from the first decade of the 21st century and simulations from a new generation of climate models whose ability to simulate historical climate has improved in many respects relative to the previous generation of models considered in AR4. Observed global mean surface temperature anomalies relative to 1880-1919 in recent years lie well outside the range of temperature anomalies in CMIP5 simulations with natural forcing only, but are consistent with the ensemble of CMIP5 simulations including both anthropogenic and natural forcing (Figure TS.9) even though some individual models overestimate the warming trend, while others underestimate it. Simulations with greenhouse gas changes only, and no aerosol changes, generally exhibit stronger warming than has been observed (Figure TS.9). Observed temperature trends over the period 1951–2010, which are characterized by warming over most of the globe with the most intense warming over the Northern Hemisphere continents, are, at most observed locations, consistent with the temperature trends in CMIP5 simulations including anthropogenic and natural forcings and inconsistent with the temperature trends in CMIP5 simulations including natural forcings only. A number of studies have investigated the effects of the Atlantic Multidecadal Oscillation (AMO) on global mean surface temperature. While some studies find a significant role for the AMO in driving multi-decadal variability in GMST, the AMO exhibited little trend over the period 1951-2010 on which these assessments are based, and the AMO is assessed with *high confidence* to have made little contribution to the GMST trend between 1951 and 2010 (considerably less than 0.1°C). {2.4, 9.8.1, 10.3; FAQ 9.1}.

[INSERT FIGURE TS.9 HERE]

Figure TS.9: Three observational estimates of global mean surface temperature (black lines) from HadCRUT4, GISTEMP, and MLOST, compared to model simulations (CMIP3 models – thin blue lines and CMIP5 models – thin yellow lines) with anthropogenic and natural forcings (a), natural forcings only (b) and greenhouse gas forcing only (c). Thick red and blue lines are averages across all available CMIP5 and CMIP3 simulations respectively. All simulated and observed data were masked using the HadCRUT4 coverage (since this dataset has the most restricted spatial coverage), and global average anomalies are shown with respect to 1880–1919, where all data are first calculated as anomalies relative to 1961–1990 in each grid box. Inset to (b) shows the three observational datasets distinguished by different colours. {Figure 10.1}

It is *extremely likely* that human activities caused more than half of the observed increase in global average surface temperature from 1951 to 2010. This assessment is supported by robust evidence from multiple

studies using different methods. In particular, the temperature trend attributable to all anthropogenic forcings combined can be more closely constrained in multi-signal detection and attribution analyses. Uncertainties in forcings and in climate models' responses to those forcings, together with difficulty in distinguishing the patterns of temperature response due to greenhouse gases and other anthropogenic forcings prevent as precise a quantification of the temperature changes attributable to greenhouse gases and other anthropogenic forcings individually. Consistent with AR4, it is assessed that more than half of the observed increase in global average surface temperature from 1951 to 2010 is *very likely* due to the observed anthropogenic increase in greenhouse gas concentrations. Greenhouse gases contributed a global mean surface warming *likely* to be between 0.5°C and 1.3°C over the period between 1951 and 2010, with the contributions from other anthropogenic forcings *likely* to be between -0.6°C and 0.1°C and from natural forcings *likely* to be between -0.1°C and 0.1°C. Together these assessed contributions are consistent with the observed warming of approximately 0.6°C over this period (Figure TS.10). {10.3}

[INSERT FIGURE TS.10 HERE]

Figure TS.10: Assessed *likely* ranges (whiskers) and their midpoints (bars) for warming trends over the 1951–2010 period due to well-mixed greenhouse gases (GHG), anthropogenic forcings (ANT), anthropogenic forcings other than well-mixed greenhouse gases (OA), natural forcings (NAT), and internal variability. The trend in the HadCRUT4 observations is shown in black with its 5 to 95% uncertainty range due only to observational uncertainty in this record. {Figure 10.5}

Solar forcing is the only known natural forcing acting to warm the climate over the 1951–2010 period but it has increased much less than greenhouse gas forcing, and the observed pattern of long-term tropospheric warming and stratospheric cooling is not consistent with the expected response to solar irradiance variations. Considering this evidence together with the assessed contribution of natural forcings to observed trends over this period, it is assessed that the contribution from solar forcing to the observed global warming since 1951 is *extremely unlikely* to be larger than that from greenhouse gases. Since solar forcing has *very likely* decreased since the advent of direct satellite measurements of total solar irradiance in 1978, there is *high confidence* that changes in total solar irradiance have not contributed to global warming during that period. However, there is *medium confidence* that the 11-year cycle of solar variability influences decadal climate fluctuations in some regions through amplifying mechanisms. {8.4, 10.3; Box 10.2}

Observed warming over the past sixty years is far outside the range of internal climate variability estimated from pre-instrumental data, and it is also far outside the range of internal variability simulated in climate models. Model-based simulations of internal variability are assessed to be adequate to make this assessment. Further, the spatial pattern of observed warming differs from those associated with internal variability. Based on this evidence, the contribution of internal variability to the 1951–2010 global mean surface temperature trend was assessed to be *likely* between -0.1°C and 0.1°C, and it is *virtually certain* that warming since 1951 cannot be explained by internal variability alone. {9.5, 10.3, 10.7}

The instrumental record shows a pronounced warming during the first half of the 20th century. Consistent with AR4, it is assessed that the early 20th century warming is *very unlikely* to be due to internal variability alone. It remains difficult to quantify the contributions to this early century warming from internal variability, natural forcing and anthropogenic forcing, due to forcing and response uncertainties and incomplete observational coverage. {10.3}

[START BOX TS.3 HERE]

Box TS.3: Climate Models and the Hiatus in Global-Mean Surface Warming of the Past 15 years

The observed global-mean surface temperature (GMST) has shown a much smaller increasing linear trend over the past 15 years than over the past 30 to 60 years (Box TS.3, Figure 1a,c). Depending on the observational data set, the GMST trend over 1998–2012 is estimated to be around one-third to one-half of the trend over 1951–2012. For example, in HadCRUT4 the trend is 0.04°C per decade over 1998–2012, compared to 0.11°C per decade over 1951–2012. The reduction in observed GMST trend is most marked in Northern-Hemisphere winter. Even with this “hiatus” in GMST trend, the decade of the 2000s has been the warmest in the instrumental record of GMST. Nevertheless, the occurrence of the hiatus in GMST trend during the past 15 years raises the two related questions of what has caused it and whether climate models are able to reproduce it. {2.4.3, 9.4.1; Box 9.2; Table 2.7}

Fifteen-year-long hiatus periods are common in both the observed and CMIP5 historical GMST time series. However, an analysis of the full suite of CMIP5 historical simulations (augmented for the period 2006–2012 by RCP4.5 simulations) reveals that 111 out of 114 realisations show a GMST trend over 1998–2012 that is higher than the entire HadCRUT4 trend ensemble (Box TS.3, Figure 1a; CMIP5 ensemble-mean trend is 0.21°C per decade). This difference between simulated and observed trends could be caused by some combination of (a) internal climate variability, (b) missing or incorrect radiative forcing, and (c) model response error. These potential sources of the difference, which are not mutually exclusive, are assessed below, as is the cause of the observed GMST trend hiatus. {2.4.3, 9.3.2, 9.4.1; Box 9.2}

(a) *Internal Climate Variability*

Hiatus periods of 10–15 years can arise as a manifestation of internal decadal climate variability, which sometimes enhances and sometimes counteracts the long-term externally forced trend. Internal variability thus diminishes the relevance of trends over periods as short as 10 to 15 years for long-term climate change. Furthermore, the timing of internal decadal climate variability is not expected to be matched by the CMIP5 historical simulations, owing to the predictability horizon of at most 10 to 20 years (CMIP5 historical simulations are typically started around nominally 1850 from a control run). However, climate models exhibit individual decades of GMST trend hiatus even during a prolonged phase of energy uptake of the climate system, in which case the energy budget would be balanced by increasing subsurface-ocean heat uptake. {2.4.3, 9.3.2, 11.2.2; Box 2.2, 9.2}

Owing to sampling limitations, it is uncertain whether an increase in the rate of subsurface-ocean heat uptake occurred during the past 15 years. However, it is *very likely* that the climate system, including the ocean below 700 m depth, has continued to accumulate energy over the period 1998–2010. Consistent with this energy accumulation, global-mean sea level has continued to rise during 1998–2012, at a rate only slightly and insignificantly lower than during 1993–2012. The consistency between observed heat-content and sea-level changes yields *high confidence* in the assessment of continued ocean energy accumulation, which is in turn consistent with the positive radiative imbalance of the climate system. By contrast, there is *limited evidence* that the hiatus in GMST trend has been accompanied by a slower rate of increase in ocean heat content over the depth range 0 to 700 m, when comparing the period 2003–2010 against 1971–2010. There is *low agreement* on this slowdown, since three of five analyses show a slowdown in the rate of increase while the other two show the increase continuing unabated. {3.2.3, 3.2.4, 3.7, 8.5.1, 13.3; Box 3.1, 13.1}

During the 15-year period beginning in 1998, the ensemble of HadCRUT4 GMST trends lies below almost all model-simulated trends (Box TS.3, Figure 1a), whereas during the 15-year period ending in 1998, it lies above 93 out of 114 modelled trends (Box TS.3, Figure 1b; HadCRUT4 ensemble-mean trend 0.26°C per decade, CMIP5 ensemble-mean trend 0.16°C per decade). Over the 62-year period 1951–2012, observed and CMIP5 ensemble-mean trend agree to within 0.02°C per decade (Box TS.3, Figure 1c; CMIP5 ensemble-mean trend 0.13°C per decade). There is hence *very high confidence* that the CMIP5 models show long-term GMST trends consistent with observations, despite the disagreement over the most recent 15-year period. Due to internal climate variability, in any given 15-year period the observed GMST trend sometimes lies near one end of a model ensemble, an effect that is pronounced in Box TS.3, Figure 1a,b since GMST was influenced by a very strong El Niño event in 1998.

Unlike the CMIP5 historical simulations referred to above, some CMIP5 predictions were initialised from the observed climate state during the late 1990s and the early 21st century. There is *medium evidence* that these initialised predictions show a GMST lower by about 0.05°C to 0.1°C compared to the historical (uninitialised) simulations and maintain this lower GMST during the first few years of the simulation. In some initialised models this lower GMST occurs in part because they correctly simulate a shift, around 2000, from a positive to a negative phase of the Interdecadal Pacific Oscillation. However, the improvement of this phasing of the Interdecadal Pacific Oscillation through initialisation is not universal across the CMIP5 predictions. Moreover, while part of the GMST reduction through initialisation indeed results from initialising at the correct phase of internal variability, another part may result from correcting a model bias that was caused by incorrect past forcing or incorrect model response to past forcing, especially in the ocean. The relative magnitudes of these effects are at present unknown; moreover, the quality of a forecasting system cannot be evaluated from a single prediction (here, a ten-year prediction within the period 1998–

2012). Overall, there is *medium confidence* that initialisation leads to simulations of GMST during 1998–2012 that are more consistent with the observed trend hiatus than are the uninitialised CMIP5 historical simulations, and that the hiatus is in part a consequence of internal variability that is predictable on the multiyear timescale. {11.1, 11.2.3; Box 11.1, 11.2, 2.5, 9.2;}

(b) Radiative Forcing

On decadal to interdecadal timescales and under continually increasing effective radiative forcing (ERF), the forced component of the GMST trend responds to the ERF trend relatively rapidly and almost linearly (*medium confidence*). The expected forced-response GMST trend is related to the ERF trend by a factor that has been estimated for the 1% per year CO₂ increases in the CMIP5 ensemble as 2.0 [1.3 to 2.7] W m⁻² °C⁻¹ (90% uncertainty range). Hence, an ERF trend can be approximately converted to a forced-response GMST trend, permitting an assessment of how much of the change in the GMST trends shown in Box TS.3, Figure 1 is due to a change in ERF trend. {Box 9.2}

The AR5 best-estimate ERF trend over 1998–2011 is 0.23 [0.12 to 0.34] W m⁻² per decade (90% uncertainty range), which is substantially lower than the trend over 1984–1998 (0.34 [0.24 to 0.44] W m⁻² per decade; note that there was a strong volcanic eruption in 1982) and the trend over 1951–2011 (0.30 [0.20 to 0.40] W m⁻² per decade; Box TS.3, Figure 1d–f; the end year 2011 is chosen because data availability is more limited than for GMST). The resulting forced-response GMST trend would approximately be 0.13 [0.06 to 0.31] °C per decade, 0.19 [0.10 to 0.40] °C per decade, and 0.17 [0.08 to 0.36] °C per decade for the periods 1998–2011, 1984–1998, and 1951–2011, respectively (the uncertainty ranges assume that the range of the conversion factor to GMST trend and the range of ERF trend itself are independent). The AR5 best-estimate ERF forcing trend difference between 1998–2011 and 1951–2011 thus might explain about one-half (0.04 °C per decade) of the observed GMST trend difference between these periods (0.06 to 0.08 °C per decade, depending on observational data set). {8.5.2}

The reduction in AR5 best-estimate ERF trend over 1998–2011 compared to both 1984–1998 and 1951–2011 is mostly due to decreasing trends in the natural forcings, -0.14 [-0.24 to -0.04] W m⁻² per decade over 1998–2011 compared to 0.0 [-0.01 to +0.01] W m⁻² per decade over 1951–2011. Solar forcing went from a relative maximum in 2000 to a relative minimum in 2009, with a peak-to-peak difference of around 0.15 W m⁻² and a linear trend over 1998–2011 of around -0.10 W m⁻² per decade. Furthermore, a series of small volcanic eruptions has increased the observed stratospheric aerosol loading after 2000, leading to an additional negative ERF linear-trend contribution of around -0.04 W m⁻² per decade over 1998–2011 (Box TS.3, Figure 1d,f). By contrast, satellite-derived estimates of tropospheric aerosol optical depth suggests little overall trend in global-mean aerosol optical depth over the last 10 years, implying little change in ERF due to aerosol-radiative interaction (*low confidence* because of *low confidence* in aerosol optical depth trend itself). Moreover, because there is only *low confidence* in estimates of ERF due to aerosol-cloud interaction, there is likewise *low confidence* in its trend over the last 15 years. {2.2.3, 8.4.2, 8.5.1, 8.5.2, 10.3.1; Box 10.2; Table 8.6, 8.7}

For the periods 1984–1998 and 1951–2011, the CMIP5 ensemble-mean ERF trend deviates from the AR5 best-estimate ERF trend by only 0.01 W m⁻² per decade (Box TS.3, Figure 1e, f). After 1998, however, some contributions to a decreasing ERF trend are missing in the CMIP5 models, such as the increasing stratospheric aerosol loading after 2000 and the unusually low solar minimum in 2009. Nonetheless, over 1998–2011 the CMIP5 ensemble-mean ERF trend is lower than the AR5 best-estimate ERF trend by 0.05 W m⁻² per decade (Box TS.3, Figure 1d). Furthermore, global-mean aerosol optical depth in the CMIP5 models shows little trend over 1998–2012, similar to the observations. Although the forcing uncertainties are substantial, there are no apparent incorrect or missing global-mean forcings in the CMIP5 models over the last 15 years that could explain the model–observations difference during the warming hiatus. {9.4.6}

(c) Model Response Error

The discrepancy between simulated and observed GMST trends during 1998–2012 could be explained in part by a tendency for some CMIP5 models to simulate stronger warming in response to increases in greenhouse-gas concentration than is consistent with observations. Averaged over the ensembles of models assessed in Section 10.3.1.1.3, the best-estimate greenhouse-gas (GHG) and other anthropogenic (OA)

scaling factors are less than one (though not significantly so, Figure 10.4), indicating that the model-mean GHG and OA responses should be scaled down to best match observations. This finding provides evidence that some CMIP5 models show a larger response to greenhouse gases and other anthropogenic factors (dominated by the effects of aerosols) than the real world (*medium confidence*). As a consequence, it is argued in Chapter 11 that near-term model projections of GMST increase should be scaled down by about 10%. This downward scaling is, however, not sufficient to explain the model-mean overestimate of GMST trend over the hiatus period. {10.3.1; 11.3.6}

Another possible source of model error is the poor representation of water vapour in the upper atmosphere. It has been suggested that a reduction in stratospheric water vapour after 2000 caused a reduction in downward longwave radiation and hence a surface-cooling contribution, possibly missed by the models. However, this effect is assessed here to be small, because there was a recovery in stratospheric water vapour after 2005. {2.2.2, 9.4.1; Box 9.2}

In summary, the observed recent warming hiatus, defined as the reduction in GMST trend during 1998–2012 as compared to the trend during 1951–2012, is attributable in roughly equal measure to a cooling contribution from internal variability and a reduced trend in external forcing (expert judgment, *medium confidence*). The forcing trend reduction is primarily due to a negative forcing trend from both volcanic eruptions and the downward phase of the solar cycle. However, there is *low confidence* in quantifying the role of forcing trend in causing the hiatus, because of uncertainty in the magnitude of the volcanic forcing trend and *low confidence* in the aerosol forcing trend. {Box 9.2}

Almost all CMIP5 historical simulations do not reproduce the observed recent warming hiatus. There is *medium confidence* that the GMST trend difference between models and observations during 1998–2012 is to a substantial degree caused by internal variability, with possible contributions from forcing error and some CMIP5 models overestimating the response to increasing greenhouse-gas forcing. The CMIP5 model trend in effective radiative forcing (ERF) shows no apparent bias against the AR5 best estimate over 1998–2012. However, *confidence* in this assessment of CMIP5 ERF trend is *low*, primarily because of the uncertainties in model aerosol forcing and processes, which through spatial heterogeneity might well cause an undetected global-mean ERF trend error even in the absence of a trend in the global-mean aerosol loading. {Box 9.2}

The causes of both the observed GMST trend hiatus and of the model–observation GMST trend difference during 1998–2012 imply that, barring a major volcanic eruption, most 15-year GMST trends in the near-term future will be larger than during 1998–2012 (*high confidence*; see Section 11.3.6.3. for a full assessment of near-term projections of GMST). The reasons for this implication are fourfold: first, anthropogenic greenhouse-gas concentrations are expected to rise further in all RCP scenarios; second, anthropogenic aerosol concentration is expected to decline in all RCP scenarios, and so is the resulting cooling effect; third, the trend in solar forcing is expected to be larger over most near-term 15-year periods than over 1998–2012 (*medium confidence*), because 1998–2012 contained the full downward phase of the solar cycle; and fourth, it is *more likely than not* that internal climate variability in the near-term will enhance and not counteract the surface warming expected to arise from the increasing anthropogenic forcing. {Box 9.2}

[INSERT BOX TS.3, FIGURE 1 HERE]

Box TS.3, Figure 1: Top: Observed and simulated GMST trends in °C per decade, over the periods 1998–2012 (a), 1984–1998 (b), and 1951–2012 (c). For the observations, 100 realisations of the HadCRUT4 ensemble are shown (red, hatched). The uncertainty displayed by the ensemble width is that of the statistical construction of the global average only, in contrast to the trend uncertainties quoted in Section 2.4.3, which include an estimate of internal climate variability. Here, by contrast, internal variability is characterised through the width of the model ensemble. For the models, all 114 available CMIP5 historical realisations are shown, extended after 2005 with the RCP4.5 scenario and through 2012 (grey, shaded). Bottom: Trends in effective radiative forcing (ERF, in W m^{-2} per decade) over the periods 1998–2011 (d), 1984–1998 (e), and 1951–2011 (f). The figure shows AR5 best-estimate ERF trends (red, hatched) and CMIP5 ERF (grey, shaded). Black lines are smoothed versions of the histograms. Each histogram is normalised so that its area sums up to one. {2.4.3, 8.5.2; Box 9.2; Figure 8.18, Box 9.2, Figure 1}

[END BOX TS.3 HERE]

TFE.3: Comparing Projections from Previous IPCC Assessments with Observations

Verification of projections is arguably the most convincing way of establishing the credibility of climate change science. Results of projected changes in CO₂, global mean surface temperature and global mean sea level from previous IPCC assessment reports are quantitatively compared with the best available observational estimates. The comparison between the four previous reports highlights the evolution in our understanding of how the climate system responds to changes in both natural and anthropogenic forcing and provides an assessment of how the projections compare with observational estimates. TFE.3, Figure 1, for example, shows the projected and observed estimates of: (i) CO₂ changes (top row), (ii) global mean surface temperature anomaly relative to 1961–1990 (middle row) and (iii) global mean sea level relative to 1990 (bottom row). Results from previous assessment reports are in the left hand column, and for completeness results from current assessment are given in the right hand column. {2.4, 3.7, 6.3, 11.3, 13.3}

[INSERT TFE.3, FIGURE 1 HERE]

TFE.3, Figure 1: (top: left) Observed globally and annually averaged CO₂ concentrations in parts per million (ppm) since 1950 compared with projections from the previous IPCC assessments. Observed global annual CO₂ concentrations are shown in dark blue. The shading shows the largest model projected range of global annual CO₂ concentrations from 1950 to 2035 from FAR (First Assessment Report; Figure A.3 in the Summary for Policymakers (SPM) of IPCC 1990), SAR (Second Assessment Report; Figure 5b in the TS of IPCC 1996), TAR (Third Assessment Report; Appendix II of IPCC 2001), and for the A2, A1B and B1 scenario presented in the AR4 (Fourth Assessment Report; Figure 10.26). (top: right) Same observed globally averaged CO₂ concentrations and the projections from this report. Only RCP8.5 has a range of values since the emission driven scenarios were only carried out for this RCP. For the other RCPs the best estimate is given. (middle: left) Estimated changes in the observed globally and annually averaged surface temperature anomaly relative to 1961–1990 (in °C) since 1950 compared with the range of projections from the previous IPCC assessments. Values are harmonized to start from the same value at 1990. Observed global annual temperature anomaly, relative to 1961–1990, from three datasets is shown as squares (NASA (dark blue), NOAA (warm mustard), and the UK Hadley Centre (bright green) data sets). The coloured shading shows the projected range of global annual mean near surface temperature change from 1990 to 2035 for models used in FAR (Figure 6.11), SAR (Figure 19 in the TS of IPCC 1996), TAR (full range of TAR, Figure 9.13(b)). TAR results are based on the simple climate model analyses presented in this assessment and not on the individual full three-dimensional climate model simulations. For the AR4 results are presented as single model runs of the CMIP3 ensemble for the historical period from 1950–2000 (light grey lines) and for three scenarios (A2, A1B and B1) from 2001–2035. For the three SRES scenarios the bars show the CMIP3 ensemble mean and the likely range given by -40 % to +60% of the mean as assessed in Meehl et al. (2007). The publication years of the assessment reports are shown. (middle: right) Projections of annual mean global mean surface air temperature (GMST) for 1950–2035 (anomalies relative to 1961–1990) under different RCPs from CMIP5 models (light grey and coloured lines, one ensemble member per model), and observational estimates the same as the middle left panel. The grey shaded region shows the indicative likely range for annual mean GMST during the period 2016–2035 for all RCPs (see Figure TS.14 for more details). The grey bar shows this same indicative likely range for the year 2035. (bottom: left) Estimated changes in the observed global annual mean sea level (GMSL) since 1950. Different estimates of changes in global annual sea level anomalies from tide gauge data (dark blue, warm mustard, dark green) and based on annual averages of altimeter data (light blue) starting in 1993 (the values have been aligned to fit the 1993 value of the tide gauge data). Squares indicate annual mean values, solid lines smoothed values. The shading shows the largest model projected range of global annual sea level rise from 1950 to 2035 for FAR (Figures 9.6 and 9.7), SAR (Figure 21 in TS of IPCC, 1996), TAR (Appendix II of IPCC, 2001; updated) based on the Coupled Model Intercomparison Project Phase 3 (CMIP3) model results available at the time of AR4 using the SRES A1B scenario. Note that in the AR4 no full range was given for the sea level projections for this period. Therefore, the figure shows results only for the SRES-A1B scenario that have been published subsequent to the AR4. The bars at the right hand side of each graph show the full range given for 2035 for each assessment report. The publication years of the assessment reports are shown. Appendix 1.A for details on the data and calculations used to create these figures. (bottom: right) Same observational estimate as bottom left. The bars are the "likely ranges (medium confidence) for global mean sea level rise at 2081–2100 with respect to 1986–2005 following the four RCPs. See Chapters 1, 11 and 13 for more details. {Figures 1.4, 1.5, 1.10, 11.9, 11.19, 11.25, 13.11}

CO₂ Changes

From 1950–2011 the observed concentrations of atmospheric CO₂ have steadily increased. Considering the period 1990–2011, the observed CO₂ concentration changes lie within the envelope of the scenarios used in the four assessment reports. As the most recent assessment, AR4 (TFE.3.Figure 1; top left) has the narrowest scenario range and the observed concentration follows this range. The AR5 results (TFE.3.Figure 1; top right) are consistent with AR4, and during 2002–2011, atmospheric CO₂ concentrations increased at a rate of 1.9 to 2.1 ppm yr⁻¹. {2.2.1, 6.3; Table 6.1}

Global Mean Temperature Anomaly

Relative to the 1961–1990 mean, the global mean surface temperature anomaly has been positive and larger than 0.25°C since 2001. Overall the observed temperature record lies within the total range of uncertainty (i.e., the combined effects of scenario uncertainty, observational uncertainty and uncertainty due to natural variability; area enclosed colored wedges (TFE.3, Figure 1, middle left: FAR, SAR, TAR, AR4: B1, A1B, A2) and by individual CMIP3 simulations and projections). This is also true for the CMIP5 results (TFE.3, Figure 1; middle right) in the sense that the observed record lies within the range of the model projections, but on the lower end of the plume. Mount Pinatubo erupted in 1991 (see FAQ 11.2 for discussion of how volcanoes impact the climate system) leading to a brief period of relative global mean cooling during the early 1990's. The FAR, SAR and TAR did not include the effects of volcanic eruptions and thus failed to include the cooling associated with the Pinatubo eruption. AR4 and AR5, however, did include the effects from volcanoes and did simulate successfully the associated cooling. During 1995–2000 the global mean temperature anomaly was quite variable – a significant fraction of this variability was due to the large El Niño in 1997–1998 and the strong back-to-back La Niña's in 1999–2001. The projections associated with these assessment reports do not attempt to capture the actual evolution of these El Niño and La Niña events, but includes them as a source of uncertainty due to natural variability as encompassed by, for example, the range given by the individual CMIP3 and CMIP5 simulations and projection (TFE.3, Figure 1). The grey wedge in TFE.3, Figure 1 (middle right) corresponds to the indicative likely range for annual temperatures, which is determined from the all RCPs assessed value for the 20-year mean 2016–2035 (see discussion of Figure TS.14 and Section 11.3.6 for details). From 1998–2012 the observational estimates have largely been on the low end of the range given by the scenarios alone in previous assessment reports and CMIP3 and CMIP5 projections. {2.4; Box 9.2}

Global Mean Sea Level

Based on both tide gauge and satellite altimetry data, relative to 1990, the global mean sea level has continued to rise. While the increase is fairly steady, both observational records show short periods of either no change or a slight decrease. The observed estimates lie within the envelope of all the projections except perhaps in the very early 1990s. The sea level rise uncertainty due to scenario-related uncertainty is smallest for the most recent assessments (AR4 and AR5) and observed estimates lie well within this scenario-related uncertainty. It is *virtually certain* that over the 20th century that sea level rose. The mean rate of sea level increase was 1.7 mm yr⁻¹ with a *very likely* range between 1.5 to 1.9 between 1901 and 2010 and this rate increased to 3.2 with a *likely* range of 2.8 to 3.6 mm yr⁻¹ between 1993 and 2010 (see TFE.2). {3.7.2, 3.7.4}

TS.4.3 Atmospheric Temperature

A number of studies since the AR4 have investigated the consistency of simulated and observed trends in free tropospheric temperatures (see section TS.2). Most, though not all, CMIP3 and CMIP5 models overestimate the observed warming trend in the tropical troposphere during the satellite period 1979–2012. Roughly one-half to two-thirds of this difference from the observed trend is due to an overestimate of the sea surface temperature trend, which is propagated upward because models attempt to maintain static stability. There is *low confidence* in these assessments, however, due to the *low confidence* in observed tropical tropospheric trend rates and vertical structure. Outside the tropics, and over the period of the radiosonde record beginning in 1961, the discrepancy between simulated and observed trends is smaller. {2.4.4, 9.4, 10.3}

Analysis of both radiosonde and satellite datasets, combined with CMIP5 and CMIP3 simulations continues to find that observed tropospheric warming is inconsistent with internal variability and simulations of the response to natural forcings alone. Over the period 1961–2010 CMIP5 models simulate tropospheric warming driven by greenhouse gas changes, with only a small offsetting cooling due to the combined effects of changes in reflecting and absorbing aerosols and tropospheric ozone. Taking this evidence together with the results of multi-signal detection and attribution analyses, it is *likely* that anthropogenic forcings, dominated by greenhouse gases, have contributed to the warming of the troposphere since 1961. Uncertainties in radiosonde and satellite records makes assessment of causes of observed trends in the upper

troposphere less confident than an assessment of the overall atmospheric temperature changes. {2.4.4, 9.4, 10.3}

CMIP5 simulations including greenhouse gas, ozone and natural forcing changes broadly reproduce the observed evolution of lower stratospheric temperature, with some tendency to underestimate the observed cooling trend over the satellite era (see Section TS.2). New studies of stratospheric temperature, considering the responses to natural forcings, greenhouse gases and ozone-depleting substances, demonstrate that it is *very likely* that anthropogenic forcings, dominated by the depletion of the ozone layer due to ozone depleting substances have contributed to the cooling of the lower stratosphere since 1979. CMIP5 models simulate only a very weak cooling of the lower stratosphere in response to historical greenhouse gas changes, and the influence of greenhouse gases on lower stratospheric temperature has not been formally detected. Considering both regions together, it is *very likely* that anthropogenic forcing, particularly greenhouse gases and stratospheric ozone depletion, has led to a detectable observed pattern of tropospheric warming and lower stratospheric cooling since 1961. {2.4, 9.4, 10.3}

TS.4.4 Oceans

The observed upper-ocean warming during the late 20th and early 21st centuries and its causes have been assessed more completely since AR4 using updated observations and more simulations (see Section TS.2.2). The long term trends and variability in the observations are most consistent with simulations of the response to both anthropogenic forcing and volcanic forcing. The anthropogenic fingerprint in observed upper-ocean warming, consisting of global mean and basin-scale pattern changes, has also been detected. This result is robust to a number of observational, model and methodological or structural uncertainties. It is *very likely* that anthropogenic forcings have made a substantial contribution to upper ocean warming (above 700m) observed since the 1970s. This anthropogenic ocean warming has contributed to global sea level rise over this period through thermal expansion. {3.2.2, 3.2.3, 3.7.2, 10.4.1, 10.4.3; Box 3.1}

Observed surface salinity changes also suggest a change in the global water cycle has occurred (see TFE.1). The long term trends show that there is a strong positive correlation between the mean climate of the surface salinity and the temporal changes of surface salinity from 1950 to 2000. This correlation shows an enhancement of the climatological salinity pattern—so fresh areas have become fresher and salty areas saltier. The strongest anthropogenic signals are in the tropics (TRO, 30°S–30°N) and the Western Pacific. The salinity contrast between the Pacific and Atlantic oceans is also increased with significant contributions from anthropogenic forcing. {3.3, 10.3.2, 10.4.2; FAQ 3.3}

On a global scale, surface and subsurface salinity changes (1955–2004) over the upper 250m of the water column are very unlikely to be explained by natural variability. However, the observed salinity changes match the modelled distribution of forced changes (greenhouse gases and tropospheric aerosols). Natural external variability taken from the simulations with just the variations in solar and volcanic forcing do not match the observations at all, thus excluding the hypothesis that observed trends can be explained by just solar or volcanic variations. These lines of evidence and our physical understanding of the physical processes leads to the conclusions that it is *very likely* that anthropogenic forcings have made a discernable contribution to surface and subsurface oceanic salinity changes since the 1960's. {10.4.2; Table 10.1}

Oxygen is an important physical and biological tracer in the ocean. Global analyses of oxygen data from the 1960's to 1990's extend the spatial coverage from local to global scales and have been combined with attribution studies for a limited range of earth system models. It is concluded that there is *medium confidence* that the observed global pattern of decrease in dissolved oxygen in the oceans can be attributed in part to human influences. {3.8.3, 10.4.4; Table 10.1}

The observations show distinct trends for ocean acidification (which is observed to be between –0.0014 and –0.0024 pH units per year). It is *very likely* that oceanic uptake of anthropogenic carbon dioxide has resulted in the acidification of surface waters. {3.8.2, 10.4.4; Box 3.2; Table 10.1}

TFE.4: The Changing Energy Budget of the Global Climate System

The global energy budget is a fundamental aspect of the Earth's climate system and depends on many phenomena within it. The ocean has stored about 93% of the increase in energy in the climate system over recent decades resulting in ocean thermal expansion and hence sea level rise. The rate of storage of energy in the Earth system must be equal to the net downward radiative flux at the top of the atmosphere, which is the difference between effective radiative forcing due to changes imposed on the system, and the radiative response of the system. There are also significant transfers of energy between components of the climate system and from one location to another. The focus here is on the Earth's global energy budget since 1970, when better global observational data coverage is available. {3.7, 9.4, 13.4; Box 3.1}

The effective radiative forcing of the climate system has been positive as a result of increases in well-mixed (long-lived) greenhouse gas concentrations, changes in short-lived greenhouse gases (tropospheric and stratospheric ozone and stratospheric water vapour), and an increase in solar irradiance (TFE.4, Figure 1a). This has been partly compensated by a negative contribution to the effective radiative forcing of the climate system as a result of changes in tropospheric aerosol, which predominantly reflect sunlight and furthermore enhance the brightness of clouds, although black carbon produces positive forcing. Explosive volcanic eruptions (such as El Chichón in Mexico in 1982 and Mount Pinatubo in the Philippines in 1991) can inject sulphur dioxide into the stratosphere, giving rise to stratospheric aerosol, which persists for several years. Stratospheric aerosol reflects some of the incoming solar radiation and thus gives a negative forcing. Changes in surface albedo from land-use change have also led to a greater reflection of shortwave radiation back to space and hence a negative forcing. Since 1970, the net effective radiative forcing of the climate system has increased, and the integrated impact of these forcings is an energy inflow over this period (TFE.4, Figure 1a). {2.3, 8.5; Box 13.1}

[INSERT TFE.4, FIGURE 1 HERE]

TFE.4, Figure 1: The Earth's energy budget from 1970 through 2011. (a) The cumulative energy inflow into the Earth system from changes in well-mixed and short-lived greenhouse gases, solar forcing, tropospheric aerosol forcing, volcanic forcing, and changes in surface albedo due to land-use change (all relative to 1860-1879) are shown by the coloured lines; these contributions are added to give the total energy inflow (black; contributions from black carbon on snow and contrails as well as contrail-induced cirrus are included but not shown separately). (b) The cumulative total energy inflow from (a, black) is balanced by the sum of the energy uptake of the Earth system (blue; energy absorbed in warming the ocean, the atmosphere, and the land, as well as in the melting of ice) and an increase in outgoing radiation inferred from changes in the global-mean surface temperature. The sum of these two terms is given for a climate feedback parameter α of 2.47, 1.23, and 0.82 $\text{W m}^{-2} \text{ } ^\circ\text{C}^{-1}$, corresponding to an equilibrium climate sensitivity of 1.5°C, 3.0°C, and 4.5°C, respectively; 1.5°C–4.5°C is assessed to be the *likely* range of equilibrium climate sensitivity. The energy budget would be closed for a particular value of α if the corresponding line coincided with the total energy inflow. For clarity, all uncertainties (shading) shown are *likely* ranges. {Box 12.2; Box 13.1, Figure 1}

As the climate system warms, energy is lost to space through increased outgoing radiation. This radiative response by the system is predominantly due to increased thermal radiation, but it is modified by climate feedbacks such as changes in water vapour, clouds, and surface albedo, which affect both outgoing long-wave and reflected shortwave radiation. The top of the atmosphere fluxes have been measured by the Earth Radiation Budget Experiment (ERBE) satellites from 1985 to 1999 and the Cloud and the Earth's Radiant Energy System (CERES) satellites from March 2000 to the present. The top of the atmosphere radiative flux measurements are highly precise, allowing identification of changes in the Earth's net energy budget from year to year within the ERBE and CERES missions, but the absolute calibration of the instruments is not sufficiently accurate to allow determination of the absolute top of the atmosphere energy flux or to provide continuity across missions. TFE.4, Figure 1b relates the cumulative total energy change of the Earth system to the change in energy storage and the cumulative outgoing radiation. Calculation of the latter is based on the observed global-mean surface temperature multiplied by the climate feedback parameter α , which in turn is related to the equilibrium climate sensitivity. The mid-range value for α , 1.23 $\text{W m}^{-2} \text{ } ^\circ\text{C}^{-1}$, corresponds to an effective radiative forcing for a doubled CO_2 concentration of 3.7 [2.96 to 4.44] W m^{-2} combined with an equilibrium climate sensitivity of 3.0°C. The climate feedback parameter α is *likely* to be in the range from 0.82 $\text{W m}^{-2} \text{ } ^\circ\text{C}^{-1}$ to 2.47 $\text{W m}^{-2} \text{ } ^\circ\text{C}^{-1}$ (corresponding to the *likely* range in equilibrium climate sensitivity of 1.5°C to 4.5°C). {9.7.1, Box 12.2}

If effective radiative forcing were fixed, the climate system would eventually warm sufficiently that the radiative response would balance the effective radiative forcing, and there would be no further change in energy storage in the climate system. However, the forcing is increasing, and the ocean's large heat capacity

means that the climate system is not in radiative equilibrium and its energy content is increasing (TFE.4, Figure 1b). This storage provides strong evidence of a changing climate. The majority of this additional heat is in the upper 700 m of the ocean, but there is also warming in the deep and abyssal ocean. The associated thermal expansion of the ocean has contributed about 40% of the observed sea level rise since 1970. A small amount of additional heat has been used to warm the continents, warm and melt glacial and sea ice, and warm the atmosphere. {13.4.2; Box 3.1, Box 13.1}

In addition to these forced variations in the Earth's energy budget, there is also internal variability on decadal time scales. Observations and models indicate that, because of the comparatively small heat capacity of the atmosphere, a decade of steady or even decreasing surface temperature can occur in a warming world. Climate model simulations suggest that these periods are associated with a transfer of heat from the upper to the deeper ocean, of the order 0.1 W m^{-2} , with a near-steady or an increased radiation to space, again of the order 0.1 W m^{-2} . While these natural fluctuations represent a large amount of heat, they are significantly smaller than the anthropogenic forcing of the Earth's energy budget, particularly on timescales of several decades or longer {9.4; Box 9.2, 13.1}.

The available independent estimates of effective radiative forcing, of observed heat storage, and of surface warming combine to give an energy budget for the Earth that is consistent with the assessed *likely* range of equilibrium climate sensitivity to within estimated uncertainties. Quantification of the terms in the Earth's energy budget and verification that these terms balance over recent decades provides strong evidence for our understanding of anthropogenic climate change {Box 13.1}.

TS.4.5 Cryosphere

The reductions in Arctic sea ice extent and northern hemisphere snow cover extent and widespread glacier retreat and increased surface melt of Greenland (see TS.2) are all evidence of systematic changes in the cryosphere. All of these changes in the cryosphere have been linked to anthropogenic forcings. {4.2.2, 4.4, 4.5, 4.6, 10.5.1, 10.5.3; Table 10.1}

Attribution studies, comparing the seasonal evolution of Arctic sea ice extent from observations from the 1950s with those simulated by coupled model simulations, demonstrate that human influence on the sea ice extent changes can be robustly detected since the early 1990s. The anthropogenic signal is also detectable for individual months from May to December, suggesting that human influence, strongest in late summer, now also extends into colder seasons. From these simulations of sea-ice and observed sea-ice extent from the instrumental record with high agreement between studies, it is concluded that anthropogenic forcings are *very likely* to have contributed to Arctic sea ice loss since 1979 (Figure TS.12). {10.5.1}

For Antarctic sea ice extent, the shortness of the observed record and differences in simulated and observed variability preclude an assessment of whether or not the observed increase since 1979 is inconsistent with internal variability. Untangling the processes involved with trends and variability in Antarctica and surrounding waters remains complex and several studies are contradictory. In conclusion there is *low confidence* in the scientific understanding of the observed increase in Antarctic sea ice extent since 1979, due to the large differences between sea-ice simulations from CMIP5 models and to the incomplete and competing scientific explanations for the causes of change and *low confidence* in estimates of internal variability (Figure TS.12). {9.4.3, 10.5.1; Table 10.1}

The Greenland ice sheet shows recent major melting episodes in response to record temperatures relative to the 20th century associated with persistent shifts in early summer atmospheric circulation, and these shifts have become more pronounced since 2007. While many Greenland instrumental records are relatively short (two decades), regional modelling and observations tell a consistent story of the response of Greenland temperatures and ice sheet runoff to shifts in regional atmospheric circulation associated with larger scale flow patterns and global temperature increases. Mass loss and melt is also occurring in Greenland through the intrusion of warm water into the major fjords containing glaciers such as Jacobshaven Glacier. It is *likely* that anthropogenic forcing has contributed to surface melting of the Greenland ice sheet since 1990. {10.5.2; Table 10.1}

Estimates of ice mass in Antarctica since 2000 show that the greatest losses are at the edges. An analysis of observations underneath a floating ice shelf off West Antarctica leads to the conclusion that ocean warming in this region and increased transport of heat by ocean circulation are largely responsible for accelerating melt rates. The observational record of Antarctic mass loss is short and the internal variability of the ice sheet is poorly understood. These factors combined with incomplete models of Antarctic ice sheet mass loss result in *low confidence* in scientific understanding of this mass loss, and consequently the attribution of the decrease in mass of Antarctic ice sheet to human influence is premature. {3.2, 4.2, 4.4.3, 10.5.2}

The evidence for the retreat of glaciers due to warming and moisture change is now more complete than at the time of AR4. There is *high confidence* in the estimates of observed mass loss and the estimates of natural variations and internal variability from long term glacier records. Based on these factors and our understanding of glacier response to climatic drivers there is high confidence that a substantial part of the mass loss of glaciers is *likely* due to human influence. It is *likely* that there has been an anthropogenic component to observed reductions in northern hemisphere snow cover since 1970. {4.3.3, 10.5.2, 10.5.3; Table 10.1}

TFE.5: Irreversibility and Abrupt Change

A number of components or phenomena within the climate system have been proposed as potentially exhibiting threshold behaviour. Crossing such thresholds can lead to an abrupt or irreversible transition into a different state of the climate system or some of its components.

Abrupt climate change is defined in AR5 as a large-scale change in the climate system that takes place over a few decades or less, persists (or is anticipated to persist) for at least a few decades, and causes substantial disruptions in human and natural systems. There is information on potential consequences of some abrupt changes, but in general there is *low confidence* and little consensus on the likelihood of such events over the 21st century. Examples of components susceptible to such abrupt change are the strength of the Atlantic Meridional Overturning Circulation (AMOC), clathrate methane release, tropical and boreal forest dieback, disappearance of summer sea ice in the Arctic Ocean, long-term drought and monsoonal circulation. {5.7, 6.4.7, 12.5.5; Table 12.4}

A change is said to be *irreversible* if the recovery timescale from this state due to natural processes is significantly longer than the time it takes for the system to reach this perturbed state. Such behaviour may arise because the timescales for perturbations and recovery processes are different, or because climate change may persist due to the long residence time of a CO₂ perturbation in the atmosphere (see TFE.8). While changes in Arctic- Ocean summer sea-ice extent, long-term droughts and monsoonal circulation are assessed to be reversible within years to decades, tropical or boreal forest dieback may only be reversible within centuries. Changes in clathrate methane and permafrost carbon release, Greenland and Antarctic ice sheet collapse may be irreversible during millennia after the causal perturbation. {5.8, 6.4.7, 12.5.5, 13.4.3, 13.4.4; Table 12.4}

Abrupt Climate Change Linked with AMOC

New transient climate model simulations have confirmed with *high confidence* that strong changes in the strength of the AMOC produce abrupt climate changes at global scale with magnitude and pattern resembling past glacial Dansgaard-Oeschger events and Heinrich stadials. Confidence in the link between changes in North Atlantic climate and low-latitude precipitation has increased since AR4. From new paleoclimate reconstructions and modelling studies, there is *very high confidence* that a reduced strength of the AMOC and the associated surface cooling in the North Atlantic region caused southward shifts of the Atlantic intertropical convergence zone and affected the American (north and south), African and Asian monsoons. {5.7}

The interglacial mode of the AMOC can recover (*high confidence*) from a short-lived freshwater input into the subpolar North Atlantic. Approximately 8,200 years ago, a marked reduction in the strength of the AMOC was driven by a sudden freshwater release in the final stages of North American ice sheet melting.

Paleoclimate observations and model results indicate, with *high confidence*, that the circulation was restored within approximately 200 years after the perturbation. {5.8.1}

While many more model simulations have been conducted since AR4 under a wide range of future forcing scenarios, projections of the AMOC behaviour have not changed. It remains *very likely* that the AMOC will weaken over the 21st century relative to preindustrial values with a best estimate decrease in 2100 of about 20–30% for the RCP4.5 scenario and 36–44% for the RCP8.5 scenario, but there is *low confidence* on the magnitude of weakening. It also remains *very unlikely* that the AMOC will undergo an abrupt transition or collapse in the 21st century for the scenarios considered (*high confidence*) (TFE.5, Figure 1). For an abrupt transition of the AMOC to occur, the sensitivity of the AMOC to forcing would have to be far greater than seen in current models, or would require meltwater flux from the Greenland ice sheet greatly exceeding even the highest of current projections. While neither possibility can be excluded entirely, it is *unlikely* that the AMOC will collapse beyond the end of the 21st century for the scenarios considered but a collapse beyond the 21st century for large sustained warming cannot be excluded. There is *low confidence* in assessing the evolution of AMOC beyond the 21st century because of limited number of analyses and equivocal results. {12.4.7, 12.5.5}

[INSERT TFE.5, FIGURE 1 HERE]

TFE.5, Figure 1: Atlantic Meridional Overturning Circulation strength at 30°N (Sv) as a function of year, from 1850 to 2300 as simulated by different AOGCMs in response to scenario RCP2.6 (left) and RCP8.5 (right). The vertical black bar shows the range of AMOC strength measured at 26°N, from 2004 to 2011 {Figure 3.11, 12.35}

Potential Irreversibility of Changes in Permafrost, Methane Clathrates and Forests

In a warming climate, permafrost thawing may induce decomposition of carbon accumulated in frozen soils which could persist for hundreds to thousands of years, leading to an increase of atmospheric CO₂ and/or CH₄ concentrations. The existing modelling studies of permafrost carbon balance under future warming that take into account at least some of the essential permafrost-related processes do not yield consistent results, beyond the fact that present-day permafrost will become a net emitter of carbon during the 21st century under plausible future warming scenarios (*low confidence*). This also reflects an insufficient understanding of the relevant soil processes during and after permafrost thaw, including processes leading to stabilization of unfrozen soil carbon, and precludes any quantitative assessment of the amplitude of irreversible changes in the climate system potentially related to permafrost degassing and associated feedbacks. {6.4.7, 12.5.5}

Anthropogenic warming will *very likely* lead to enhanced methane emissions from both terrestrial and oceanic clathrates. Deposits of methane clathrates below the sea floor are susceptible to destabilization via ocean warming. However, sea level rise due to changes in ocean mass enhances clathrate stability in the ocean. While difficult to formally assess, initial estimates of the 21st century feedback from methane clathrate destabilization are small but not insignificant. It is *very unlikely* that methane from clathrates will undergo catastrophic release during the 21st century (*high confidence*). On multi-millennial timescales, such methane emissions may provide a positive feedback to anthropogenic warming and may be irreversible, due to the difference between release and accumulation timescales. {6.4.7, 12.5.5}

The existence of critical climate change driven dieback thresholds in the Amazonian and other tropical rainforests purely driven by climate change remains highly uncertain. The possibility of a critical threshold being crossed in precipitation volume and duration of dry seasons cannot be ruled out. The response of boreal forest to projected climate change is also highly uncertain, and the existence of critical thresholds cannot at present be ruled out. There is *low confidence* in projections of the collapse of large areas of tropical and/or boreal forests. {12.5.5}

Potential Irreversibility of Changes in the Cryosphere

The reversibility of sea ice loss has been directly assessed in sensitivity studies to CO₂ increase and decrease with AOGCMs or ESMs. None of them show evidence of an irreversible change in Arctic sea ice at any point. By contrast, as a result of the strong coupling between surface and deep waters in the Southern Ocean, the Antarctic sea ice in some models integrated with ramp-up and ramp-down atmospheric CO₂ concentration exhibits some hysteresis behaviour. {12.5.5}

At present, both the Greenland and Antarctic ice sheets have a positive surface mass balance (snowfall exceeds melting), although both are losing mass because ice outflow into the sea exceeds the net surface mass balance. A positive feedback operates to reduce ice sheet volume and extent when a decrease of the surface elevation of the ice sheet induces a decreased surface mass balance. This arises generally through increased surface melting, and therefore applies in the 21st century to Greenland, but not to Antarctica, where surface melting is currently very small. Surface melting in Antarctica is projected to become important after several centuries under high WMGHG radiative forcing scenarios. {4.4, 13.4.4; Box 5.2, 13.2}

Abrupt change in ice-sheet outflow to the sea may be caused by unstable retreat of the grounding line in regions where the bedrock is below sea level and slopes downwards towards the interior of the ice sheet. This mainly applies to West Antarctica, but also to parts of East Antarctica and Greenland. Grounding line retreat can be triggered by ice-shelf decay, due to warmer ocean water under ice shelves enhancing submarine ice-shelf melt, or melt water ponds on the surface of the ice shelf promoting ice-shelf fracture. Because ice sheet growth is a slow process, such changes would be irreversible in the definition adopted here. {4.4.5, Box 13.2}

There is *high confidence* that the volumes of the Greenland and West Antarctic ice sheets were reduced during periods of the past few million years that were globally warmer than present. Ice sheet model simulations and geological data suggest that the West Antarctic ice sheet is very sensitive to subsurface ocean warming and imply *with medium confidence* a West Antarctic ice sheet retreat if atmospheric CO₂ concentration remains above approximately 400 ppm for several millennia. {5.8, 13.4.4; Box 13.2}

The available evidence indicates that global warming beyond a threshold would lead to the near-complete loss of the Greenland Ice Sheet over a millennium or longer, causing a global mean sea level rise of approximately 7 m. Studies with fixed present-day ice sheet topography indicate that the threshold is greater than 2°C but less than 4°C of global mean surface temperature rise with respect to preindustrial. Taking into account the increased vulnerability of the ice sheet as the surface elevation decreases due to the loss of ice, a study with a dynamical ice sheet suggests the threshold could be as low as 1°C. Considering the present state of scientific uncertainty, a *likely* range cannot be quantified. The complete loss of the Greenland ice sheet is not inevitable because this would take a millennium or more; if temperatures decline before the ice sheet has completely vanished, the ice sheet might regrow. However, some part of the mass loss might be irreversible, depending on the duration and degree of exceedance of the threshold, because the ice sheet may have multiple steady states, due to its interaction with regional climate. {13.4.3, 13.4.4}

TS.4.6 Water Cycle

Since the AR4, new evidence has emerged of a detectable human influence on several aspects of the water cycle. There is *medium confidence* that observed changes in near-surface specific humidity since 1973 contain a detectable anthropogenic component. The anthropogenic water vapour fingerprint simulated by an ensemble of climate models has been detected in lower tropospheric moisture content estimates derived from SSM/I data covering the period 1988–2006. An anthropogenic contribution to increases in tropospheric specific humidity is found with *medium confidence*. {2.5, 10.3}

Attribution studies of global zonal mean terrestrial precipitation and Arctic precipitation both find a detectable anthropogenic influence. Overall there is *medium confidence* in a significant human influence on global scale changes in precipitation patterns, including increases in northern hemisphere mid to high latitudes. Remaining observational and modeling uncertainties and the large effect of internal variability on observed precipitation preclude a more confident assessment. {2.5, 7.6, 10.3}

Based on the collected evidence for attributable changes (with varying levels of confidence and likelihood) in specific humidity, terrestrial precipitation, and ocean surface salinity through its connection to precipitation and evaporation, and from physical understanding of the water cycle, it is *likely* that human influence has affected the global water cycle since 1960. This is a major advance since AR4. {2.4, 2.5, 3.3, 9.4.1, 10.3, 10.4.2; Table 10.1; FAQ 3.3}

TS.4.7 *Climate Extremes*

Several new attribution studies have found a detectable anthropogenic influence in the observed increased frequency of warm days and nights and decreased frequency of cold days and nights. Since the AR4 and SREX, there is new evidence for detection of human influence on extremely warm daytime temperature and there is new evidence that the influence of anthropogenic forcing may be detected separately from the influence of natural forcing at global scales and in some continental and sub-continental regions. This strengthens the conclusions from both AR4 and SREX, and it is now *very likely* that anthropogenic forcing has contributed to the observed changes in the frequency and intensity of daily temperature extremes on the global scale since the mid-20th century. It is *likely* that human influence has significantly increased the probability of occurrence of heat waves in some locations. See TFE.9 and TFE.9, Table 1 for a summary of the assessment of extreme weather and climate events. {10.6}

Since the AR4, there is some new limited direct evidence for an anthropogenic influence on extreme precipitation, including a formal detection and attribution study and indirect evidence that extreme precipitation would be expected to have increased given the evidence of anthropogenic influence on various aspects of the global hydrological cycle and *high confidence* that the intensity of extreme precipitation events will increase with warming, at a rate well exceeding that of the mean precipitation. . In land regions where observational coverage is sufficient for assessment, there is *medium confidence* that anthropogenic forcing has contributed to a global-scale intensification of heavy precipitation over the second half of the 20th century. {7.6, 10.6}

Globally, there is *low confidence* in attribution of changes in tropical cyclone activity to human influence. This is due to insufficient observational evidence, lack of physical understanding of the links between anthropogenic drivers of climate and tropical cyclone activity, and the low level of agreement between studies as to the relative importance of internal variability, and anthropogenic and natural forcings. In the North Atlantic region there is *medium confidence* that a reduction in aerosol forcing over the North Atlantic has contributed at least in part to the observed increase in tropical cyclone activity there since the 1970s. There remains substantial disagreement on the relative importance of internal variability, greenhouse gas forcing, and aerosols for this observed trend. {2.6, 10.6, 14.6}

While the AR4 concluded that it is *more likely than not* that anthropogenic influence has contributed to an increased risk of drought in the second half of the 20th century, an updated assessment of the observational evidence indicates that the AR4 conclusions regarding global increasing trends in hydrological droughts since the 1970s are no longer supported. Owing to the *low confidence* in observed large-scale trends in dryness combined with difficulties in distinguishing decadal-scale variability in drought from long-term climate change, there is now *low confidence* in the attribution of changes in drought over global land since the mid-20th century to human influence. {2.6, 10.6}

TS.4.8 *From Global to Regional*

Taking a longer term perspective shows the substantial role played by external forcings in driving climate variability on hemispheric scales in pre-industrial times (Box TS.5). It is *very unlikely* that Northern Hemisphere temperature variations from 1400 to 1850 can be explained by internal variability alone. There is *medium confidence* that external forcing contributed to Northern Hemispheric temperature variability from 850 to 1400 and that external forcing contributed to European temperature variations over the last 5 centuries. {5.3.3, 5.5.1, 10.7.2, 10.7.5; Table 10.1}

Changes in atmospheric circulation are important for local climate change since they could lead to greater or smaller changes in climate in a particular region than elsewhere. It is *likely* that human influence has altered sea level pressure patterns globally. There is *medium confidence* that stratospheric ozone depletion has contributed to the observed poleward shift of the southern Hadley Cell border during Austral summer. It is *likely* that stratospheric ozone depletion has contributed to the positive trend in the Southern Annular Mode seen in Austral summer since the mid-20th century which corresponds to sea level pressure reductions over the high latitudes and increase in the subtropics (Figure TS.11). {10.3}

[INSERT FIGURE TS.11 HERE]

Figure TS.11: Simulated and observed 1951–2011 trends in the Southern Annular Mode (SAM) index by season. The SAM index is a difference between zonal mean sea level pressure (SLP) at 40°S and 65°S. The SAM index is defined without normalization, so that the magnitudes of simulated and observed trends can be compared. Black lines show observed trends from the HadSLP2r dataset (solid), and the 20th century Reanalysis (dotted). Grey bars show 5th–95th percentile ranges of control trends, and red boxes show the 5th–95th percentile range of trends in historical simulations including anthropogenic and natural forcings. Coloured bars show ensemble mean trends and their associated 5–95% confidence ranges simulated in response to greenhouse gas (light green), aerosol (dark green), ozone (magenta) and natural forcing changes (blue) in CMIP5 individual-forcing simulations. {Figure 10.13b}

The evidence is stronger that observed changes in the climate system can now be attributed to human activities on global and regional scales in many components (Figure TS.12). Observational uncertainty has been explored much more thoroughly than previously, and fingerprints of human influence have been deduced from a new generation of climate models. There is improved understanding of ocean changes, including salinity changes, that are consistent with large scale intensification of the water cycle predicted by climate models. The changes in near surface temperatures, free atmosphere temperatures, ocean temperatures, and Northern Hemisphere snow cover and sea ice extent, when taken together, show not just global mean changes, but distinctive regional patterns consistent with the expected fingerprints of change from anthropogenic forcings and the expected responses from volcanic eruptions (Figure TS.12). {10.3–10.6, 10.9}

Human influence has been detected in nearly all of the major assessed components of the climate system (Figure TS.12). Taken together, the combined evidence increases the overall level of confidence in the attribution of observed climate change, and reduces the uncertainties associated with assessment based on a single climate variable. From this combined evidence it is *virtually certain* that human influence has warmed the global climate system. Anthropogenic influence has been identified in changes in temperature near the surface of the earth, in the atmosphere and in the oceans, as well as changes in the cryosphere, the water cycle and some extremes. There is strong evidence that excludes solar forcing, volcanoes, and internal variability as the strongest drivers of warming since 1950. {10.9; Table 10.1; FAQ 5.1}

[INSERT FIGURE TS.12 HERE]

Figure TS.12: Detection and attribution signals (decadal averages) in the climate system, at regional scales (top panels) and global scales (bottom 4 panels). Brown panels are land surface temperature time series, blue panels are ocean heat content time series, and white panels are sea-ice time series. Each panel shows observations (black or black and shades of grey), and the 5–95% range of the simulated response to natural forcings (blue shading) and natural and anthropogenic forcings (pink shading), together with the corresponding ensemble means (dark blue and dark red respectively). The observed surface temperature is from HadCRUT4. Three observed records of ocean heat content (OHC) are shown. Sea-ice anomalies (rather than absolute values) are plotted and based on models in Figure 10.16. The observations are either solid or dashed and indicate the quality of the observations and estimates. For land and ocean surface temperatures panels and precipitation panels, solid observation lines indicate where spatial coverage of areas being examined, is above 50% coverage and dashed observation lines where coverage is below 50%. For example, data coverage of Antarctica never goes above 50% of the land area of the continent. For ocean heat content and sea-ice panels the solid observations line is where the coverage of data is good and higher in quality, and the dashed line is where the data coverage is only adequate.¹¹ This figure is based in Figure 10.21 except presented as decadal averages rather than yearly averages. {Figure 10.21}

Over every continent except Antarctica, anthropogenic influence has *likely* made a substantial contribution to surface temperature increases since the mid-20th century (Figure TS.12). It is *likely* that there has been significant anthropogenic contribution to the very substantial warming in Arctic land surface temperatures over the past 50 years. For Antarctica large observational uncertainties result in *low confidence* that anthropogenic influence has contributed to observed warming averaged over available stations. Detection and attribution at regional scales is complicated by the greater role played by dynamical factors (circulation

¹¹ For surface temperature, the blue shaded band is based on 52 simulations from 17 climate models using only natural forcings, while the red shaded band is based on 147 simulations from 44 climate models using natural and anthropogenic forcings. For ocean heat content, 10 simulations from 10 models, and 13 simulations from 13 models were used respectively. For sea ice extent, a subset of models are considered that simulated the mean and seasonal cycle of the sea ice extent within 20% of the observed sea-ice climatology for the period 1981–2005 (Arctic: 24 simulations from 11 models for both red and blue shaded bands, Antarctic: 21 simulations from 6 models for both red and blue shaded bands).

changes), a greater range of forcings that may be regionally important, and the greater difficulty of modelling relevant processes at regional scales. Nevertheless, human influence has *likely* contributed to temperature increases in many sub-continental regions. {10.3, Box 5.1}

The coherence of observed changes with simulations of anthropogenic and natural forcing in the physical system is remarkable (Figure TS.12), particularly for temperature related variables. Surface temperature and ocean heat content show emerging anthropogenic and natural signals in both records, and a clear separation from the alternative hypothesis of just natural variations. These signals do not just appear in the global means, but also appear at regional scales on continents and in ocean basins in each of these variables. Sea-ice extent emerges clearly from the range of internal variability for the Arctic. At sub-continental scales human influence is *likely* to have substantially increased the probability of occurrence of heat waves in some locations. {Table 10.1}

[START BOX TS.4 HERE]

Box TS.4: Model Evaluation

Climate models have continued to be improved since the AR4, and many models have been extended into Earth System Models by including the representation of biogeochemical cycles important to climate change. Box TS.4, Figure 1 provides a partial overview of model capabilities as assessed in this report, including improvements or lack thereof relative to models that were assessed in the AR4 or that were available at the time of the AR4. {9.1, 9.8.1; Box 9.1}

The ability of climate models to simulate surface temperature has improved in many, though not all, important aspects relative to the generation of models assessed in the AR4. There continues to be *very high confidence* that models reproduce the observed large-scale time-mean surface temperature patterns (pattern correlation of ~0.99), although systematic errors of several degrees Celsius are found in some regions. There is *high confidence* that on the regional scale (sub-continental and smaller), time-mean surface temperature is better simulated than at the time of the AR4; however, confidence in model capability is lower than for the large scale. Models are able to reproduce the magnitude of the observed global-mean or northern-hemisphere-mean temperature variability on interannual to centennial time scales. Models are also able to reproduce the large-scale patterns of temperature during the Last Glacial Maximum (Section 9.4.1.5) indicating an ability to simulate a climate state much different from the present (see also Box TS.5). {9.4.1, 9.6.1}

There is *very high confidence* that models reproduce the general features of the global and annual mean surface temperature changes over the historical period, including the warming in the second half of the 20th century and the cooling immediately following large volcanic eruptions. Most simulations of the historical period do not reproduce the observed reduction in global-mean surface warming trend over the last 10–15 years (see Box TS.3). There is *medium confidence* that the trend difference between models and observations during 1998–2012 is to a substantial degree caused by internal variability, with possible contributions from forcing inadequacies in models and some models overestimating the response to increasing greenhouse-gas forcing. Most, though not all, models overestimate the observed warming trend in the tropical troposphere over the last 30 years, and tend to underestimate the long-term lower-stratospheric cooling trend. {9.4.1; Box 9.2}

The simulation of large-scale patterns of precipitation has improved somewhat since the AR4, although models continue to perform less well for precipitation than for surface temperature. The spatial pattern correlation between modelled and observed annual mean precipitation has increased from 0.77 for models available at the time of the AR4 to 0.82 for current models. At regional scales, precipitation is not simulated as well, and the assessment remains difficult owing to observational uncertainties. {9.4.1, 9.6.1}

Many models are able to reproduce the observed changes in upper-ocean heat content from 1960 to present. The time series of the multi-model mean falls within the range of the available observational estimates for most of the period. {9.4.2}

There is robust evidence that the downward trend in Arctic summer sea-ice extent is better simulated than at the time of the AR4. About one-quarter of the models show a trend as strong as, or stronger, than the trend in observations over the satellite era 1979–2012. Most models simulate a small decreasing trend in Antarctic sea-ice extent, albeit with large inter-model spread, in contrast to the small increasing trend in observations. {9.4.3}

There has been substantial progress since the AR4 in the assessment of model simulations of extreme events. Changes in the frequency of extreme warm and cold days and nights over the second half of the 20th century are consistent between models and observations, with the ensemble-mean global-mean time series generally falling within the range of observational estimates. The majority of models underestimate the sensitivity of extreme precipitation to temperature variability or trends, especially in the tropics. {9.5.4}

In about two-thirds of the models that include an interactive carbon cycle, the simulated global land and ocean carbon sinks over the latter part of the 20th century fall within the range of observational estimates. However, models systematically underestimate the northern-hemisphere land sink implied by atmospheric inversion techniques. {9.4.5}

Regional downscaling methods provide climate information at the smaller scales needed for many climate impact studies. There is *high confidence* that downscaling adds value both in regions with highly variable topography and for various small-scale phenomena. {9.6.4}

The model spread in equilibrium climate sensitivity ranges from 2.1°C to 4.7°C and is very similar to the assessment in the AR4. There is *very high confidence* that the primary factor contributing to the spread in equilibrium climate sensitivity continues to be the cloud feedback. This applies to both the modern climate and the last glacial maximum. There is likewise *very high confidence* that, consistent with observations, models show a strong positive correlation between tropospheric temperature and water vapour on regional to global scales, implying a positive water-vapour feedback in both models and observations. {5.3.3, 9.4.1, 9.7}

Climate models are based on physical principles, and they reproduce many important elements of observed climate. Both aspects contribute to our confidence in the models' suitability for their application in detection and attribution studies (see Chapter 10) and for quantitative future predictions and projections (see Chapters 11–14). There is increasing evidence that some elements of observed variability or trends are well correlated with inter-model differences in model projections for quantities such as Arctic summer sea-ice trends, the snow–albedo feedback, and the carbon loss from tropical land. However, there is still no universal strategy for transferring a model's past performance to a relative weight of this model in a multi-model-ensemble mean of climate projections. {9.8.3}

[INSERT BOX TS.4, FIGURE 1 HERE]

Box TS.4, Figure1: Summary of how well the current-generation climate models simulate important features of the climate of the 20th century. Confidence in the assessment increases towards the right as suggested by the increasing strength of shading. Model quality increases from bottom to top. The colour coding indicates improvements from the models available at the time of the AR4 to the current assessment. There have been a number of improvements since the AR4, and some some modelled quantities are not better simulated. The major climate quantities are listed in this summary and none shows degradation. The assessment is mostly based on the multi-model mean, not excluding that deviations for individual models could exist. Assessed model quality is simplified for representation in this figure; details of each assessment are found in Chapter 9. {9.8.1; Figure 9.44}

The figure highlights the following key features, with the sections that back up the assessment added in brackets:

(a) Trends in:

AntSIE:	Antarctic sea-ice extent {9.4.3}
ArctSIE:	Arctic sea-ice extent {9.4.3}
fgCO ₂ :	Global ocean carbon sink {9.4.5}
LST:	Lower-stratospheric temperature {9.4.1.}
NBP:	Global land carbon sink {9.4.5}
OHC:	Global ocean heat content {9.4.2}
TotalO ₃ :	Total-column ozone {9.4.1}
TAS:	Surface air temperature {9.4.1}
TTT:	Tropical tropospheric temperature {9.4.1}

(b) Extremes:

Droughts	Droughts {9.5.4}
Hurric-hr	Year-to-year count of Atlantic hurricanes in high-resolution AGCMs {9.5.4}
PR_ext	Global distribution of precipitation extremes {9.5.4}
PR_ext-hr	Global distribution of precipitation extremes in high-resolution AGCMs {9.5.4}

Box TS.5: Paleoclimate

Reconstructions from paleoclimate archives allow current changes in atmospheric composition, sea level and climate (including extreme events such as droughts and floods), as well as future projections, to be placed in a broader perspective of past climate variability (see Section TS.2). {5, 5.5.5, 10.5.5}

Past climate information also documents the behaviour of slow components of the climate system including the carbon cycle, ice sheets and the deep ocean for which instrumental records are short compared to their characteristic time scales of responses to perturbations, thus informing on mechanisms of abrupt and irreversible changes. Together with the knowledge of past external climate forcings, syntheses of paleoclimate data have documented polar amplification, characterized by enhanced temperature changes in the Arctic compared to the global mean, in response to high or low CO₂ concentrations. {5.2.1, 5.2.2, 5.6, 5.7, 5.8, 6.2, 8.4.2, 13.2.1, 13.4; Box 5.1, 5.2}

Since AR4, the inclusion of paleoclimate simulations in the PMIP3 (Paleoclimate Modelling Intercomparison Project)/CMIP5 framework has enabled paleoclimate information to be more closely linked with future climate projections. Paleoclimate information for the mid-Holocene (6,000 years ago), the Last Glacial Maximum (approximately 21,000 years ago), and last millennium has been used to test the ability of models to simulate realistically the magnitude and large-scale patterns of past changes. Combining information from paleoclimate simulations and reconstructions enables the response of the climate system to radiative perturbations to be quantified, constraints to be placed on the range of equilibrium climate sensitivity, and past patterns of internal climate variability to be documented on inter-annual to multi-centennial scales. {5.3.1, 5.3.2, 5.3.3, 5.3.4, 5.3.5, 5.4, 5.5.1, 9.4.1, 9.4.2, 9.5.3, 9.7.2, 10.7.2, 14.2.2}

Box TS.5, Figure 1 illustrates the comparison between the last millennium PMIP3/CMIP5 simulations and reconstructions, together with the associated solar, volcanic and well-mixed greenhouse gas radiative forcings. For average annual Northern Hemisphere temperatures, the period 1983–2012 was *very likely* the warmest 30-year period of the last 800 years (*high confidence*) and *likely* the warmest 30-year period of the last 1400 years (*medium confidence*). This is supported by comparison of instrumental temperatures with multiple reconstructions from a variety of proxy data and statistical methods, and is consistent with AR4. In response to solar, volcanic and anthropogenic radiative changes, climate models simulate multi-decadal temperature changes in the last 1200 years in the Northern Hemisphere that are generally consistent in magnitude and timing with reconstructions, within their uncertainty ranges. Continental-scale temperature reconstructions show, with *high confidence*, multi-decadal intervals during the Medieval Climate Anomaly (ca. 950 to 1250) that were in some regions as warm as the mid-20th century and in others as warm as in the late 20th century. With *high confidence*, these intervals were not as synchronous across seasons and regions as the warming since the mid-20th century. Based on the comparison between reconstructions and simulations, there is *high confidence* that not only external orbital, solar and volcanic forcing but also internal variability contributed substantially to the spatial pattern and timing of surface temperature changes between the Medieval Climate Anomaly and the Little Ice Age (ca. 1450 to 1850). However, there is only *very low confidence* in quantitative estimates of their relative contributions. It is very unlikely that northern hemisphere temperature variations from 1400 to 1850 can be explained by internal variability alone. There is

medium confidence that external forcing contributed to Northern Hemispheric temperature variability from 850 to 1400 and that external forcing contributed to European temperature variations over the last 5 centuries. {5.3.5, 5.5.1, 10.7.2, 10.7.5; Table 10.1}

[INSERT BOX TS.5, FIGURE 1 HERE]

Box TS.5, Figure 1: Last-millennium simulations and reconstructions. (a) 850–2000 PMIP3/CMIP5 radiative forcing due to volcanic, solar and well mixed greenhouse gas. Different colors illustrate the two existing datasets for volcanic forcing (CEA and GRA) and the four estimates of solar forcing (DB, MEA, SBF and VSK). For solar forcing, solid (dashed) lines stand for reconstruction variants in which background changes in irradiance are (not) considered; (b) 850–2000 PMIP3/CMIP5 simulated (red) and reconstructed (shading) NH temperature changes. The thick red line depicts the multi-model mean while the thin red lines show the multi-model 90% range. The overlap of reconstructed temperatures is shown by grey shading; all data are expressed as anomalies from their 1500–1850 mean and smoothed with a 30-year filter. Note that some reconstructions represent a smaller spatial domain than the full NH or a specific season, while annual temperatures for the full NH mean are shown for the simulations. (c), (d), (e) and (f) Arctic and North America annual mean temperature, and Europe and Asia June-July-August (JJA) temperature, from 950 to 2000 from reconstructions (black line), and PMIP3/CMIP5 simulations (thick red, multi-model mean; thin red 90% multi-model range). All red curves are expressed as anomalies from their 1500–1850 mean and smoothed with a 30-year filter. The shaded envelope depicts the uncertainties from each reconstruction (Arctic: 90% confidence bands, North American: ± 2 standard deviation. Asia: ± 2 root mean square error. Europe: 95% confidence bands). For comparison with instrumental record, the CRUTEM4 dataset is shown (yellow line). All lines are smoothed by applying a 30 year moving average. Map shows the individual regions for each reconstruction. {5.3.5; Table 5.A.1; Figures 5.1, 5.8, 5.12}

TS.5 Projections of Global and Regional Climate Change

TS.5.1 Introduction

Projections of changes in the climate system are made using a hierarchy of climate models ranging from simple climate models, to models of intermediate complexity, to comprehensive climate models, and Earth System Models. These models simulate changes based on a set of scenarios of anthropogenic forcings. A new set of scenarios, the Representative Concentration Pathways (RCPs), was used for the new climate model simulations carried out under the framework of the Coupled Model Intercomparison Project Phase 5 (CMIP5) of the World Climate Research Programme. A large number of comprehensive climate models and Earth System Models have participated in CMIP5, whose results form the core of the climate system projections.

This section summarizes the assessment of these climate change projections. First, future forcing and scenarios are presented. The following subsections then address various aspects of projections of global and regional climate change, including near-term (up to about mid-century) and long-term (end of the 21st century) projections in the atmosphere, ocean and cryosphere; projections of carbon and other biogeochemical cycles; projections in sea level change; and finally changes to climate phenomena and other aspects of regional climate over the 21st century. Projected changes are given relative to the 1986–2005 average unless indicated otherwise. Projections of climate change on longer term and information on climate stabilization and targets are provided in TFE.8. Methods to counter climate change, termed geoengineering, have been proposed and an overview is provided in Box TS.7. {11.3, 12.3–12.5, 13.5–13.7, 14.1–14.6, Annex I}

TS.5.2 Future Forcing and Scenarios

In this assessment report a series of new Representative Concentration Pathways (RCP) are used that largely replace the SRES scenarios (see Box TS.6; see Annex II for Climate System Scenario Tables). They produce a range of responses from ongoing warming, to approximately stabilized forcing, to a stringent mitigation scenario (RCP2.6) that stabilizes and then slowly reduces the radiative forcing after mid-21st century. In contrast to the AR4, the climate change from the RCP scenarios in the AR5 is framed as a combination of adaptation and mitigation. Mitigation actions starting now in the various RCP scenarios do not produce discernibly different climate change outcomes for the next 30 years or so, while long-term climate change after mid-century is appreciably different across the RCPs. {Box 1.1}

[START BOX TS.6 HERE]

Box TS.6: The New RCP Scenarios and CMIP5 Models

Future anthropogenic emissions of greenhouse gases (GHG), aerosol particles and other forcing agents such as land use change are dependent on socio-economic factors, and may be affected by global geopolitical agreements to control those emissions to achieve mitigation. AR4 made extensive use of the SRES scenarios that do not include additional climate initiatives, which means that no scenarios were included that explicitly assume implementation of the United Nations Framework Convention on Climate Change (UNFCCC) or the emissions targets of the Kyoto Protocol. However, GHG emissions are directly affected by non-climate change policies designed for a wide range of other purposes. The SRES scenarios were developed using a sequential approach, i.e., socio-economic factors fed into emissions scenarios, which were then used in simple climate models to determine concentrations of greenhouse gases, and other agents required to drive the more complex atmosphere-ocean global climate models (AOGCMs). In this report, outcomes of climate simulations that use new scenarios (some of which include implied policy actions to achieve mitigation) referred to as “Representative Concentration Pathways” (RCPs) are assessed. These RCPs represent a larger set of mitigation scenarios and were selected to have different targets in terms of radiative forcing at 2100 (about 2.6, 4.5, 6.0 and 8.5 W m⁻²; see Figure TS.15). The scenarios should be considered plausible and illustrative, and do not have probabilities attached to them. {12.3.1; Box 1.1}

The RCPs were developed using Integrated Assessment Models (IAMs) that typically include economic, demographic, energy, and simple climate components. The emission scenarios they produce are then run through a simple model to produce time series of greenhouse gas concentrations that can be run in AOGCMs. The emission time series from the RCPs can then be used directly in Earth System Models (ESMs) that include interactive biogeochemistry (at least a land and ocean carbon cycle).

The CMIP5 multi-model experiment (coordinated through the World Climate Research Programme) presents an unprecedented level of information on which to base assessments of climate variability and change. CMIP5 includes new ESMs in addition to AOGCMs, new model experiments, and more diagnostic output. CMIP5 is much more comprehensive than the preceding CMIP3 multi-model experiment that was available at the time of the IPCC AR4. CMIP5 has more than twice as many models, many more experiments (that also include experiments to address understanding of the responses in the future climate change scenario runs), and nearly 2×10^{15} bytes of data (as compared to over 30×10^{12} bytes of data in CMIP3). A larger number of forcing agents are treated more completely in the CMIP5 models, with respect to aerosols and land use particularly. Black carbon aerosol is now a commonly included forcing agent. Considering CO₂, both ‘concentrations-driven’ projections and ‘emissions-driven’ projections are assessed from CMIP5. These allow quantification of the physical response uncertainties as well as climate-carbon cycle interactions. {1.5.2}

The assessment of the mean values and ranges of global mean temperature changes in AR4 would not have been substantially different if the CMIP5 models had been used in that report. The differences in global temperature projections can largely be attributed to the different scenarios. The global mean temperature response simulated by CMIP3 and CMIP5 models is very similar, both in the mean and the model range, transiently and in equilibrium. The range of temperature change across all scenarios is wider because the RCPs include a strong mitigation scenario (RCP2.6) that had no equivalent among the SRES scenarios used in CMIP3. For each scenario, the 5–95% range of the CMIP5 projections is obtained by approximating the CMIP5 distributions by a normal distribution with same mean and standard deviation and assessed as being “likely” for projections of global temperature change for the end of the 21st century. Probabilistic projections with simpler models calibrated to span the range of equilibrium climate sensitivity assessed by the AR4 provide uncertainty ranges that are consistent with those from CMIP5. In AR4 the uncertainties in global temperature projections were found to be approximately constant when expressed as a fraction of the model mean warming (constant fractional uncertainty). For the higher RCPs, the uncertainty is now estimated to be smaller than with the AR4 method for long-term climate change, because the carbon cycle climate feedbacks are not relevant for the concentration driven RCP projections (in contrast, the assessed projection uncertainties of global temperature in AR4 did account of carbon cycle climate feedbacks, even though these were not part of the CMIP3 models). When forced with RCP8.5, CO₂ emissions, as opposed to the RCP8.5 CO₂ concentrations, CMIP5 Earth System Models (ESMs) with interactive carbon cycle simulate, on average, a 50 (–140 to +210) ppm (CMIP5 model spread) larger atmospheric CO₂ concentration and 0.2°C larger global surface temperature increase by 2100. For the low RCPs the fractional uncertainty is

larger because internal variability and non-CO₂ forcings make a larger relative contribution to the total uncertainty. {12.4.1, 12.4.9}

There is overall consistency between the projections of temperature and precipitation based on CMIP3 and CMIP5, both for large-scale patterns and magnitudes of change (Box TS.6, Figure 1). Model agreement and confidence in projections depends on the variable and on spatial and temporal averaging, with better agreement for larger scales. Confidence is higher for temperature than for those quantities related to the water cycle or atmospheric circulation. Improved methods to quantify and display model robustness have been developed to indicate where lack of agreement across models on local trends is a result of internal variability, rather than models actually disagreeing on their forced response. Understanding of the sources and means of characterizing uncertainties in long-term large scale projections of climate change has not changed significantly since AR4, but new experiments and studies have continued to work towards a more complete and rigorous characterization. {9.7.3, 12.2, 12.4.1, 12.4.4, 12.4.5, 12.4.9; Box 12.1}

The well-established stability of geographical patterns of temperature and precipitation change during a transient experiment remains valid in the CMIP5 models (see Box TS.6, Figure 1). Patterns are similar over time and across scenarios and to first order can be scaled by the global mean temperature change. There remain limitations to the validity of this technique when it is applied to strong mitigation scenarios, to scenarios where localized forcing (e.g., aerosols) are significant and vary in time and for variables other than average seasonal mean temperature and precipitation {12.4.2}.

[INSERT BOX TS.6, FIGURE 1 HERE]

Box TS.6, Figure 1: Patterns of temperature (left column) and percent precipitation change (right column) for the CMIP3 models average (first row) and CMIP5 models average (second row), scaled by the corresponding global average temperature changes. The patterns are computed in both cases by taking the difference between the averages over the last twenty years of the 21st century experiments (2080–2099 for CMIP3 and 2081–2100 for CMIP5) and the last twenty years of the historic experiments (1980–1999 for CMIP3, 1986–2005 for CMIP5) and rescaling each difference by the corresponding change in global average temperature. This is done first for each individual model, then the results are averaged across models. Stippling indicates a measure of significance of the difference between the two corresponding patterns obtained by a bootstrap exercise. Two subsets of the pooled set of CMIP3 and CMIP5 ensemble members of the same size as the original ensembles, but without distinguishing CMIP3 from CMIP5 members, were randomly sampled 500 times. For each random sample the corresponding patterns and their difference are computed, then the true difference is compared, grid-point by grid-point, to the distribution of the bootstrapped differences, and only grid-points at which the value of the difference falls in the tails of the bootstrapped distribution (less than the 2.5 percentiles or the 97.5 percentiles) are stippled. {Figure 12.41}

[END BOX TS.6 HERE]

The range in anthropogenic aerosol emissions across all scenarios has a larger impact on near-term climate projections than the corresponding range in long-lived greenhouse gases, particularly on regional scales and for hydrological cycle variables. The RCP scenarios do not span the range of future aerosol emissions found in the SRES and alternative scenarios (see Box TS.6). {11.3.1, 11.3.6}

If rapid reductions in sulphate aerosol are undertaken for improving air quality or as part of decreasing fossil-fuel CO₂ emissions, then there is *medium confidence* that this could lead to rapid near-term warming. There is robust evidence that accompanying controls on methane (CH₄) emissions would offset some of this sulphate-induced warming, although the cooling from methane mitigation will emerge more slowly than the warming from sulphate mitigation due to the different timescales over which atmospheric concentrations of these substances decrease in response to decreases in emissions. While removal of black carbon aerosol could also counter warming associated with sulphate removal, uncertainties are too large to constrain the net sign of the global temperature response to black carbon emission reductions, which depends on reduction of co-emitted (reflective) aerosols and on aerosol indirect effects. {11.3.6}

Including uncertainties in projecting the chemically reactive greenhouse gases methane (CH₄) and nitrous oxide (N₂O) from RCP emissions gives a range in abundance pathways that is *likely* 30% larger than the range in RCP concentrations used to force the CMIP5 climate models. Including uncertainties in emission estimates from agricultural, forest, and land-use sources, in atmospheric lifetimes, and in chemical feedbacks, results in a much wider range of abundances for N₂O, CH₄, and HFCs and their radiative forcing.

In the case of CH₄ it *likely* extends the range up to 500 ppb above RCP8.5 and 270 ppb below RCP2.6 through to 2100, with smaller ranges in the near term. {11.3.5}

There is *low confidence* in projections of natural forcing. Major volcanic eruptions cause a negative radiative forcing up to several W m⁻², with a typical lifetime of one year, but the possible occurrence and timing of future eruptions is unknown. Except for the 11-year solar cycle, changes in the total solar irradiance are uncertain. Except where explicitly indicated, future volcanic eruptions and changes in total solar irradiance additional to a repeating 11 year solar cycle are not included in the projections of near- and long-term climate assessed. {8, 11.3.1}

TS.5.3 Quantification of Climate System Response

Estimates of the Equilibrium Climate Sensitivity (ECS) based on observed climate change, climate models and feedback analysis, as well as paleoclimate evidence indicate that ECS is positive, *likely* in the range 1.5°C to 4.5°C with *high confidence*, *extremely unlikely* less than 1°C (*high confidence*) and *very unlikely* greater than 6°C (*medium confidence*). Earth system sensitivity over millennia timescales including long-term feedbacks not typically included in models could be significantly higher than ECS (see TFE.6 for further details). {5.3.1, 10.8; Box 12.2}

With *high confidence* the transient climate response (TCR) is positive, *likely* in the range 1°C to 2.5°C and *extremely unlikely* greater than 3°C, based on observed climate change and climate models (see TFE.6 for further details). {10.8; Box 12.2}

The ratio of global mean surface temperature change to total cumulative anthropogenic carbon emissions is relatively constant and independent of the scenario, but is model dependent, as it is a function of the model cumulative airborne fraction of carbon and the transient climate response. For any given temperature target, higher emissions in earlier decades therefore imply lower emissions by about the same amount later on. The transient climate response to cumulative carbon emission (TCRE) is *likely* between 0.8°C to 2.5°C per 1000 PgC (*high confidence*), for cumulative carbon emissions less than about 2000PgC until the time at which temperatures peak (see TFE.8 for further details). {10.8, 12.5.4; Box 12.2}

TS.5.4 Near-Term Climate Change

Near-term decadal climate prediction provides information not available from existing seasonal to interannual (months to a year or two) predictions or from long-term (mid 21st century and beyond) climate change projections. Prediction efforts on seasonal to interannual timescales require accurate estimates of the initial climate state with less focus extended to changes in external forcing¹², while long-term climate projections rely more heavily on estimations of external forcing with little reliance on the initial state of internal variability. Estimates of near-term climate depend on the committed warming (caused by the inertia of the oceans as they respond to historical external forcing) the time evolution of internally-generated climate variability, and the future path of external forcing. Near-term predictions out to about a decade (Figure TS.13) depend more heavily on an accurate depiction of the internally generated climate variability. {11.1, 12, 14}

[INSERT FIGURE TS.13 HERE]

Figure TS.13: Decadal prediction forecast quality of several climate indices. Top row: Time series of the 2–5 year average ensemble-mean initialized hindcast anomalies and the corresponding non-initialized experiments for three climate indices: Global Mean Surface Temperature (GMST, left) and the Atlantic Multidecadal Variability (AMV, right). The observational time series, GISS global-mean temperature and ERSST for the AMV, are represented with dark grey (positive anomalies) and light grey (negative anomalies) vertical bars, where a four-year running mean has been applied for consistency with the time averaging of the predictions. Predicted time series are shown for the CMIP5 Init (solid) and NoInit (dotted) simulations with hindcasts started every five years over the period 1960–2005. The lower and upper quartile of the multi-model ensemble are plotted using thin lines. The AMV index was computed as the sea surface temperature anomalies averaged over the region Equator –60°N and 80°W–0°W minus the sea surface temperature anomalies averaged over 60°S–60°N. Note that the vertical axes are different for each time series. Middle row: Correlation of the ensemble-mean prediction with the observational reference along the forecast time for four-year

¹² Seasonal-to-interannual predictions typically include the impact of external forcing.

averages of the three sets of CMIP5 hindcasts for Init (solid) and NoInit (dashed). The one-sided 95% confidence level with a t distribution is represented in grey. The effective sample size has been computed taking into account the autocorrelation of the observational time series. A two-sided t test (where the effective sample size has been computed taking into account the autocorrelation of the observational time series) has been used to test the differences between the correlation of the initialized and non-initialized experiments, but no differences were found statistically significant with a confidence equal or higher than 90%. Bottom row: Root mean square error (RMSE) of the ensemble-mean prediction along the forecast time for four-year averages of the CMIP5 hindcasts for Init (solid) and NoInit (dashed). A two-sided F test (where the effective sample size has been computed taking into account the autocorrelation of the observational time series) has been used to test the ratio between the RMSE of the Init and NoInit, and those forecast times with differences statistically significant with a confidence equal or higher than 90% are indicated with an open square. {Figure 11.3}

Further near-term warming from past emissions is unavoidable due to thermal inertia of the oceans. This warming will be increased by ongoing emissions of GHGs over the near term, and the climate observed in the near term will also be strongly influenced by the internally generated variability of the climate system. Previous IPCC Assessments only described climate-change projections wherein the externally forced component of future climate was included but no attempt was made to initialize the internally generated climate variability. Decadal climate predictions, on the other hand, are intended to predict both the externally forced component of future climate change, and the internally generated component. Near-term predictions do not provide detailed information of the evolution of weather. Instead they can provide estimated changes in the time evolution of the statistics of near-term climate. {11.1, 11.2.2; Box 11.1, FAQ 11.1}

Retrospective prediction experiments have been used to assess forecast quality. There is *high confidence* that the retrospective prediction experiments for forecast periods of up to 10 years exhibit positive skill when verified against observations over large regions of the planet and of the global mean. Observation-based initialization of the forecasts contributes to the skill of predictions of annual mean temperature for the first couple of years and to the skill of predictions of the global-mean surface temperature and the temperature over the North Atlantic, regions of the South Pacific and the tropical Indian Ocean up to 10 years (*high confidence*) partly due to a correction of the forced response. Probabilistic temperature predictions are statistically reliable (see Section 11.2.3 for definition of reliability) due to the correct representation of global trends, but still unreliable at the regional scale when probabilities are computed from the multi-model ensemble (*medium confidence*). Predictions initialized over 2000–2005 improve estimates of the recent global-mean temperature hiatus (*medium confidence*). Predictions of precipitation over continental areas with large forced trends also exhibit positive skill. {11.2.2, 11.2.3; Box 9.2}

TS.5.4.1. Projected Near-Term Changes in Climate

Projections of near-term climate show small sensitivity to greenhouse gas scenarios compared to model spread, but substantial sensitivity to uncertainties in aerosol emissions, especially on regional scales and for hydrological cycle variables (*high confidence*). In some regions, the local and regional responses in precipitation and in mean and extreme temperature to land use change will be larger than those due to large-scale greenhouse gases and aerosol forcing (*medium confidence*). These scenarios presume that there are no major volcanic eruptions and that anthropogenic aerosol emissions are rapidly reduced during the near term. {11.3.1, 11.3.2, 11.3.6}

TS.5.4.2 Projected Near-Term Changes in Temperature

In the absence of major volcanic eruptions—which would cause significant but temporary cooling—and, assuming no significant future long term changes in solar irradiance, it is *likely* that the GMST anomaly for the period 2016–2035, relative to the reference period of 1986–2005 will be in the range 0.3°C to 0.7°C (*medium confidence*). This is based on an assessment of observationally-constrained projections and predictions initialized with observations. This range is consistent with the range obtained by using CMIP5 5–95% model trends for 2012–2035. It is also consistent with the CMIP5 5–95% range for all four RCP scenarios of 0.36°C to 0.79°C, using the 2006–2012 reference period, after the upper and lower bounds are reduced by 10% to take into account the evidence that some models may be too sensitive to anthropogenic forcing (see Table TS.1 and Figure TS.14). {11.3.6}

INSERT FIGURE TS.14 HERE]

Figure TS.14: Synthesis of near-term projections of global mean surface air temperature (GMST). (a) Projections of annual mean GMST 1986–2050 (anomalies relative to 1986–2005) under all RCPs from CMIP5 models (grey and coloured lines, one ensemble member per model), with four observational estimates (HadCRUT4, ERA-Interim, GISTEMP, NOAA) for the period 1986–2012 (black lines). (b) as (a) but showing the 5–95% range of annual mean CMIP5 projections (using one ensemble member per model) for all RCPs using a reference period of 1986–2005 (light grey shade) and all RCPs using a reference period of 2006–2012, together with the observed anomaly for (2006–2012)–(1986–2005) of 0.16°C (dark grey shade). The percentiles for 2006 onwards have been smoothed with a 5 year running mean for clarity. The maximum and minimum values from CMIP5 using all ensemble members and the 1986–2005 reference period are shown by the grey lines (also smoothed). Black lines show annual mean observational estimates. The red shaded region shows the indicative likely range for annual mean GMST during the period 2016–2035 based on the “ALL RCPs Assessed” *likely* range for the 20 year mean GMST anomaly for 2016–2035, which is shown as a black bar in both panels (b) and (c) (see text for details). The temperature scale relative to pre-industrial climate on the right hand side assumes a warming of GMST prior to 1986–2005 of 0.61°C estimated from HadCRUT4. (c) A synthesis of projections for the mean GMST anomaly for 2016–2035 relative to 1986–2005. The box and whiskers represent the 66% and 90% ranges. Shown are: unconstrained SRES CMIP3 and RCP CMIP5 projections; observationally constrained projections for the SRES A1B and the RCP4.5 and 8.5 scenarios; unconstrained projections for all four RCP scenarios using two reference periods as in panel (b) (light grey and dark grey shades), consistent with panel (b); 90% range estimated using CMIP5 trends for the period 2012–2035 and the observed GMST anomaly for 2012; an overall *likely* (>66%) assessed range for all RCP scenarios. The dots for the CMIP5 estimates show the maximum and minimum values using all ensemble members. The medians (or maximum likelihood estimate; green filled bar) are indicated by a grey band. Adapted from Figure 11.25. See Chapter 11, Section 11.3.6 for details. {Figure 11.25}

There is *high confidence* that higher concentrations of greenhouse gases and lower amounts of sulphate aerosol lead to greater warming. In the near-term, differences in global mean surface air temperature across RCP scenarios for a single climate model are typically smaller than across climate models for a single RCP scenario. In 2030, the CMIP5 multi-model ensemble mean values for global mean temperature differ by less than 0.3°C between the RCP scenarios, whereas the model spread (defined as the 5–95% range of the decadal means of the models) is around 0.8°C. The inter-scenario spread increases in time and by 2050 is comparable to the model spread. Regionally, the largest differences in surface air temperature between RCP scenarios are found in the Arctic. {11.3.2. 11.3.6}

The projected warming of global mean temperatures implies *high confidence* that new levels of warming relative to pre-industrial climate will be crossed, particularly under higher greenhouse gas emissions scenarios. Relative to a reference period of 1850–1900, under RCP4.5 or RCP6.0, it is *more likely than not* that the mean GMST for the period 2016–2035 will be more than 1°C above the mean for 1850–1900, and *very unlikely* that it will be more than 1.5°C above the 1850–1900 mean (*medium confidence*). {11.3.6}

A future volcanic eruption similar in size to the 1991 eruption of Mount Pinatubo would cause a rapid drop in global mean surface air temperature of about 0.5°C in the following year, with recovery over the next few years. Larger eruptions, or several eruptions occurring close together in time, would lead to larger and more persistent effects. {11.3.6}

Possible future changes in solar irradiance could influence the rate at which global mean surface air temperature increases, but there is *high confidence* that this influence will be small in comparison to the influence of increasing concentrations of greenhouse gases in the atmosphere. {11.3.6}

The spatial patterns of near-term warming projected by the CMIP5 models following the RCP scenarios (see Figure TS.15) are broadly consistent with the AR4. It is *very likely* that anthropogenic warming of surface air temperature over the next few decades will proceed more rapidly over land areas than over oceans, and it is *very likely* that the anthropogenic warming over the Arctic in winter will be greater than the global mean warming, consistent with the AR4. Relative to background levels of internally generated variability there is *high confidence* that the anthropogenic warming relative to the reference period is expected to be larger in the tropics and subtropics than in mid-latitudes. {11.3.2}

It is *likely* that in the next decades the frequency of warm days and warm nights will increase in most regions, while the frequency of cold days and cold nights will decrease. Models also project increases in the duration, intensity and spatial extent of heat-waves and warm spells for the near term. These changes may proceed at a different rate than the mean warming. For example, several studies project that European high-

percentile summer temperatures are projected to warm faster than mean temperatures (see also TFE.9). {11.3.2}

TS.5.4.3 Projected Near-Term Changes in the Water Cycle

Zonal mean precipitation will *very likely* increase in high and some of the mid latitudes, and will *more likely than not* decrease in the subtropics. At more regional scales precipitation changes may be dominated by a combination of natural internal variability, volcanic forcing and anthropogenic aerosol effects. {11.3.2}

Over the next few decades increases in near-surface specific humidity are *very likely*. It is *likely* that there will be increases in evaporation in many regions. There is *low confidence* in projected changes in soil moisture and surface run off. {11.3.2}

In the near term, it is *likely* that the frequency and intensity of heavy precipitation events will increase over land. These changes are primarily driven by increases in atmospheric water vapor content, but also affected by changes in atmospheric circulation. The impact of anthropogenic forcing at regional scales is less obvious, as regional-scale changes are strongly affected by natural variability and also depend upon the course of future aerosol emissions, volcanic forcing and land use changes (see also TFE.9). {11.3.2}

TS.5.4.4 Projected Near-Term Changes in Atmospheric Circulation

Internally generated climate variability and multiple radiative forcing agents (e.g., volcanoes, greenhouse gases, ozone and anthropogenic aerosols) will all contribute to near-term changes in the atmospheric circulation. For example, it is *likely* that the annual-mean Hadley Circulation and the Southern Hemisphere mid-latitude westerlies will shift poleward, while it is *likely* that the projected recovery of stratospheric ozone and increases in greenhouse gas concentrations will have counteracting impacts on the width of the Hadley Circulation and the meridional position of the Southern Hemisphere storm track. Therefore it is *unlikely* that they will continue to expand poleward as rapidly as in recent decades. {11.3.2}

There is *low confidence* in near-term projections of the position and strength of Northern Hemisphere storm tracks. Natural variations are larger than the projected impact of greenhouse gases in the near-term. {11.3.2}

There is *low confidence* in basin-scale projections of changes in intensity and frequency of tropical cyclones in all basins to the mid-21st century. This *low confidence* reflects the small number of studies exploring near-term tropical cyclone activity, the differences across published projections of tropical cyclone activity, and the large role for natural variability. There is *low confidence* in near-term projections for increased tropical cyclone intensity in the Atlantic; this projection is in part due to projected reductions in aerosol loading. {11.3.2}

TS.5.4.5 Projected Near-Term Changes in the Ocean

It is *very likely* that globally-averaged surface and vertically-averaged ocean temperatures will increase in the near-term. In the absence of multiple major volcanic eruptions, it is *very likely* that globally-averaged surface and depth-averaged temperatures averaged for 2016–2035 will be warmer than those averaged over 1986–2005. {11.3.3}

It is *likely* that salinity will increase in the tropical and (especially) subtropical Atlantic, and decrease in the western tropical Pacific over the next few decades. Overall, it is *likely* that there will be some decline in the Atlantic Meridional Overturning Circulation by 2050 (*medium confidence*). However, the rate and magnitude of weakening is very uncertain and decades when this circulation increases are also to be expected. {11.3.3}

TS.5.4.6 Projected Near-Term Changes in the Cryosphere

A nearly ice-free Arctic Ocean (sea ice extent less than 10^6 km²) in September is *likely* before mid-century under RCP8.5 (*medium confidence*). This assessment is based on a subset of models that most closely reproduce the climatological mean state and 1979 to 2012 trend of Arctic sea ice cover. It is *very likely* that

there will be further shrinking and thinning of Arctic sea ice cover, and decreases of northern high-latitude spring time snow cover and near surface permafrost as global mean surface temperature rises (see Figures TS.17 and TS.18). There is *low confidence* in projected near-term decreases in the Antarctic sea ice extent and volume. {11.3.4}

TS.5.4.7 Possibility of Near-Term Abrupt Changes in Climate

There are various mechanisms that could lead to changes in global or regional climate that are abrupt by comparison with rates experienced in recent decades. The likelihood of such changes is generally lower for the near term than for the long term. For this reason the relevant mechanisms are primarily assessed in the TS.5 sections on long-term changes and in TFE.5. {11.3.4}

TS.5.4.8 Projected Near-Term Changes in Air Quality

There is *high confidence* that baseline surface ozone (O₃), upon which local pollution builds, will decrease over most regions as rising temperatures enhance global O₃ destruction, but it will increase with rising methane (*high confidence*). Projections based on the RCP scenarios differ regionally, in general projecting 2030 pollution to decrease over Europe, North America, and South America, and to increase over South Asia (*medium confidence*), with mixed results elsewhere. For O₃, continental-scale changes across the RCPs range from -4 to +5 ppb by 2030 and -14 to +5 ppb by 2100. This range is driven more by pollutant emissions than physical climate changes (*medium confidence*). There is *low confidence* in projecting extreme pollution episodes involving ozone and particulate matter, due to difficulty projecting associated stagnation episodes that involve meteorological blocking. Nevertheless, during extreme pollution episodes, warmer temperatures can trigger positive feedbacks in chemistry and local emissions, further enhancing pollution levels (*medium confidence*). Future air pollution levels under the RCPs, for both surface ozone and particulate matter, are lower than under SRES scenarios with comparable greenhouse gases (*high confidence*). {11.3.5; Annex II}

TS.5.5 Long-Term Climate Change

TS.5.5.1 Projected Long-Term Changes in Global Temperature

Global mean temperatures will continue to rise over the 21st century under all of the RCPs. From around the mid-21st century, the rate of global warming begins to be more strongly dependent on the scenario (Figure TS.15). {12.4.1}

Under the assumptions of the concentration-driven RCPs, global-mean surface temperatures for 2081–2100, relative to 1986–2005 will *likely* be in the 5–95% range of the CMIP5 models; 0.3°C to 1.7°C (RCP2.6), 1.1 to 2.6°C (RCP4.5), 1.4°C to 3.1°C (RCP6.0), 2.6°C to 4.8°C (RCP8.5) (see Table TS.1). With *high confidence*, the 5–95% range of CMIP5 is assessed as *likely* rather than *very likely* based on the assessment of TCR (see TFE.6). The 5–95% range of CMIP5 for global mean temperature change is also assessed as *likely* for mid-21st century, but only with *medium confidence*. With respect to preindustrial conditions, global temperatures averaged in the period 2081–2100 are projected to *likely* exceed 1.5°C above preindustrial for RCP4.5, RCP6.0 and RCP8.5 (*high confidence*) and are likely to exceed 2°C above preindustrial for RCP6.0 and RCP8.5 (*high confidence*). Temperature change above 2°C relative to preindustrial under RCP2.6 is *unlikely* (*medium confidence*). Warming above 4°C by 2081–2100 is *unlikely* in all RCPs (*high confidence*) except for RCP8.5 where it is *as likely as not* (*medium confidence*). {12.4.1; Tables 12.2, 12.3}

[INSERT FIGURE TS.15 HERE]

Figure TS.15: Top left: Total global mean radiative forcing for the 4 RCP scenarios based on the MAGICC energy balance model. Note that the actual forcing simulated by the CMIP5 models differs slightly between models. Bottom left: Time series of global annual mean surface air temperature anomalies (relative to 1986–2005) from CMIP5 concentration-driven experiments. Projections are shown for each RCP for the multimodel mean (solid lines) and ±1.64 standard deviation (5–95%) across the distribution of individual models (shading). Those ranges are interpreted as “*likely*” changes at the end of the 21st century. Discontinuities at 2100 are due to different numbers of models performing the extension runs beyond the 21st century and have no physical meaning. Numbers in the same colours as the lines indicate the number of different models contributing to the different time periods. Maps: Multimodel ensemble average of annual mean surface air temperature change (compared to 1986–2005 base period) for 2016–2035 and

2081–2100, for RCP2.6, 4.5, 6.0 and 8.5. Hatching indicates regions where the multi model mean signal is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean signal is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change. The number of CMIP5 models used is indicated in the upper right corner of each panel. {Box 12.1; Figures 12.4, 12.5, 12.11; Annex I}

[INSERT TABLE TS.1 HERE]

Table TS.1: Projected change in global mean surface air temperature and global mean sea level rise for the mid- and late 21st century. {12.4.1; Table 12.2, Table 13.5}

TS.5.5.2 Projected Long-Term Changes in Regional Temperature

There is very high confidence that globally averaged changes over land will exceed changes over the ocean at the end of the 21st century by a factor that is likely in the range 1.4 to 1.7. In the absence of a strong reduction in the Atlantic Meridional Overturning, the Arctic region is projected to warm most (very high confidence) (Figure TS.15). As global mean surface temperature rises, the pattern of atmospheric zonal-mean temperatures show warming throughout the troposphere and cooling in the stratosphere, consistent with previous assessments. The consistency is especially clear in the tropical upper troposphere and the northern high latitudes {12.4.3; Box 5.1}.

It is *virtually certain* that, in most places, there will be more hot and fewer cold temperature extremes as global mean temperatures increase. These changes are expected for events defined as extremes on both daily and seasonal time scales. Increases in the frequency, duration and magnitude of hot extremes along with heat stress are expected, however occasional cold winter extremes will continue to occur. 20-year return values of low temperature events are projected to increase at a rate greater than winter mean temperatures in most regions, with the largest changes in the return values of low temperatures at high latitudes. 20-year return values for high temperature events are projected to increase at a rate similar to or greater than the rate of increase of summer mean temperatures in most regions. Under RCP8.5 it is *likely* that, in most land regions, a current 20-year high temperature event will occur more frequently by the end of the 21st century (at least doubling its frequency, but in many regions becoming an annual or two-year event) and a current 20-year low temperature event will become exceedingly rare (See also TFE.9). {12.4.3}

Models simulate a decrease in cloud amount in the future over most of the tropics and mid-latitudes, due mostly to reductions in low clouds. Changes in marine boundary layer clouds are most uncertain. Increases in cloud fraction and cloud optical depth and therefore cloud reflection are simulated in high latitudes, poleward of 50°. {12.4.3}

TS.5.5.3 Projected Long-Term Changes in Atmospheric Circulation

Mean sea level pressure is projected to decrease in high latitudes and increase in the mid-latitudes as global temperatures rise. In the tropics, the Hadley and Walker circulations are *likely* to slow down. Poleward shifts in the mid-latitude jets of about 1 to 2 degrees latitude are *likely* at the end of the 21st century under RCP8.5 in both hemispheres (*medium confidence*), with weaker shifts in the Northern Hemisphere. In austral summer, the additional influence of stratospheric ozone recovery in the Southern Hemisphere opposes changes due to greenhouse gases there, though the net response varies strongly across models and scenarios. Substantial uncertainty and thus *low confidence* remains in projecting changes in Northern Hemisphere storm tracks, especially for the North Atlantic basin. The Hadley cell is *likely* to widen, which translates to broader tropical regions and a poleward encroachment of subtropical dry zones. In the stratosphere, the Brewer-Dobson circulation is *likely* to strengthen. {12.4.4}

TS.5.5.4 Projected Long-Term Changes in the Water Cycle

On the planetary scale, relative humidity is projected to remain roughly constant, but specific humidity to increase in a warming climate. The projected differential warming of land and ocean promotes changes in atmospheric moistening that lead to small decreases in near-surface relative humidity over most land areas with the notable exception of parts of tropical Africa (*medium confidence*) (see TFE.1, Figure 1). {12.4.5}

It is *virtually certain* that, in the long term, global precipitation will increase with increased global mean surface temperature. Global mean precipitation will increase at a rate per °C smaller than that of atmospheric

water vapour. It will *likely* increase by 1 to 3% °C⁻¹ for scenarios other than RCP2.6. For RCP2.6 the range of sensitivities in the CMIP5 models is 0.5 to 4% °C⁻¹ at the end of the 21st century. {7.6.2, 7.6.3, 12.4.1}

Changes in average precipitation in a warmer world will exhibit substantial spatial variation under RCP8.5. Some regions will experience increases, other regions will experience decreases, and yet others will not experience significant changes at all (see Figure TS.16). There *is high confidence* that the contrast of annual mean precipitation between dry and wet regions and that the contrast between wet and dry seasons will increase over most of the globe as temperatures increase. The general pattern of change indicates that high latitudes are *very likely* to experience greater amounts of precipitation due to the increased specific humidity of the warmer troposphere as well as increased transport of water vapour from the tropics by the end of this century under the RCP8.5 scenario. Many mid-latitude and subtropical arid and semi-arid regions will *likely* experience less precipitation and many moist mid-latitude regions will *likely* experience more precipitation by the end of this century under the RCP8.5 scenario. Maps of precipitation change for the four RCP scenarios are shown in Figure TS.16. {12.4.2, 12.4.5}

Globally, for short-duration precipitation events, a shift to more intense individual storms and fewer weak storms is *likely* as temperatures increase. Over most of the mid-latitude land-masses and over wet tropical regions, extreme precipitation events will *very likely* be more intense and more frequent in a warmer world. The global average sensitivity of the 20-year return value of the annual maximum daily precipitation ranges from 4% per °C of local temperature increase (average of CMIP3 models) to 5.3% per °C of local temperature increase (average of CMIP5 models) but regionally there are wide variations. {12.4.2, 12.4.5}

[INSERT FIGURE TS.16 HERE]

Figure TS.16: Maps of multi-model results for the scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5 in 2081–2100 of average percent change in mean precipitation. Changes are shown relative to 1986–2005. The number of CMIP5 models to calculate the multi-model mean is indicated in the upper right corner of each panel. Hatching indicates regions where the multi model mean signal is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean signal is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). {Figure 12.22; Annex I}

Annual surface evaporation is projected to increase as global temperatures rise over most of the ocean and is projected to change over land following a similar pattern as precipitation. Decreases in annual runoff are *likely* in parts of southern Europe, the Middle East, and southern Africa by the end of this century under the RCP8.5 scenario. Increases in annual runoff are *likely* in the high northern latitudes corresponding to large increases in winter and spring precipitation by the end of this century under the RCP8.5 scenario. Regional to global-scale projected decreases in soil moisture and increased risk of agricultural drought are *likely* in presently dry regions and are projected with *medium confidence* by the end of this century under the RCP8.5 scenario. Prominent areas of projected decreases in evaporation include southern Africa and north western Africa along the Mediterranean. Soil moisture drying in the Mediterranean and southern African regions is consistent with projected changes in Hadley circulation and increased surface temperatures, so surface drying in these regions as global temperatures increase is *likely* with *high confidence* by the end of this century under the RCP8.5 scenario. In regions where surface moistening is projected, changes are generally smaller than natural variability on the twenty-year time scale. A summary of the projected changes in the water cycle from the CMIP5 models is shown in TFE.1, Figure 1. {12.4.5; Box 12.1}

TS.5.5.5 Projected Long-Term Changes in the Cryosphere

It is *very likely* that the Arctic sea ice cover will continue shrinking and thinning year-round in the course of the 21st century as global mean surface temperature rises. At the same time, in the Antarctic, a decrease in sea ice extent and volume is expected, but with *low confidence*. The CMIP5 multi-model projections give average reductions in Arctic sea ice extent for 2081–2100 compared to 1986–2005 ranging from 8% for RCP2.6 to 34% for RCP8.5 in February and from 43% for RCP2.6 to 94% for RCP8.5 in September (*medium confidence*) (Figure TS.17). A nearly ice-free Arctic Ocean (sea ice extent less than 10⁶ km²) in September before mid-century is *likely* under RCP8.5 (*medium confidence*), based on an assessment of a subset of models that most closely reproduce the climatological mean state and 1979–2012 trend of the Arctic sea ice cover. Some climate projections exhibit 5 to 10 year periods of sharp summer Arctic sea ice decline – even steeper than observed over the last decade – and it is *likely* that such instances of rapid ice loss will occur in the future. There is little evidence in global climate models of a tipping point (or critical

threshold) in the transition from a perennially ice-covered to a seasonally ice-free Arctic Ocean beyond which further sea ice loss is unstoppable and irreversible. In the Antarctic, the CMIP5 multi-model mean projects a decrease in sea ice extent that ranges from 16% for RCP2.6 to 67% for RCP8.5 in February and from 8% for RCP2.6 to 30% for RCP8.5 in September for 2081–2100 compared to 1986–2005. There is however *low confidence* in those projections because of the wide inter-model spread and the inability of almost all of the available models to reproduce the overall increase of the Antarctic sea ice areal coverage observed during the satellite era. {12.4.6, 12.5.5}

It is *very likely* that Northern Hemisphere snow cover will reduce as global temperatures rise over the coming century. A retreat of permafrost extent with rising global temperatures is *virtually certain*. Snow cover changes result from precipitation and ablation changes, which are sometimes opposite. Projections of the Northern Hemisphere spring snow covered area by the end of the 21st century vary between –7% (RCP2.6) and –25% (RCP8.5) decrease and are fairly coherent among models (Figure TS.18). The projected changes in permafrost are a response not only to warming, but also to changes in snow cover, which exerts a control on the underlying soil. By the end of the 21st century, diagnosed near-surface permafrost area is projected to decrease by between 37% (RCP2.6) to 81% (RCP8.5) (*medium confidence*). {12.4.6}

[INSERT FIGURE TS.17 HERE]

Figure TS.17: Northern Hemisphere sea-ice extent in September over the late 20th century and the whole 21st century for the scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5 in the CMIP5 models, and corresponding maps of multi-model results in 2081–2100 of Northern Hemisphere September sea ice extent. In the time series, the number of CMIP5 models to calculate the multi-model mean is indicated (subset in brackets). Time series are given as 5 year running means. The projected mean sea ice extent of a subset of models that most closely reproduce the climatological mean state and 1979–2012 trend of the Arctic sea ice is given (solid lines), with the min-max range of the subset indicated with shading. Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The CMIP5 multi-model mean is indicated with dashed lines. In the maps, the CMIP5 multi-model mean is given in white color, the results for the subset in grey colour. Filled areas mark the averages over the 2081–2100 period, lines mark the sea ice extent averaged over the 1986–2005 period. The observed sea ice extent is given in pink as a time series and averaged over 1986–2005 as a pink line in the map. {Figures 12.18, 12.29, 12.31}

[INSERT FIGURE TS.18 HERE]

Figure TS.18: Top: Northern Hemisphere spring (March to April average) relative snow covered area (RSCA) in CMIP5, obtained by dividing the simulated 5-year box smoothed spring snow covered area (SCA) by the simulated average spring SCA of 1986–2005 reference period. Bottom: Northern hemisphere diagnosed near-surface permafrost area in CMIP5, using 20-year average monthly surface air temperatures and snow depths. Lines indicate the multi model average, shading indicates the inter-model spread (one standard deviation). {Figures 12.32, 12.33}

TS.5.5.6 Projected Long-Term Changes in the Ocean

Over the course of the 21st century, the global ocean will warm in all RCP scenarios. The strongest warming signal is found at the surface in subtropical and tropical regions. At greater depth the warming is most pronounced in the Southern Ocean. In some regions, ocean warming in the top few hundred meters can exceed 0.5°C (RCP2.6) to 2.5°C (RCP8.5), and 0.3°C (RCP2.6) to 0.7°C (RCP8.5) at a depth of about 1 km by the end of the century. For RCP4.5 by the end of the 21st century, half of the energy taken up by the ocean is in the uppermost 700 m, and 85% is in the uppermost 2000 m. Due to the long time scales of this heat transfer from the surface to depth, ocean warming will continue for centuries, even if greenhouse gas emissions are decreased or concentrations kept constant, and will result in a continued contribution to sea level rise (see Section TS5.7). {12.4.3, 12.4.7}

TFE.6: Climate Sensitivity and Feedbacks

The description of climate change as a response to a forcing that is amplified by feedbacks goes back many decades. The concepts of radiative forcing and climate feedbacks continue to be refined, and limitations are now better understood; for instance, feedbacks may be much faster than the surface warming, feedbacks depend on the type of forcing agent (e.g., greenhouse gas vs. solar forcing), or may have intrinsic timescales (associated mainly with vegetation change and ice sheets) of several centuries to millennia. The analysis of physical feedbacks in models and from observations remains a powerful framework that provides constraints on transient future warming for different scenarios, on climate sensitivity and, combined with estimates of

carbon cycle feedbacks (see TFE.5), determines the greenhouse gas emissions that are compatible with climate stabilization or targets (see TFE.8). {7.1, 9.7.2, 12.5.3; Box 12.2}

The water vapour/lapse rate, albedo and cloud feedbacks are the principal determinants of equilibrium climate sensitivity (ECS, the equilibrium change in annual mean global surface temperature following a doubling of the atmospheric CO₂ concentration). All of these feedbacks are assessed to be positive, but with different levels of likelihood assigned ranging from likely to extremely likely. Therefore, there is *very high confidence* that the net feedback is strongly positive and the black body response of the climate to a forcing will therefore be amplified. Cloud feedbacks continue to be the largest uncertainty. The net feedback from water vapour and lapse rate changes together is *extremely likely* positive and approximately doubles the black body response. The mean value and spread of these two processes in climate models are essentially unchanged from AR4, but are now supported by stronger observational evidence and better process understanding of what determines relative humidity distributions. Clouds respond to climate forcing mechanisms in multiple ways and individual cloud feedbacks can be positive or negative. Key issues include the representation of both deep and shallow cumulus convection, microphysical processes in ice clouds, and partial cloudiness that results from small-scale variations of cloud-producing and cloud-dissipating processes. New approaches to diagnosing cloud feedback in GCMs have clarified robust cloud responses, while continuing to implicate low cloud cover as the most important source of intermodel spread in simulated cloud feedbacks. The net radiative feedback due to all cloud types is *likely* positive. This conclusion is reached by considering a plausible range for unknown contributions by processes yet to be accounted for, in addition to those occurring in current climate models. Observations alone do not currently provide a robust, direct constraint, but multiple lines of evidence now indicate positive feedback contributions from changes in both the height of high clouds and the horizontal distribution of clouds. The additional feedback from low cloud amount is also positive in most climate models, but that result is not well understood, nor effectively constrained by observations, so *confidence* in it is *low*. {7.2.4, 7.2.5, 7.2.6}

The representation of aerosol-cloud processes in climate models continues to be a challenge. Aerosol and cloud variability at scales significantly smaller than those resolved in climate models, and the subtle responses of clouds to aerosol at those scales, mean that, for the foreseeable future, climate models will continue to rely on parameterizations of aerosol-cloud interactions or other methods that represent subgrid variability. This implies large uncertainties for estimates of the forcings associated with aerosol-cloud interactions. {7.4, 7.5.3, 7.5.4}

Equilibrium climate sensitivity (ECS) and Transient Climate Response (TCR) are useful metrics summarising the global climate system's temperature response to an externally-imposed radiative forcing. ECS is defined as the equilibrium change in annual mean global mean surface temperature following a doubling of the atmospheric CO₂ concentration (see Glossary), while TCR is defined as the annual mean global mean surface temperature change at the time of CO₂ doubling following a linear increase in CO₂ forcing over a period of 70 years (see Glossary). Both metrics have a broader application than these definitions imply: ECS determines the eventual warming in response to stabilisation of atmospheric composition on multi-century timescales, while TCR determines the warming expected at a given time following any steady increase in forcing over a 50- to 100-year timescale. {Box 12.2, 12.5.3}

ECS and TCR can be estimated from various lines of evidence (see TFE.6, Figures 1 and 2). The estimates can be based on the values of ECS and TCR diagnosed from climate models, or they can be constrained by analysis of feedbacks in climate models, patterns of mean climate and variability in models compared to observations, temperature fluctuations as reconstructed from paleoclimate archives, observed and modelled short term perturbations of the energy balance like those caused by volcanic eruptions, and the observed surface and ocean temperature trends since preindustrial. For many applications, the limitations of the forcing-feedback analysis framework and the dependence of feedbacks on timescales and the climate state must be kept in mind. {5.3.1, 5.3.3, 9.7.1, 9.7.2, 9.7.3, 10.8.1, 10.8.2, 12.5.3; Box 5.2; Table 9.5}

Newer studies of constraints on ECS are based on the observed warming since preindustrial, analysed using simple and intermediate complexity models, improved statistical methods, and several different and newer datasets. Together with results from feedback analysis and paleoclimate constraints these studies show ECS is *likely* between 1.5°C to 4.5°C (*medium confidence*) and *extremely unlikely* less than 1.0°C. {5.3.1, 5.3.3, 10.8.2; Box 5.2, 12.2}

Estimates based on AOGCMs and feedback analysis indicate a range of 2 to 4.5°C, with the CMIP5 model mean at 3.2°C, similar to CMIP3. High climate sensitivities are found in some perturbed parameter ensembles models, but recent comparisons of perturbed-physics ensembles against the observed climate find that models with ECS values in the range 3 to 4°C show the smallest errors for many fields. Relationships between climatological quantities and climate sensitivity are often found within a specific perturbed parameter ensemble model but in many cases the relationship is not robust across perturbed parameter ensembles models from different models or in CMIP3/5. The assessed literature suggests that the range of climate sensitivities and transient responses covered by CMIP3/5 cannot be narrowed significantly by constraining the models with observations of the mean climate and variability. Studies based on perturbed parameter ensembles models and CMIP3 support the conclusion that a credible representation of the mean climate and variability is very difficult to achieve with ECSs below 2°C. {9.2.2, 9.7.3; Box 12.2}

New estimates of ECS based on reconstructions and simulations of the Last Glacial Maximum (21,000 years to 19,000 years ago) show that values below 1°C as well as above 6°C are *very unlikely*. In some models climate sensitivity differs between warm and cold climates because of differences in the representation of cloud feedbacks. Estimates of an Earth System sensitivity including slow feedbacks (e.g., ice sheets or vegetation) are even more difficult to relate to climate sensitivity of the current climate state. The main limitations of ECS estimates from paleoclimate states are uncertainties in proxy data, spatial coverage of the data, uncertainties in some forcings, and structural limitations in models used in model-data comparisons. {5.3, 10.8.2, 12.5.3}

Bayesian methods to constrain ECS or TCR are sensitive to the assumed prior distributions. They can in principle yields narrower estimates by combining constraints from the observed warming trend, volcanic eruptions, model climatology, and paleoclimate, and that has been done in some studies, but there is no consensus on how this should be done robustly. This approach is sensitive to the assumptions regarding the independence of the various lines of evidence, the possibility of shared biases in models or feedback estimates, and the assumption that each individual line of evidence is unbiased. The combination of different estimates in this assessment is based on expert judgment. {10.8.2; Box 12.2}

The grey shaded range marks the *likely* 1°C to 2.5°C range, the grey solid line marks the *extremely unlikely* greater than 3°C. Adapted from Box 12.2, Figure 2. See Figure 10.20a and Chapter 10 Supplementary Material for full caption and details. {Box 12.2, Figure 2}

Based on the combined evidence from observed climate change including the observed 20th century warming, climate models, feedback analysis and paleoclimate, as discussed above, equilibrium climate sensitivity (ECS) is *likely* in the range 1.5 to 4.5°C with *high confidence*. ECS is positive, *extremely unlikely* less than 1°C (*high confidence*), and *very unlikely* greater than 6°C (*medium confidence*). The tails of the ECS distribution are now better understood. Multiple lines of evidence provide *high confidence* that an ECS value less than 1°C is *extremely unlikely*. The upper limit of the likely range is unchanged compared to AR4. The lower limit of the likely range of 1.5°C is less than the lower limit of 2°C in AR4. This change reflects the evidence from new studies of observed temperature change, using the extended records in atmosphere and ocean. These studies suggest a best fit to the observed surface and ocean warming for ECS values in the lower part of the *likely* range. Note that these studies are not purely observational, because they require an estimate of the response to radiative forcing from models. In addition, the uncertainty in ocean heat uptake remains substantial. Accounting for short-term variability in simple models remains challenging, and it is important not to give undue weight to any short time period which might be strongly affected by internal

variability. On the other hand, AOGCMs show very good agreement with observed climatology with ECS values in the upper part of the 1.5–4.5°C range, but the simulation of key feedbacks like clouds remains challenging in those models. The estimates from the observed warming, paleoclimate, and from climate models are consistent within their uncertainties, each is supported by many studies and multiple datasets, and in combination they provide *high confidence* for the assessed *likely* range. Even though this assessed range is similar to previous reports, confidence today is much higher as a result of high quality and longer observational records with a clearer anthropogenic signal, better process understanding, more and better understood evidence from paleoclimate reconstructions, and better climate models with higher resolution that capture many more processes more realistically. All these lines of evidence individually support the assessed *likely* range of 1.5 to 4.5°C. {3.2, 9.7.3, 10.8; Box 9.2, 13.1}

On timescales of many centuries and longer, additional feedbacks with their own intrinsic timescales (e.g., vegetation, ice sheets) may become important but are not usually modelled in AOGCMs. The resulting equilibrium temperature response to a doubling of CO₂ on millennial timescales or Earth System Sensitivity is less well constrained but *likely* to be larger than ECS, implying that lower atmospheric CO₂ concentrations are compatible with limiting warming to below a given temperature level. These slow feedbacks are less likely to be proportional to global mean temperature change, implying that Earth System Sensitivity changes over time. Estimates of Earth System Sensitivity are also difficult to relate to climate sensitivity of the current climate state. {5.3.3, 10.8.2, 12.5.3}

For scenarios of increasing radiative forcing, TCR is a more informative indicator of future climate change than ECS. This assessment concludes with *high confidence* that the transient climate response (TCR) is *likely* in the range 1°C to 2.5°C, close to the estimated 5–95% range of CMIP5 (1.2°C to 2.4°C), is positive and *extremely unlikely* greater than 3°C. As with the ECS, this is an expert-assessed range, supported by several different and partly independent lines of evidence, each based on multiple studies, models and datasets. TCR is estimated from the observed global changes in surface temperature, ocean heat uptake and radiative forcing including detection/attribution studies identifying the response patterns to increasing greenhouse gas concentrations, and the results of CMIP3 and CMIP5. Estimating TCR suffers from fewer difficulties in terms of state- or time-dependent feedbacks, and is less affected by uncertainty as to how much energy is taken up by the ocean. Unlike ECS, the ranges of TCR estimated from the observed warming and from AOGCMs agree well, increasing our confidence in the assessment of uncertainties in projections over the 21st century. The assessed ranges of ECS and TCR are largely consistent with the observed warming, the estimated forcing, and the projected future warming. {9.7.1, 10.8.1, 12.5.3; Table 9.5}

TS.5.6 Long-Term Projections of Carbon and Other Biogeochemical Cycles

Projections of the global carbon cycle to 2100 using the CMIP5 Earth System Models (ESMs) represent a wider range of complex interactions between the carbon cycle and the physical climate system.

With *very high confidence*, ocean carbon uptake of anthropogenic CO₂ will continue under all four Representative Concentration Pathways through to 2100, with higher uptake in higher concentration pathways. The future evolution of the land carbon uptake is much more uncertain. A majority of CMIP5 ESMs project a continued net carbon uptake by land ecosystems through 2100. Yet, a minority of models simulate a net CO₂ source to the atmosphere by 2100 due to the combined effect of climate change and land use change. In view of the large spread of model results and incomplete process representation, there is *low confidence* on the magnitude of modelled future land carbon changes. {6.4.3}

There is *high confidence* that climate change will partially offset increases in global land and ocean carbon sinks caused by rising atmospheric CO₂. Yet, there are regional differences among CMIP5 ESMs, in the response of ocean and land CO₂ fluxes to climate. There is high agreement between models that tropical ecosystems will store less carbon in a warmer climate. There is medium agreement between the CMIP5 ESMs that at high latitudes warming will increase land carbon storage, although none of these models accounts for decomposition of carbon in permafrost, which may offset increased land carbon storage. There is *high confidence* that reductions in permafrost extent due to warming will cause thawing of some currently frozen carbon. However, there is low confidence on the magnitude of carbon losses through CO₂ and CH₄

emissions to the atmosphere with a range from 50 to more than 250 PgC between 2000 and 2100 for RCP8.5. {6.4.2, 6.4.3}

The loss of carbon from frozen soils constitutes a positive radiative feedback that is missing in current coupled ESM projections. There is high agreement between CMIP5 ESMs that ocean warming and circulation changes will reduce the rate of ocean carbon uptake in the Southern Ocean and North Atlantic, but that carbon uptake will nevertheless persist in those regions. {6.4.2}

It is *very likely*, based on new experimental results and modelling, that nutrient shortage will limit the effect of rising atmospheric CO₂ on future land carbon sinks, for the four RCP scenarios. There is *high confidence* that low nitrogen availability will limit carbon storage on land, even when considering anthropogenic nitrogen deposition. The role of phosphorus limitation is more uncertain. {6.4.6}

For the ESMs simulations driven by CO₂ concentrations, representation of the land and ocean carbon cycle allows quantification of the fossil fuel emissions compatible with the RCP scenarios. Between 2012 and 2100, ESM results imply cumulative compatible fossil fuel emissions of 270 [140 to 410] PgC for RCP2.6, 780 [595 to 1005] PgC for RCP4.5, 1060 [840 to 1250] PgC for RCP6.0, and 1685 [1415 to 1910] PgC for RCP8.5 (CMIP5 model spread) (Figure TS.19). For RCP2.6, the models project an average 50% (range 14–96%) emission reduction by 2050 relative to 1990 levels. It is about *as likely as not* that sustained globally negative emissions will be required to achieve the reductions in atmospheric CO₂ in RCP2.6. See also Box TS.7. {6.4.3; Table 6.12}

[INSERT FIGURE TS.19 HERE]

Figure TS.19: Compatible fossil fuel emissions simulated by the CMIP5 models for the four RCP scenarios. Top: timeseries of annual emission (PgC yr⁻¹). Dashed lines represent the historical estimates and RCP emissions calculated by the integrated assessment models (IAM) used to define the RCP scenarios, solid lines and plumes show results from CMIP5 ESMs (model mean, with 1 standard deviation shaded). Bottom: cumulative emissions for the historical period (1860–2005) and 21st century (defined in CMIP5 as 2006–2100) for historical estimates and RCP scenarios. Left bars are cumulative emissions from the IAMs, right bars are the CMIP5 ESMs multi-model mean estimate, and dots denote individual ESM results. From the CMIP5 ESMs results, total carbon in the land-atmosphere-ocean system can be tracked and changes in this total must equal fossil fuel emissions to the system. Hence the compatible emissions are given by cumulative Emissions = $\Delta C_A + \Delta C_L + \Delta C_O$, while emission rate = $d/dt [C_A + C_L + C_O]$, where C_A , C_L , C_O are carbon stored in atmosphere, land and ocean respectively. Other sources and sinks of CO₂ such as from volcanism, sedimentation or rock weathering, which are very small on centennial timescales are not considered here. {Box 6.4; Figure 6.25}

When forced with RCP8.5 CO₂ emissions, as opposed to the RCP8.5 CO₂ concentrations, CMIP5 ESMs with interactive carbon cycles simulate, on average, a 50 (–140 to +210) ppm (CMIP5 model spread) larger atmospheric CO₂ concentration and a 0.2 (–0.4 to +0.9) °C (CMIP5 model spread) larger global surface temperature increase by 2100. {12.4.8}

It is *virtually certain* that the increased storage of carbon by the ocean will increase acidification in the future, continuing the observed trends of the past decades. Ocean acidification in the surface ocean will follow atmospheric CO₂ and it will also increase in the deep ocean as CO₂ continues to penetrate the abyss. The CMIP5 models consistently project worldwide increased ocean acidification to 2100 under all RCPs. The corresponding decrease in surface ocean pH by the end of 21st century is 0.065 (0.06 to 0.07) for RCP2.6, 0.145 (0.14 to 0.15) for RCP4.5, 0.203 (0.20 to 0.21) for RCP6.0, and 0.31 (0.30 to 0.32) for RCP8.5 (CMIP5 model spread) (Figure TS.20). Surface waters are projected to become seasonally corrosive to aragonite in parts of the Arctic and in some coastal upwelling systems within a decade, and in parts of the Southern Ocean within 1–3 decades in most scenarios. Aragonite, a less stable form of calcium carbonate, undersaturation becomes widespread in these regions at atmospheric CO₂ levels of 500–600 ppm. {6.4.4}

[INSERT FIGURE TS.20 HERE]

Figure TS.20: (a) Timeseries (model averages and min-max ranges) and (b) maps of multi-model surface ocean pH for the scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5 in 2081–2100. The maps in (b) show change in global ocean surface pH in 2081–2100 relative to 1986–2005. The number of CMIP5 models to calculate the multi-model mean is indicated in the upper right corner of each panel. {Figure 6.28}

It is *very likely* that the dissolved oxygen content of the ocean will decrease by 3 to 6% during the 21st century in response to surface warming (see Box 6.5, and Section 6.4.5). CMIP5 models suggest that this decrease in dissolved oxygen will predominantly occur in the subsurface mid-latitude oceans, caused by enhanced stratification, reduced ventilation and warming. However, there is no consensus on the future development of the volume of hypoxic and suboxic waters in the open-ocean because of large uncertainties in potential biogeochemical effects and in the evolution of tropical ocean dynamics. {6.4.5}

With *very high confidence*, the physical, biogeochemical carbon cycle in the ocean and on land will continue to respond to climate change and atmospheric CO₂ increases that arise during the 21st century (see TFE.7 and TFE 8).

TFE.7: Carbon Cycle Perturbation and Uncertainties

The natural carbon cycle has been perturbed since the beginning of the Industrial Revolution (circa 1750) by the anthropogenic release of CO₂ to the atmosphere, virtually all from fossil fuel combustion and land use change, with a small contribution from cement production. Fossil fuel burning is a process related to energy production. Fossil fuel carbon comes from geological deposits of coal, oil and gas that were buried in the Earth crust for millions of years. Land use change CO₂ emissions are related to the conversion of natural ecosystems into managed ecosystems for food, feed and timber production with CO₂ being emitted from the burning of plant material or from the decomposition of dead plants and soil organic carbon. For instance when a forest is cleared, the plant material may be released to the atmosphere quickly through burning or over many years as the dead biomass and soil carbon decay on their own. {6.1, 6.3; Table 6.1}

The human caused excess of CO₂ in the atmosphere is partly removed from the atmosphere by carbon sinks in land ecosystems and in the ocean, currently leaving about 45% of the CO₂ emissions in the atmosphere. Natural carbon sinks are due to physical, biological and chemical processes acting on different time scales. An excess of atmospheric CO₂ supports photosynthetic CO₂ fixation by plants that is stored as plant biomass or in the soil. The residence times of stored carbon on land depends on the compartments (plant / soil) and composition of the organic carbon, with time horizons varying from days to centuries. The increased storage in terrestrial ecosystems not affected by land use change is likely to be caused by enhanced photosynthesis at higher CO₂ levels and N deposition, and changes in climate favoring carbon sinks such as longer growing seasons in mid-to-high latitudes. {6.3, 6.3.1}

The uptake of anthropogenic CO₂ by the ocean is primarily a response to increasing CO₂ in the atmosphere. Excess atmospheric CO₂ absorbed by the surface ocean or transported to the ocean through aquatic systems (e.g., rivers, ground waters) gets buried in coastal sediments or transported to deep waters where it is stored for decades to centuries. The deep ocean carbon can dissolve ocean carbonate sediments to store excess CO₂ on time scales of centuries to millennia. Within a thousand years, the remaining atmospheric fraction of the CO₂ emissions will be between 15 and 40%, depending on the amount of carbon released (TFE.7, Figure 1). On geological time scales of 10,000 years or longer, additional CO₂ is removed very slowly from the atmosphere by rock weathering, pulling the remaining atmospheric CO₂ fraction down to 10 to 25% after 10,000 years. {Box 6.1}

[INSERT TFE.7, FIGURE 1 HERE]

TFE.7, Figure 1: Percentage of initial atmospheric CO₂ perturbation remaining in the atmosphere in response to an idealized instantaneous CO₂ emission pulse in year 0 as calculated by a range of coupled climate-carbon cycle models. Multi-model mean (blue line) and the uncertainty interval (± 2 standard deviations, shading) simulated during 100 years (left panel) and 1,000 years (right panel) following the instantaneous emission pulse of 100 PgC. (adapted from Box 6.1, Figure 1). {Box 6.1}

The carbon cycle response to future climate and CO₂ changes can be viewed as two strong and opposing feedbacks. The concentration-carbon feedback determines changes in storage due to elevated CO₂, and the climate-carbon feedback determines changes in carbon storage due to changes in climate. There is *high confidence* that increased atmospheric CO₂ will lead to increased land and ocean carbon uptake but by an uncertain amount. Models agree on the positive sign of land and ocean response to rising CO₂ but show only medium and low agreement for the magnitude of ocean and land carbon uptake respectively (TFE.7, Figure

2). Future climate change will decrease land and ocean carbon uptake compared to the case with constant climate (*medium confidence*). This is further supported by paleoclimate observations and modelling indicating that there is a positive feedback between climate and the carbon cycle on century to millennial time scales. Models agree on the sign, globally negative, of land and ocean response to climate change but show low agreement on the magnitude of this response, especially for the land (TFE.7, Figure 2). A key update since AR4 is the introduction of nutrient dynamics in some land carbon models, in particular the limitations on plant growth imposed by nitrogen availability. There is *high confidence* that, at the global scale, relative to CMIP5 carbon only ESMs, CMIP5 ESMs including a land nitrogen cycle will reduce the strength of both the concentration-carbon feedback and the climate-carbon feedback of land ecosystems (TFE.7, Figure 2). Inclusion of N-cycle processes increases the spread across the CMIP5 ensemble. The CMIP5 spread in ocean sensitivity to CO₂ and climate appears reduced compared to AR4 (TFE.7, Figure 2). {6.2.3, 6.4.2}

[INSERT TFE.7, FIGURE 2 HERE]

TFE.7, Figure 2: Comparison of carbon cycle feedback metrics between the ensemble of 7 GCMs and 4 EMICs at the time of AR4 (C⁴MIP) under the SRES-A2 scenario and the 8 CMIP5 models under the 140-year 1% CO₂ increase per year scenario. Black dots represent a single model simulation and coloured bars the mean of the multi-model results, grey dots are used for models with a coupled terrestrial nitrogen cycle. The comparison with C⁴MIP models is for context, but these metrics are known to be variable across different scenarios and rates of change (see Section 6.4.2.2). The SRES A2 scenario is closer in rate of change to a 0.5% CO₂ increase per year scenario and as such it should be expected that the CMIP5 climate-carbon sensitivity terms are comparable, but the concentration-carbon sensitivity terms are likely to be around 20% smaller for CMIP5 than for C⁴MIP due to lags in the ability of the land and ocean to respond to higher rates of CO₂ increase. This dependence on scenario reduces confidence in any quantitative statements of how CMIP5 carbon cycle feedbacks differ from C⁴MIP. {6.4.2}

With *very high confidence*, ocean carbon uptake of anthropogenic CO₂ emissions will continue under all four Representative Concentration Pathways through to 2100, with higher uptake corresponding to higher concentration pathways. The future evolution of the land carbon uptake is much more uncertain, with a majority of models projecting a continued net carbon uptake under all RCPs, but with some models simulating a net loss of carbon by the land due to the combined effect of climate change and land use change. In view of the large spread of model results and incomplete process representation, there is *low confidence* on the magnitude of modelled future land carbon changes. [6.4.3, Figure 6.24]

Biogeochemical cycles and feedbacks other than the carbon cycle play an important role in the future of the climate system, although the carbon cycle represents the strongest of these. Changes in the nitrogen cycle, in addition to interactions with CO₂ sources and sinks, affect emissions of N₂O both on land and from the ocean. The human-caused creation of reactive nitrogen has increased steadily over the last two decades and is dominated by the production of ammonia for fertilizer and industry, with important contributions from legume cultivation and combustion of fossil fuels. {6.3}

Many processes, however, are not yet represented in coupled climate-biogeochemistry models (e.g., other processes involving other biogenic elements such as P, Si, Fe) so their magnitudes have to be estimated in offline or simpler models, which make their quantitative assessment difficult. It is *likely* that there will be non-linear interactions between many of these processes, but these are not yet well quantified. Therefore any assessment of the future feedbacks between climate and biogeochemical cycles still contains large uncertainty. {6.4}

TFE.8: Climate Targets and Stabilization

The concept of stabilization is strongly linked to the ultimate objective of the UNFCCC, which is “to achieve [...] stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.” Recent policy discussions focused on limits to a global temperature increase, rather than to greenhouse gas concentrations, as climate targets in the context of the UNFCCC objectives. The most widely discussed is that of 2°C, i.e., to limit global temperature increase relative to preindustrial times to below 2°C, but targets other than 2°C have been proposed (e.g., returning warming to well below 1.5°C global warming relative to preindustrial, or returning below an atmospheric CO₂ concentration of 350 ppm). Climate targets generally mean avoiding a warming beyond a predefined

threshold. Climate impacts however are geographically diverse and sector specific, and no objective threshold defines when dangerous interference is reached. Some changes may be delayed or irreversible, and some impacts could be beneficial. It is thus not possible to define a single critical objective threshold without value judgments and without assumptions on how to aggregate current and future costs and benefits. This section does not advocate or defend any threshold or objective, nor does it judge the economic or political feasibility of such goals, but assesses, based on the current understanding of climate and carbon cycle feedbacks, the climate projections following the RCP scenarios in the context of climate targets, and the implications of different long-term temperature stabilization objectives on allowed carbon emissions. Further below it is highlighted that temperature stabilization does not necessarily imply stabilization of the entire Earth system.

Temperature targets imply an upper limit on the total radiative forcing (RF). Differences in RF between the four RCP scenarios are relatively small up to 2030, but become very large by the end of the 21st century and dominated by CO₂ forcing. Consequently, in the near term, global-mean surface temperatures are projected to continue to rise at a similar rate for the four RCP scenarios. Around the mid-21st century, the rate of global warming begins to be more strongly dependent on the scenario. By the end of the 21st century, global mean temperatures will be warmer than present day under all the RCPs, global temperature change being largest (>0.3°C per decade) in the highest RCP8.5 and significantly lower in RCP2.6, particularly after ~2050 when global surface temperature response stabilizes (and declines thereafter) (see Figure TS.15). {11.3.1, 12.3.3, 12.4.1}

In the near term (2016–2035), global mean surface warming is *more likely than not* to exceed 1°C and *very unlikely* to be more than 1.5°C relative to preindustrial (assuming 0.61°C warming has occurred prior to 1986–2005) (*medium confidence*). By the end of the century (2081–2100), global mean surface warming, relative to preindustrial, is *likely* to exceed 1.5°C for RCP4.5, RCP6.0 and RCP8.5 (*high confidence*) and is *likely* to exceed 2°C for RCP6.0 and RCP8.5 (*high confidence*). Global mean surface warming above 2°C under RCP2.6 is *unlikely* (*medium confidence*). Global mean surface warming above 4°C by 2081–2100 is *unlikely* in all RCPs (*high confidence*) except for RCP8.5 where it is *as likely as not* (*medium confidence*). All targets here are defined as global average surface temperature change relative to preindustrial. {11.3.6, 12.4.1; Table 12.3}

Continuing greenhouse gas emissions beyond 2100 as in the RCP8.5 extension induces a total radiative forcing above 12 W m⁻² by 2300, global warming reaching 7.8°C [3.0 to 12.6°C] for 2281–2300 relative to 1986–2005. Under the RCP4.5 extension, where radiative forcing is kept constant (around 4.5 W m⁻²) beyond 2100, global warming reaches 2.5°C [1.5 to 3.5°C]. Global warming reaches 0.6°C [0.0 to 1.2°C] under the RCP2.6 extension where sustained negative emissions lead to a further decrease in radiative forcing, reaching values below present-day radiative forcing by 2300. See also Box TS.7. {12.3.1, 12.4.1, 12.5.1}

The total amount of anthropogenic CO₂ released in the atmosphere since preindustrial (often termed cumulative carbon emission, although it only applies to CO₂ emissions) is a good indicator of the atmospheric CO₂ concentration and hence of the global warming response. The ratio of global mean surface temperature change to total cumulative anthropogenic CO₂ emissions is relatively constant over time and independent of the scenario. This near-linear relationship between total CO₂ emissions and global temperature change makes it possible to define a new quantity, the transient climate response to cumulative carbon emission (TCRE), as the transient global mean surface temperature change for a given amount of cumulated anthropogenic CO₂ emissions, usually 1000 PgC. TCRE is model dependent, as it is a function of the cumulative CO₂ airborne fraction and the transient climate response, both quantities varying significantly across models. Taking into account the available information from multiple lines of evidence (observations, models and process understanding), the near linear relationship between cumulative CO₂ emissions and peak global mean temperature is well established in the literature and robust for cumulative total CO₂ emissions up to about 2000 PgC. It is consistent with the relationship inferred from past cumulative CO₂ emissions and observed warming, is supported by process understanding of the carbon cycle and global energy balance, and emerges as a robust result from the entire hierarchy of models. Expert judgment based on the available evidence suggests that TCRE is *likely* between 0.8°C–2.5°C per 1000 PgC, for cumulative emissions less than about 2000 PgC until the time at which temperature peaks (TFE.8, Figure 1a). {6.4.3, 12.5.4; Box 12.2}

CO₂ induced warming is projected to remain approximately constant for many centuries following a complete cessation of emissions. A large fraction of climate change is thus irreversible on a human time scale, except if net anthropogenic CO₂ emissions were strongly negative over a sustained period. The assessment of TCRE, limiting the warming caused by anthropogenic CO₂ emissions alone to be *likely* less than 2°C, total CO₂ emissions from all anthropogenic sources would need to be below a cumulative budget of about 1000 PgC over the entire industrial era. About half, estimated in the range of 460 to 630 PgC, of this budget was already emitted by 2011 (TFE.8, Figure 1a). Higher emissions in earlier decades therefore imply lower or even negative emissions later on. Accounting for non-CO₂ forcings contributing to peak warming implies lower cumulated CO₂ emissions (TFE.8, Figure 1a). Non-CO₂ forcing constituents are important, requiring either assumptions on how CO₂ emission reductions are linked to changes in other forcings, or separate emission budgets and climate modeling for short lived and long-lived gases. So far, not many studies have considered non-CO₂ forcings. Those that do consider them found significant effects, in particular warming of several tenths of a degree for abrupt reductions in emissions of short-lived species, like aerosols. Accounting for an unanticipated release of greenhouse gases from permafrost or methane hydrates, not included in studies assessed here, would also reduce the anthropogenic CO₂ emissions compatible with a given temperature target. Requiring a higher likelihood of temperatures remaining below a given temperature target would further reduce the compatible emissions (TFE.8, Figure 1c). The concept of a fixed cumulative CO₂ budget holds not just for 2°C, but for any temperature level explored with models so far (up to about 5°C, see Figures 12.44–12.46). Higher temperature targets would allow larger cumulative budgets, while lower temperature target would require lower cumulative budgets (TFE.8, Figure 1). {6.3.1, 12.5.2, 12.5.4}

[INSERT TFE.8, FIGURE 1 HERE]

TFE.8, Figure 1: Global mean temperature increase since 1861–1880 as a function of cumulative total global CO₂ emissions from various lines of evidence. (a) Decadal average results are shown over all CMIP5 EMIC and ESMs for each RCP respectively, with coloured lines (multi-model average), decadal markers (dots) and with three decades (2001–2010, 2041–2050 and 2091–2100) highlighted with a star, square and diamond, respectively. The historical time period up to decade 2001–2010 is taken from the CMIP5 historical runs prolonged by RCP8.5 for 2005–2010 and is indicated with a black thick line and black symbols. Coloured ranges illustrate the model spread (90% range) over all CMIP5 ESMs and EMICs and do not represent a formal uncertainty assessment. Ranges are filled as long as data of all models is available and until peak temperature. They are faded out for illustrative purposes afterward. CMIP5 simulations with 1% yr⁻¹ CO₂ increase only are illustrated by the dark grey area (range definition similar to RCPs above) and the black thin line (multi-model average). The light grey cone represents this report's assessment of the transient climate response to emissions (TCRE) from CO₂ only. Estimated cumulative historical CO₂ emissions from 1850 to 2011 with associated uncertainties are illustrated by the grey bar at the bottom of panel a. (b) Comparison of historical model results with observations. The magenta line and uncertainty ranges are based on observed emissions from CDIAC extended by values of the Global Carbon project until 2010 and observed temperature estimates of HadCRUT4. The uncertainties in the last decade of observations are based on the assessment in this report. The black thick line is identical to the one in panel a. The thin green line with crosses is as the black line but for ESMs only. The yellow-brown line and range show these ESM results until 2010, when corrected for HadCRUT4's incomplete geographical coverage over time. All values are given relative to the 1861–1880 base period. All time-series are derived from decadal averages to illustrate the long-term trends. Note that observations are in addition subject to internal climate variability, adding an uncertainty of about 0.1°C. (c) Cumulative CO₂ emissions over the entire industrial era, consistent with four illustrative peak global temperature limits (1.5°C, 2°C, 2.5°C, and 3°C, respectively) when taking into account warming by all forcings. Horizontal bars indicate consistent cumulative emission budgets as a function of the fraction of models (CMIP5 ESMs and EMICs) that at least hold warming below a given temperature limit. Note that the fraction of models cannot be interpreted as a probability. The budgets are derived from the RCP8.5 runs, with relative high non-CO₂ forcing over the 21st century. If non-CO₂ are significantly reduced, the CO₂ emissions compatible with a specific temperature limit might be slightly higher, but only to a very limited degree, as illustrated by the other coloured lines in panel a, which assume significantly lower non-CO₂ forcing. {Figure 12.45}

The climate system has multiple timescales, ranging from annual to multi-millennial, associated with different thermal and carbon reservoirs. These long time scales induce a commitment warming “already in the pipe-line”. Stabilization of the forcing would not lead to an instantaneous stabilization of the warming. For the RCP scenarios and their extensions to 2300, the fraction of realized warming, at that time when radiative forcing stabilizes, would be about 75 to 85% of the equilibrium warming. For a 1% yr⁻¹ CO₂ increase to 2 × CO₂ or 4 × CO₂ and constant forcing thereafter, the fraction of realized warming would much smaller, about 40 to 70% at the time when the forcing is kept constant. Due to the long timescales in the deep ocean, full equilibrium is reached only after hundreds to thousands of years.

The commitment to past emissions is a persistent warming for hundreds of years, continuing at about the level of warming that has been realized when emissions were ceased. The persistence of this CO₂-induced warming after emission have ceased results from a compensation between the delayed commitment warming described above and the slow reduction in atmospheric CO₂ resulting from ocean and land carbon uptake. This persistence of warming also results from the nonlinear dependence of radiative forcing on atmospheric CO₂, i.e., the relative decrease in forcing being smaller than the relative decrease in CO₂ concentration. For high climate sensitivities, and in particular if sulphate aerosol emissions are eliminated at the same time as greenhouse gas emissions, the commitment from past emission can be strongly positive, and is a superposition of a fast response to reduced aerosols emissions and a slow response to reduced CO₂. {12.5.4}

Stabilization of global temperature does not imply stabilization for all aspects of the climate system. Processes related to vegetation change, changes in the ice sheets, deep ocean warming and associated sea level rise and potential feedbacks linking for example ocean and the ice sheets have their own intrinsic long timescales. Ocean acidification will *very likely* continue in the future as long as the oceans will continue to take up atmospheric CO₂. Committed land ecosystem carbon cycle changes will manifest themselves further beyond the end of the 21st century. It is *virtually certain* that global mean sea level rise will continue beyond 2100, with sea level rise due to thermal expansion to continue for centuries to millennia. Global mean sea level rise depends on the pathway of CO₂ emissions, not only on the cumulative total; reducing emissions earlier rather than later, for the same cumulative total, leads to a larger mitigation of sea level rise. {6.4.4, 12.5.4, 13.5.4}

[START BOX TS.7 HERE]

Box TS.7: Climate Geoengineering Methods

Geoengineering is defined as the deliberate large-scale intervention in the Earth system to counter undesirable impacts of climate change on the planet. Carbon Dioxide Reduction (CDR) aims to slow or perhaps reverse projected increases in the future atmospheric CO₂ concentrations, accelerating the natural removal of atmospheric CO₂ and increasing the storage of carbon in land, ocean and geological reservoirs. Solar Radiation Management (SRM) aims to counter the warming associated with increasing greenhouse gas concentrations by reducing the amount of sunlight absorbed by the climate system. A related technique seeks to deliberately decrease the greenhouse effect in the climate system by altering high-level cloudiness. {6.5, 7.7; FAQ 7.3}

CDR methods could provide mitigation of climate change if CO₂ can be reduced, but there are uncertainties, side effects and risks, and implementation would depend on technological maturity along with economic, political and ethical considerations. CDR would need to be deployed at large-scale and over at least one century to be able to significantly reduce CO₂ concentrations. There are biogeochemical, and currently technical limitations that make it difficult to provide quantitative estimates of the potential for CDR. CO₂ removals from the atmosphere by CDR would be partially offset by outgassing of CO₂ previously stored in ocean and terrestrial carbon reservoirs. Some of the climatic and environmental side effects of CDR methods are associated with altered surface albedo from afforestation, ocean de-oxygenation from ocean fertilization, and enhanced N₂O emissions. Land-based CDR methods would probably face competing demands for land. The level of confidence on the effectiveness of CDR methods and their side effects on carbon and other biogeochemical cycles is *low*. {6.5; Box 6.2; FAQ 7.3}

Solar Radiation Management (SRM) remains unimplemented and untested but, if realisable, could offset a global temperature rise and some of its effects. There is *medium confidence* that SRM through stratospheric aerosol injection is scalable to counter the radiative forcing (RF) and some of the climate effects expected from a twofold increase in CO₂ concentration. There is no consensus on whether a similarly large RF could be achieved from cloud brightening SRM due to insufficient understanding of aerosol-cloud interactions. It does not appear that land albedo change SRM could produce a large RF. Limited literature on other SRM methods precludes their assessment. {7.7.2, 7.7.3}

Numerous side effects, risks and shortcomings from SRM have been identified. SRM would produce an inexact compensation for the RF by greenhouse gases. Several lines of evidence indicate that SRM would

produce a small but significant decrease in global precipitation (with larger differences on regional scales) if the global surface temperature were maintained. Another side effect that is relatively well characterised is the likelihood of modest polar stratospheric ozone depletion associated with stratospheric aerosol SRM. There could also be other as yet unanticipated consequences {7.6.3, 7.7.3, 7.7}

As long as greenhouse gas concentrations continued to increase, the SRM would require commensurate increase, exacerbating side effects. Additionally, scaling SRM to substantial levels would carry the risk that if the SRM were terminated for any reason, there is *high confidence* that surface temperatures would increase rapidly (within a decade or two) to values consistent with the greenhouse gas forcing, which would stress systems sensitive to the rate of climate change. Finally, SRM would not compensate for ocean acidification from increasing CO₂. {7.7.3, 7.7.4}

[END BOX TS.7 HERE]

TS.5.7 Long-Term Projections of Sea Level Change

TS.5.7.1 Projections of Global Mean Sea Level Change for the 21st Century

Global mean sea level rise for 2081–2100 (relative to 1986–2005) for the RCPs will *likely* be in the 5–95% ranges derived from CMIP5 climate projections in combination with process-based models of glacier and ice-sheet SMB, with possible ice-sheet dynamical changes assessed from the published literature. These *likely* ranges are 0.26 to 0.54 m (RCP2.6), 0.32 to 0.62 m (RCP4.5), 0.33 to 0.62 m (RCP6.0), 0.45 to 0.81 (RCP8.5) m (*medium confidence*) (see Table TS.1 and Figure TS.21). For RCP8.5 the range at 2100 is 0.53 to 0.97 m. The central projections for global mean sea level rise in all scenarios lie within a range of 0.05 m until the middle of the century, when they begin to diverge; by the end of the century, they have a spread of about 0.3 m. Although RCP4.5 and RCP6.0 are very similar at the end of the century, RCP4.5 has a greater rate of rise earlier in the century than RCP6.0. GMSL rise depends on the pathway of CO₂ emissions, not only on the cumulative total; reducing emissions earlier rather than later, for the same cumulative total, leads to a larger mitigation of sea level rise. {12.4.1, 13.4.1, 13.5.1; Table 13.5}

[INSERT FIGURE TS.21 HERE]

Figure TS.21: Projections from process-based models with *likely* ranges and median values for global mean sea level rise and its contributions in 2081–2100 relative to 1986–2005 for the four RCP scenarios and scenario SRES A1B used in the AR4. The contributions from ice sheets include the contributions from ice-sheet rapid dynamical change, which are also shown separately. The contributions from ice-sheet rapid dynamics and anthropogenic land water storage are treated as having uniform probability distributions, and as independent of scenario (except that a higher rate of change is used for Greenland ice-sheet outflow under RCP8.5). This treatment does not imply that the contributions concerned will not depend on the scenario followed, only that the current state of knowledge does not permit a quantitative assessment of the dependence. See discussion in Sections 13.5.1 and 13.5.3 and Supplementary Material for methods. Based on current understanding, only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause global mean sea level to rise substantially above the *likely* range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter during the 21st century. {Figure 13.10}

[INSERT FIGURE TS.22 HERE]

Figure TS.22: Projections from process-based models of global mean sea level rise relative to 1986–2005 for the four emissions scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5. The solid lines show the median projections, the dashed lines show the *likely* ranges for RCP4.5 and RCP6.0, and the shading the *likely* ranges for RCP2.6 and RCP8.5. The time means for 2081–2100 are shown as coloured vertical bars. See Sections 13.5.1 and 13.5.3 and Supplementary Material for methods. Based on current understanding, only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause global mean sea level to rise substantially above the *likely range* during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter during the 21st century. {Table 13.5; Figures 13.10, 13.11}

Confidence in the projected *likely* ranges comes from the consistency of process-based models with observations and physical understanding. The basis for higher projections has been considered and it has been concluded that there is currently insufficient evidence to evaluate the probability of specific levels above the *likely* range. Based on current understanding, only the collapse of marine-based sectors of the Antarctic ice sheet, if initiated, could cause GMSL to rise substantially above the *likely* range during the 21st

century. There is a lack of consensus on the probability for such a collapse, and the potential additional contribution to GMSL rise cannot be precisely quantified, but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise during the 21st century. {13.5.1, 13.5.3}

Under all the RCP scenarios, the time-mean rate of global mean sea level rise during the 21st century is *very likely* to exceed the rate observed during 1971–2010. In the projections, the rate of rise initially increases. In RCP2.6 it becomes roughly constant (central projection $\sim 4.5 \text{ mm yr}^{-1}$) before the middle of the century, and subsequently declines slightly. The rate of rise becomes roughly constant in RCP4.5 and RCP6.0 by the end of the century, whereas acceleration continues throughout the century in RCP8.5 (reaching 11 [7 to 15] mm yr^{-1} during 2081–2100). {13.5.1; Table 13.5}

In all RCP scenarios, thermal expansion is the largest contribution, accounting for about 30–55% of the total. Glaciers are the next largest. By 2100, 15–55% of the present glacier volume is projected to be eliminated under RCP2.6, and 35 to 85% under RCP8.5 (*medium confidence*). The increase in surface melting in Greenland is projected to exceed the increase in accumulation, and there is *high confidence* that the surface mass balance changes on the Greenland ice sheet will make a positive contribution to sea level rise over the 21st century. On the Antarctic ice sheet, surface melting is projected to remain small, while there is *medium confidence* that snowfall will increase (Figure TS.21). {13.3.3, 13.4.3, 13.4.4, 13.5.1; Table 13.5}

There is *medium confidence* in the ability to model future rapid changes in ice-sheet dynamics on decadal timescales. At the time of the AR4, scientific understanding was not sufficient to allow an assessment of the possibility of such changes. Since the publication of the AR4, there has been substantial progress in understanding the relevant processes as well as in developing new ice-sheet models that are capable of simulating them. However, the published literature as yet provides only a partially sufficient basis for making projections related to particular scenarios. In our projections of GMSL rise by 2081–2100, the *likely* range from rapid changes in ice outflow is 0.03 to 0.20 m from the two ice sheets combined, and its inclusion is the most important reason why the projections are greater than those given in the AR4. {13.1.5, 13.5.1, 13.5.3}

Semi-empirical models are designed to reproduce the observed sea level record over their period of calibration, but do not attribute sea level rise to its individual physical components. For RCPs, some semi-empirical models project a range that overlaps the process-based *likely* range while others project a median and 95-percentile that are about twice as large as the process-based models. In nearly every case, the semi-empirical model 95-percentile is higher than the process-based *likely* range. For 2081–2100 (relative to 1986–2005) under RCP4.5, semi-empirical models give median projections in the range 0.56 to 0.97 m, and their 95-percentiles extend to about 1.2 m. This difference implies either that there is some contribution which is presently unidentified or underestimated by process-based models, or that the projections of semi-empirical models are overestimates. Making projections with a semi-empirical model assumes that sea level change in the future will have the same relationship as it has had in the past to radiative forcing or global mean temperature change. This may not hold if potentially non-linear physical processes do not scale in the future in ways which can be calibrated from the past. There is no consensus in the scientific community about the reliability of SEM projections, and *confidence* in them is assessed to be *low*. {13.5.2, 13.5.3}

TS.5.7.2 Projections of Global Mean Sea Level Change Beyond 2100

It is *virtually certain* that global mean sea level rise will continue beyond 2100. The few available model results indicate global mean sea level rise by 2300 to be less than 1 m for greenhouse gas concentrations that peak and decline and do not exceed 500 ppm CO_2 -equivalent but 1 to 3 m for concentrations above 700 ppm CO_2 -equivalent (*medium confidence*). Sea-level rise of 1 to 3 m per degree of warming is expected if the warming is sustained for several millennia (*low confidence*). {13.5.4}

Sea level rise due to ocean thermal expansion will continue for centuries to millennia. The amount of ocean thermal expansion increases with global warming (models give a range of 0.2 to 0.6 $\text{m } ^\circ\text{C}^{-1}$). The glacier contribution decreases over time as their volume (currently $\sim 0.43 \text{ m}$ sea level equivalent) decreases. In Antarctica, beyond 2100 and with higher greenhouse gas scenarios, the increase in surface melting could exceed the increase in accumulation. {13.5.2, 13.5.4}

The available evidence indicates that global warming greater than a certain threshold would lead to the near-complete loss of the Greenland Ice Sheet over a millennium or more, causing a global mean sea level rise of about 7 m. Studies with fixed present-day ice sheet topography indicate the threshold is greater than 2°C but less than 4°C of global mean surface temperature rise with respect to preindustrial. Taking into account the increased vulnerability of the ice sheet as the surface elevation decreases due to the loss of ice, a study with a dynamical ice sheet suggests the threshold could be as low as 1°C. Considering the present state of scientific uncertainty, a *likely* range cannot be quantified. The complete loss of the ice sheet is not inevitable because this would take a millennium or more; if temperatures decline before the ice sheet is eliminated, the ice sheet might regrow. However, some part of the mass loss might be irreversible, depending on the duration and degree of exceedance of the threshold, because the ice sheet may have multiple steady states, due to its interaction with its regional climate. {13.4.3, 13.5.4}

Currently available information indicates that the dynamical contribution of the ice sheets will continue beyond 2100, but *confidence* in projections is *low*. In Greenland, ice outflow induced from interaction with the ocean is self-limiting as the ice-sheet margin retreats inland from the coast. By contrast, the bedrock topography of Antarctica is such that there may be enhanced rates of mass loss as the ice retreats. About 3.3 m of equivalent global sea level of the West Antarctic ice sheet is grounded on areas with downward sloping bedrock, which may be subject to potential ice loss via the marine ice-sheet instability. Due to relatively weak snowfall on Antarctica and the slow ice motion in its interior, it can be expected that the West Antarctic ice sheet would take at least several thousand years to regrow if it was eliminated by dynamic ice discharge. Consequently any significant ice loss from West Antarctic that occurs within the next century will be irreversible on a multi-centennial to millennial time scale. {13.4.4, 13.5.4}

TS.5.7.3 Projections of Regional Sea Level Change

Regional sea level will change due to dynamical ocean circulation changes, changes in the heat content of the ocean, mass redistribution in the entire Earth system, and changes in atmospheric pressure. Ocean dynamical change results from changes in wind and buoyancy forcing (heat and freshwater), associated changes in the circulation, and redistribution of heat and freshwater. Over timescales longer than a few days, regional sea level also adjusts nearly isostatically to regional changes in sea level atmospheric pressure relative to its mean over the ocean. Ice-sheet mass loss (both contemporary and past), glacier mass loss and changes in terrestrial hydrology cause water mass redistribution among the cryosphere, the land and the oceans, giving rise to distinctive regional changes in the solid Earth, Earth rotation and the gravity field. In some coastal locations, changes in the hydrological cycle, ground subsidence associated with anthropogenic activity, tectonic processes, and coastal processes can dominate the relative sea level change, i.e., the change in sea surface height relative to the land. {13.1.3, 13.6.2, 13.6.3, 13.6.4}

By the end of the 21st century, sea level change will have a strong regional pattern, which will dominate over variability, with many regions *likely* experiencing substantial deviations from the global mean change (Figure TS.23). It is *very likely* that over about 95% of the ocean will experience regional sea level rise, while most regions experiencing a sea level fall are located near current and former glaciers and ice sheets. Local sea level changes deviate more than 10% and 25% from the global mean projection for as much as 30% and 9% of the ocean area, respectively, indicating that spatial variations can be very large. Regional changes in sea level reach values of up to 30% above the global mean value in the Southern Ocean and around North America, between 10% to 20% in equatorial regions, and up to 50% below the global mean in the Arctic region and some regions near Antarctica. About 70% of the coastlines worldwide are projected to experience a sea level change within 20% of the global mean sea level change. Over decadal periods, the rates of regional sea level change as a result of climate variability can differ from the global average rate by more than 100%. {13.6.5}

[INSERT FIGURE TS.23 HERE]

Figure TS.23: Ensemble mean net regional sea level change (m) evaluated from 21 CMIP5 models for the RCP scenarios (a) 2.6, (b) 4.5, (c) 6.0 and (d) 8.5 between 1986–2005 and 2081–2100. Each map includes effects of atmospheric loading, plus land-ice, GIA and terrestrial water sources. {Figure 13.20}

TS.5.7.4 Projections of Change in Sea Level Extremes and Waves During the 21st Century

It is *very likely* that there will be a significant increase in the occurrence of future sea level extremes (see also TFE.9, Table 1). This increase will primarily be the result of an increase in mean sea level (*high confidence*), with extreme return periods decreasing by at least an order of magnitude in some regions by the end of the 21st century. There is *low confidence* in region-specific projections of storminess and associated storm surges. {13.7.2}

It is *likely (medium confidence)* that annual mean significant wave heights will increase in the Southern Ocean as a result of enhanced wind speeds. Southern-Ocean generated swells are *likely* to affect heights, periods, and directions of waves in adjacent basins. It is *very likely* that wave heights and the duration of the wave season will increase in the Arctic Ocean as a result of reduced sea-ice extent. In general, there is *low confidence* in region-specific projections due to the *low confidence* in tropical and extratropical storm projections, and to the challenge of down-scaling future wind states from coarse resolution climate models. {13.7.3}

TS.5.8 Climate Phenomena and Regional Climate Change

This section assesses projected changes over the 21st century in large-scale climate phenomena that affect regional climate (Table TS.2). Some of these phenomena are defined by climatology (e.g., monsoons), and some by interannual variability (e.g., El Niño), the latter affecting climate extremes such as floods, droughts and heat waves. Changes in statistics of weather phenomena such as tropical cyclones and extratropical storms are also summarized here. {14.8}

[INSERT TABLE TS.2 HERE]

Table TS.2: Overview of projected regional changes and their relation to major climate phenomena. A phenomenon is considered relevant when there is both sufficient confidence that it has an influence on the given region, and when there is sufficient confidence that the phenomenon will change, particularly under the RCP4.5 or higher end scenarios. See Section 14.8 and Table 14.2 for full assessment of the confidence in these changes, and their relevance for regional climate. {14.8; Table 14.2}

TS.5.8.1 Monsoon Systems

Global measures of monsoon by the area and summer precipitation are *likely* to increase in the 21st century, while the monsoon circulation weakens. Monsoon onset dates are *likely* to become earlier or not to change much while monsoon withdrawal dates are *very likely* to delay, resulting in a lengthening of the monsoon season (Figure TS.24). The increase in seasonal-mean precipitation is pronounced in the East and South Asian summer monsoons while the change in other monsoon regions is subject to larger uncertainties. {14.2.1}

[INSERT FIGURE TS.24 HERE]

Figure TS.24: Future change in monsoon statistics between the present-day (1986–2005) and the future (2080–2099) based on CMIP5 ensemble from RCP2.6 (dark blue; 19 models), RCP4.5 (blue; 24), RCP6.0 (yellow; 14), and RCP8.5 (red; 24) simulations. (a) GLOBAL: Global monsoon area (GMA), global monsoon intensity (GMI), standard deviation of inter-annual variability in seasonal precipitation (Psd), seasonal maximum 5-day precipitation total (R5d), and monsoon season duration (DUR). Regional land monsoon domains determined by 24 multi-model mean precipitation in the present-day. (b)-(h) Future change in regional land monsoon statistics: seasonal average precipitation (Pav), Psd, R5d, and DUR in (b) North America (NAMS), (c) North Africa (NAF), (d) South Asia (SAS), (e) East Asia (EAS), (f) Australia-Maritime continent (AUSMC), (g) South Africa (SAF), and (h) South America (SAMS). Units are % except for DUR (days). Box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles. All the indices are calculated for the summer season (May–September for the Northern, and November–March for the Southern Hemisphere) over each model's monsoon domains. {Figures 14.3, 14.4, 14.6, 14.7}

There is *medium confidence* that monsoon-related interannual rainfall variability will increase in the future. Future increase in precipitation extremes related to the monsoon is *very likely* in South America, Africa, East Asia, South Asia, Southeast Asia and Australia. {14.2.1, 14.8.5, 14.8.7, 14.8.9, 14.8.11, 14.8.12, 14.8.13}

There is *medium confidence* that overall precipitation associated with the Asian-Australian monsoon will increase but with a north-south asymmetry: Indian monsoon rainfall is projected to increase, while projected changes in the Australian summer monsoon rainfall are small. There is *medium confidence* in that the Indian summer monsoon circulation weakens, but this is compensated by increased atmospheric moisture content,

leading to more rainfall. For the East Asian summer monsoon, both monsoon circulation and rainfall are projected to increase. {14.2.2, 14.8.9, 14.8.11, 14.8.13}

There is *low confidence* in projections of the North American and South American monsoon precipitation changes, but *medium confidence* that the North American monsoon will arrive and persist later in the annual cycle, and *high confidence* in expansion of South American Monsoon area. {14.2.3, 14.8.3, 14.8.4; 14.8.5}

There is *low confidence* in projections of a small delay in the West African rainy season, with an intensification of late-season rains. The limited skills of model simulations for the region suggest *low confidence* in the projections. {14.2.4, 14.8.7}

TS.5.8.2 Tropical Phenomena

It is *virtually certain* that precipitation change will vary in space, increasing in some regions and decreasing in some others. The spatial distribution of tropical rainfall changes is *likely* shaped by the current climatology and ocean warming pattern. The first effect is to increase rainfall near the currently rainy regions, and the second effect increases rainfall where the ocean warming exceeds the tropical mean. There is *medium confidence* that tropical rainfall projections are more reliable for the seasonal than annual-mean changes. {7.6.2, 12.4.5, 14.3.1}

There is *medium confidence* in future increase in seasonal-mean precipitation on the equatorial flank of the Inter-Tropical Convergence Zone and a decrease in precipitation in the subtropics including parts of North and Central Americas, the Caribbean, South America, Africa and West Asia. There is *medium confidence* that the interannual occurrence of zonally-oriented South Pacific Convergence Zone events will increase, leading possibly to more frequent droughts in the southwest Pacific. There is *medium confidence* that the South Atlantic Convergence Zone will shift southwards, leading to a precipitation increase over southeastern South America and a reduction immediately north of the convergence zone. {14.3.1, 14.8.3, 14.8.4, 14.8.5, 14.8.7, 14.8.11, 14.8.14}

The tropical Indian Ocean is *likely* to feature a zonal pattern with reduced warming and decreased rainfall in the east (including Indonesia), and enhanced warming and increased rainfall in the west (including East Africa). The Indian Ocean dipole mode of interannual variability is *very likely* to remain active, affecting climate extremes in East Africa, Indonesia, and Australia. {14.3.3, 14.8.7, 14.8.12}

There is *low confidence* in the projections for the tropical Atlantic - both for the mean and interannual modes, because of large errors in model simulations in the region. Future projections in Atlantic hurricanes, tropical South American and West African precipitation are therefore of *low confidence*. {14.3.4, 14.6.1, 14.8.5 and 14.8.7}

There is *low confidence* in projections of future changes in the Madden-Julian Oscillation due to the poor skill in model simulations of this intraseasonal phenomenon and the sensitivity to ocean warming patterns. Future projections of regional climate extremes in West Asia, Southeast Asia and Australia are therefore of *low confidence*. {9.5.2, 14.3.4, 14.8.10, 14.8.12, 14.8.13}

TS.5.8.3 El Niño-Southern Oscillation

El Niño-Southern Oscillation *very likely* remains as a dominant mode of interannual variability in the future and regional rainfall variability it induces *likely* intensifies. Natural modulations of the variance and spatial pattern of El Niño-Southern Oscillation are so large that confidence in any projected change for the 21st century remains *low*. The projected change in El Niño amplitude is small for both RCP4.5 and RCP8.5 compared to the spread of the change among models (Figure TS.25). Over the North Pacific and North America, patterns of temperature and precipitation anomalies related to El Niño and La Niña (teleconnections) are *likely* to move eastwards in the future, while confidence is *low* in changes in climate impacts on other regions including Central and South Americas, the Caribbean, Africa, most of Asia, Australia and most Pacific Islands. {14.4, 14.8.3, 14.8.4, 14.8.5, 14.8.7, 14.8.9, 14.8.11, 14.8.12, 14.8.13, 14.8.14}

[INSERT FIGURE TS.25 HERE]

Figure TS.25: Standard deviation in CMIP5 multi-model ensembles of sea surface temperature variability over the eastern equatorial Pacific Ocean (Nino3 region: 5°S–5°N, 150°W–90°W), a measure of El Niño amplitude, for the pre-industrial (PI) control and 20th century (20C) simulations, and 21st century projections using RCP4.5 and RCP8.5. Open circles indicate multi-model ensemble means, and the red cross symbol is the observed standard deviation for the 20th century. Box-whisker plots show the 16th, 25th, 50th, 75th, and 84th percentiles. {Figure 14.14}

TS.5.8.4 Cyclones

Projections for the 21st century indicate that it is *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged, concurrent with a *likely* increase in both global mean tropical cyclone maximum wind speed and rain rates (Figure TS.26). The influence of future climate change on tropical cyclones is *likely* to vary by region, but there is *low confidence* in region-specific projections. The frequency of the most intense storms will *more likely than not* increase substantially in some basins. More extreme precipitation near the centers of tropical cyclones making landfall are *likely* in North and Central America, East Africa, West, East, South and Southeast Asia as well as in Australia and many Pacific islands. {14.6.1, 14.8.3, 14.8.4, 14.8.7, 14.8.9, 14.8.10, 14.8.11, 14.8.12, 14.8.13, 14.8.14}

[INSERT FIGURE TS.26 HERE]

Figure TS.26: Projected changes in tropical cyclone statistics. All values represent expected percent change in the average over period 2081–2100 relative to 2000–2019, under an A1B-like scenario, based on expert judgment after subjective normalisation of the model projections. Four metrics were considered: the percent change in I) the total annual frequency of tropical storms, II) the annual frequency of Category 4 and 5 storms, III) the mean Lifetime Maximum Intensity (LMI; the maximum intensity achieved during a storm's lifetime), and IV) the precipitation rate within 200 km of storm center at the time of LMI. For each metric plotted, the solid blue line is the best guess of the expected percent change, and the coloured bar provides the 67% (likely) confidence interval for this value (note that this interval ranges across –100% to +200% for the annual frequency of Category 4 and 5 storms in the North Atlantic). Where a metric is not plotted, there is insufficient data (denoted “X”) available to complete an assessment. A randomly drawn (and coloured) selection of historical storm tracks are underlaid to identify regions of tropical cyclone activity. See Section 14.6.1 for details. {14.6.1}

The global number of extra-tropical cyclones is *unlikely* to decrease by more than a few percent and future changes in storms are *likely* to be small compared to natural interannual variability and substantial variations between models. A small poleward shift is *likely* in the Southern Hemisphere storm track but the magnitude of this change is model-dependent. It is *unlikely* that the response of the North Atlantic storm track in climate projections is a simple poleward shift. There is *medium confidence* in a projected poleward shift in the North Pacific storm track. There is *low confidence* in the impact of storm track changes on regional climate at the surface. More precipitation in extra-tropical cyclones leads to a winter precipitation increase in Arctic, Northern Europe, North America, and the mid-high latitude Southern Hemisphere. {11.3.2, 12.4.4, 14.6.2, 14.8.2, 14.8.3, 14.8.5, 14.8.6, 14.8.13, 14.8.15}

TS.5.8.5 Annular and Dipolar Modes of Variability

Future boreal wintertime North Atlantic Oscillation is *very likely* to exhibit large natural variations as observed in the past. The North Atlantic Oscillation is *likely* to become slightly more positive (on average), with some, but not very well documented implications for winter conditions in the Arctic, North America and Eurasia. The austral summer/autumn positive trend in Southern Annular Mode is *likely* to weaken considerably as stratospheric ozone recovers through the mid-21st century with some, but not very well documented, implications for South America, Africa, Australia, New Zealand and Antarctica. {11.3.2, 14.5.2 and 14.8.5, 14.8.7, 14.8.13, 14.8.15}

TS.5.8.6 Additional Phenomena

It is *unlikely* that the Atlantic Multi-Decadal Oscillation will change its behaviour as the mean climate changes. However, natural fluctuations in the Atlantic Multi-Decadal Oscillation over the coming few decades are *likely* to influence regional climates at least as strongly as will human-induced changes with implications for Atlantic major hurricane frequency, the West African monsoon, North American and European summer conditions. {14.2.4, 14.5.1, 14.6.1, 14.7.6, 14.8.2, 14.8.3, 14.8.6, 14.8.8}

There is *medium confidence* that the frequency of Northern and Southern Hemisphere blocking will not increase, but *confidence is low* in the trends in blocking intensity and persistence. {Box 14.2}

TFE.9: Climate Extremes

Assessing changes in climate extremes poses unique challenges, not just because of the intrinsically rare nature of these events, but because they invariably happen in conjunction with disruptive conditions. They are strongly influenced by both small and large-scale weather patterns, modes of variability, thermodynamic processes, land-atmosphere feedbacks and antecedent conditions. Much progress has been made since AR4 including the comprehensive assessment of extremes undertaken by the IPCC Special Report on Managing the Risk of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX) but also due to the amount of observational evidence available, improvements in our understanding and the ability of models to simulate extremes. {1.3.3, 2.6, 7.6, 9.5.4}

For some climate extremes such as droughts, floods and heat waves, several factors need to be combined to produce an extreme event. Analyses of rarer extremes such as 1-in-20 to 1-in-100 year events using Extreme Value Theory are making their way into a growing body of literature. Other recent advances concern the notion of “fraction of attributable risk” that aims to link a particular extreme event to specific causal relationships. {1.3.3, 2.6.1, 2.6.2, 10.6.2, 12.4.3; Box 2.4}

TFE.9, Table 1 indicates the changes that have been observed in a range of weather and climate extremes over the last 50 years, the assessment of the human contribution to those changes, and how those extremes are expected to change in the future. The table also compares the current assessment with that of the AR4 and the SREX where applicable. {2.6, 3.7, 10.6, 11.3, 12.4, 14.6}

[INSERT TFE.9, TABLE 1 HERE]

TFE.9, Table 1: Extreme weather and climate events: Global-scale assessment of recent observed changes, human contribution to the changes, and projected further changes for the early (2016–2035) and late (2081–2100) 21st century. Bold indicates where the AR5 (black) provides a revised* global-scale assessment from the SREX (blue) or AR4 (red). Projections for early 21st century were not provided in previous assessment reports. Projections in the AR5 are relative to the reference period of 1986–2005, and use the new RCP scenarios.

Temperature Extremes, Heat Waves and Warm Spells

It is *very likely* that both maximum and minimum temperature extremes have warmed over most land areas since the mid-20th century. These changes are well simulated by current climate models, and it is *very likely* that anthropogenic forcing has affected the frequency of these extremes and *virtually certain* that further changes will occur. This supports AR4 and SREX conclusions although with greater confidence in the anthropogenic forcing component. {2.6.1, 9.5.4, 10.6.1, 12.4.3}

For land areas with sufficient data there has been an overall increase in the number of warm days and nights. Similar decreases are seen in the number of cold days and nights. It is *very likely* that increases in unusually warm days and nights and/or reductions in unusually cold days and nights including frosts have occurred over this period across most continents. Warm spells or heat waves containing consecutive extremely hot days or nights are often associated with quasi-stationary anticyclonic circulation anomalies and are also affected by pre-existing soil conditions and the persistence of soil moisture anomalies that can amplify or dampen heat waves particularly in moisture-limited regions. Most global land areas, with a few exceptions, have experienced more heat waves since the middle of the 20th century. Several studies suggest that increases in mean temperature account for most of the changes in heat wave frequency, however, heat wave intensity/amplitude is highly sensitive to changes in temperature variability and the shape of the temperature distribution and heat wave definition also plays a role. While in some regions instrumental periods prior to the 1950s had more heat waves (e.g., USA), for other regions such as Europe, an increase in heat wave frequency in the period since the 1950s stands out in long historical temperature series. {2.6, 2.6.1, 5.5.1; Box 2.4; Table 2.12, 2.13; FAQ 2.2}

The observed features of temperature extremes and heat waves are well simulated by climate models and are similar to the spread amongst observationally-based estimates in most regions. Regional downscaling now

offers credible information on the spatial scales required for assessing extremes and improvements in the simulation of the El Niño-Southern Oscillation from CMIP3 to CMIP5 and other large-scale phenomenon is crucial. However simulated changes in frequency and intensity of extreme events is limited by observed data availability and quality issues and by the ability of models to reliably simulate certain feedbacks and mean changes in key features of circulation such as blocking. {2.6, 2.7, 9.4, 9.5.3, 9.5.4, 9.6, 9.6.1, 10.3, 10.6, 14.4; Box 14.2}

Since AR4, the understanding of mechanisms and feedbacks leading to changes in extremes has improved. There continues to be strengthening evidence for a human influence on the observed frequency of extreme temperatures and heat waves in some regions. Near-term (decadal) projections suggest *likely* increases in temperature extremes but with little distinguishable separation between emissions scenarios (TFE.9, Figure 1). Changes may proceed at a different rate than the mean warming however, with several studies showing that projected European high-percentile summer temperatures will warm faster than mean temperatures. Future changes associated with the warming of temperature extremes in the long-term are *virtually certain* and scale with the strength of emissions scenario i.e., greater anthropogenic emissions correspond to greater warming of extremes (TFE.9, Figure 1). For high emissions scenarios, it is *likely* that, in most land regions, a current one-in-20 year maximum temperature event will at least double in frequency but in many regions will become an annual or a one-in-two year event by the end of the 21st century. The magnitude of both high and low temperature extremes is expected to increase at least at the same rate as the mean, but with 20-year return values for low temperature events projected to increase at a rate greater than winter mean temperatures in most regions. {10.6.1, 11.3.2, 12.4.3}

[INSERT TFE.9, FIGURE 1 HERE]

TFE.9, Figure 1: Global projections of the occurrence of (a) cold days (TN10p)- percentage of days annually with daily maximum surface air temperature (Tmax) below the 10th percentile of Tmax for 1961 to 1990, (b) wettest consecutive 5 days (RX5day) - percentage change in annual maximum consecutive 5-day precipitation totals, (c) warm days (TX90p)-percentage of days annually with daily maximum surface air temperature (Tmax) exceeding the 90th percentile of Tmax for 1961 to 1990 and (d) very wet day precipitation (R95p) - percentage change relative to 1986–2005 of annual precipitation from days >95th percentile. Results are shown from CMIP5 for the RCP2.6, RCP4.5 and RCP8.5 scenarios. Solid lines indicate the ensemble median and shading indicates the interquartile spread between individual projections (25th and 75th percentiles). Maps show (e) the change from 1986–2005 to 2081–2100 in twenty year return values (RV) of daily maximum temperatures, TXx, and (f) the 2081–2100 return period (RP) for rare daily precipitation values, RX1day, that have a 20 year return period during 1986–2005. Both maps are based on the CMIP5 RCP8.5 scenario. See Box 2.4, Table 1 for index definitions. {Figures 11.17, 12.13, 12.26}

Precipitation Extremes

It is *likely* that the number of heavy precipitation events over land has increased in more regions than it has decreased in since the mid-20th century, and there is *medium confidence* that anthropogenic forcing has contributed to this increase. {2.6.2, 10.6.1}

There has been substantial progress between CMIP3 and CMIP5 in the ability of models to simulate more realistic precipitation extremes. However, evidence suggests that the majority of models underestimate the sensitivity of extreme precipitation to temperature variability or trends especially in the tropics which implies that models may underestimate the projected increase in extreme precipitation in the future. While progress has been made in understanding the processes that drive extreme precipitation, challenges remain in quantifying cloud and convective effects in models for example. The complexity of land-surface and atmospheric processes limits confidence in regional projections of precipitation change, especially over land, although there is a component of a “wet-get-wetter” and “dry-get-drier” response over oceans at the large scale. Even so, there is *high confidence* that, as the climate warms, extreme precipitation rates (e.g., on daily timescales) will increase faster than the time average. Changes in local extremes on daily and sub-daily timescales are expected to increase by roughly 5 to 10% per °C of warming (*medium confidence*). {7.6, 9.5.4}

For the near- and long-term, CMIP5 projections confirm a clear tendency for increases in heavy precipitation events in the global mean seen in the AR4, but there are substantial variations across regions (TFE.9, Figure 1). Over most of the mid-latitude land-masses and over wet tropical regions, extreme precipitation will *very likely* be more intense and more frequent in a warmer world. {11.3.2, 12.4.5}

Floods and Droughts

There continues to be a lack of evidence and thus *low confidence* regarding the sign of trend in the magnitude and/or frequency of floods on a global scale over the instrumental record. There is *high confidence* that past floods larger than those recorded since 1900 have occurred during the past five centuries in northern and central Europe, western Mediterranean region, and eastern Asia. There is *medium confidence* that modern large floods are comparable to or surpass historical floods in magnitude and/or frequency in the Near East, India, and central North America. {2.6.2, 5.5.5}

Compelling arguments both for and against significant increases in the land area affected by drought and/or dryness since the mid-20th century have resulted in a *low confidence* assessment of observed and attributable large-scale trends. This is primarily due to a lack and quality of direct observations, dependencies of inferred trends on the index choice, geographical inconsistencies in the trends and difficulties in distinguishing decadal scale variability from long term trends. On millennial timescales, there is *high confidence* that proxy information provides evidence of droughts of greater magnitude and longer duration than observed during the 20th century in many regions. There is *medium confidence* that more megadroughts occurred in monsoon Asia and wetter conditions prevailed in arid Central Asia and the South American monsoon region during the Little Ice Age (1450 to 1850) compared to the Medieval Climate Anomaly (950 to 1250). {2.6.2, 5.5.4, 5.5.5, 10.6.1}

Under the RCP8.5 scenario, projections by the end of the century indicate an increased risk of drought is *likely (medium confidence)* in presently dry regions linked to regional to global-scale projected decreases in soil moisture. Soil moisture drying is most prominent in the Mediterranean, Southwest US, and southern Africa, consistent with projected changes in the Hadley circulation and increased surface temperatures, and surface drying in these regions is *likely (high confidence)* by the end of the century under the RCP8.5 scenario. {12.4.5}

Extreme Sea Level

It is *likely* that the magnitude of extreme high sea level events has increased since 1970 and that most of this rise can be explained by increases in mean sea level. When mean sea level changes is taken into account, changes in extreme high sea levels are reduced to less than 5 mm yr⁻¹ at 94% of tide gauges. In the future it is *very likely* that there will be a significant increase in the occurrence of sea level extremes and similarly to past observations, this increase will primarily be the result of an increase in mean sea level. {3.7.5, 13.7.2}

Tropical and Extratropical Cyclones

There is *low confidence* in long-term (centennial) changes in tropical cyclone activity, after accounting for past changes in observing capabilities. However over the satellite era, increases in the frequency and intensity of the strongest storms in the North Atlantic are robust (*very high confidence*). However, the cause of this increase is debated and there is *low confidence* in attribution of changes in tropical cyclone activity to human influence due to insufficient observational evidence, lack of physical understanding of the links between anthropogenic drivers of climate and tropical cyclone activity and the low level of agreement between studies as to the relative importance of internal variability, and anthropogenic and natural forcings. {2.6.3, 10.6.1, 14.6.1}

Some high-resolution atmospheric models have realistically simulated tracks and counts of tropical cyclones and models generally are able to capture the general characteristics of storm tracks and extratropical cyclones with evidence of improvement since the AR4. Storm track biases in the North Atlantic have improved slightly, but models still produce a storm track that is too zonal and underestimate cyclone intensity. {9.4.1, 9.4.5}

While projections indicate that it is *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged, concurrent with a *likely* increase in both global mean tropical cyclone maximum wind speed and rainfall rates, there is lower confidence in region-specific projections of frequency and intensity. However, due to improvements in model resolution and downscaling techniques, it is *more*

likely than not that the frequency of the most intense storms will increase substantially in some basins under projected 21st century warming (see Figure TS.26). {11.3.2, 14.6.1}

Research subsequent to the AR4 and SREX continues to support a *likely* poleward shift of storm tracks since the 1950s. However over the last century there is *low confidence* of a clear trend in storminess due to inconsistencies between studies or lack of long-term data in some parts of the world (particularly in the Southern Hemisphere). {2.6.4, 2.7.6}

Despite systematic biases in simulating storm tracks, most models and studies are in agreement that the global number of extra-tropical cyclones is *unlikely* to decrease by more than a few per cent. A small poleward shift is *likely* in the Southern Hemisphere storm track. It is *more likely than not (medium confidence)* for a projected poleward shift in the North Pacific storm track but it is *unlikely* that the response of the North Atlantic storm track is a simple poleward shift. There is *low confidence* in the magnitude of regional storm track changes, and the impact of such changes on regional surface climate. {14.6.2}

TS.6 Key Uncertainties

This final section of the Technical Summary provides the reader with a short overview of key uncertainties in the understanding of the climate system and the ability to project changes in response to anthropogenic influences. The overview is not comprehensive and does not describe in detail the basis of for these findings. These are found in the main body of this Technical Summary and in the underlying chapters to which each bullet points in the curly brackets.

TS.6.1 Key Uncertainties in Observation of Changes in the Climate System

- There is only *medium to low confidence* in the rate of change of tropospheric warming and its vertical structure. Estimates of tropospheric warming rates encompass surface temperature warming rate estimates. There is *low confidence* in the rate and vertical structure of the stratospheric cooling. {2.4.4}
- *Confidence* in global precipitation change over land is *low* prior to 1950 and *medium* afterwards because of data incompleteness. {2.5.1}
- Substantial ambiguity and therefore *low confidence* remains in the observations of global-scale cloud variability and trends. {2.5.7}
- There is *low confidence* in an observed global-scale trend in drought or dryness (lack of rainfall), due to lack of direct observations, methodological uncertainties and choice and geographical inconsistencies in the trends. {2.6.2}
- There is *low confidence* that any reported long-term (centennial) changes in tropical cyclone characteristics are robust, after accounting for past changes in observing capabilities. {2.6.3}
- Robust conclusions on long-term changes in large-scale atmospheric circulation are presently not possible because of large variability on interannual to decadal time scales and remaining differences between data sets. {2.7}
- Different global estimates of sub-surface ocean temperatures have variations at different times and for different periods, suggesting that sub-decadal variability in the temperature and upper heat content (0–700 m) is still poorly characterized in the historical record. {3.2}
- Below ocean depths of 700 m the sampling in space and time is too sparse to produce annual global ocean temperature and heat content estimates prior to 2005. {3.2.4}
- Observational coverage of the ocean deeper than 2000 m is still limited and hampers more robust estimates of changes in global ocean heat content and carbon content. This also limits the quantification of the contribution of deep ocean warming to sea level rise. {3.2, 3.7, 3.8; Box 3.1}

- The number of continuous observational time series measuring the strength of climate relevant ocean circulation features (e.g., the meridional overturning circulation) is limited and the existing time series are still too short to assess decadal and longer trends. {3.6}.
- In Antarctica, available data are inadequate to assess the status of change of many characteristics of sea ice (e.g., thickness and volume). {4.2.3}
- On a global scale the mass loss from melting at calving fronts and iceberg calving are not yet comprehensively assessed. The largest uncertainty in estimated mass loss from glaciers comes from the Antarctic, and the observational record of ice-ocean interactions around both ice sheets remains poor. {4.3.3, 4.4}

TS.6.2 Key Uncertainties in Drivers of Climate Change

- Uncertainties in aerosol-cloud interactions and the associated radiative forcing remain large. As a result, uncertainties in aerosol forcing remain the dominant contributor to the overall uncertainty in net anthropogenic forcing, despite a better understanding of some of the relevant atmospheric processes and the availability of global satellite monitoring. {2.2, 7.4, 7.5, 8.5}
- The cloud feedback is *likely* positive but its quantification remains difficult. {7.2}
- Paleoclimate reconstructions and Earth System Models indicate that there is a positive feedback between climate and the carbon cycle, but confidence remains *low* in the strength of this feedback, particularly for the land. {6.4}

TS.6.3 Key Uncertainties in Understanding the Climate System and its Recent Changes

- The simulation of clouds has shown modest improvement since AR4, however it remains challenging. {7.2, 9.2.1, 9.4.1, 9.7.2}
- Observational uncertainties for climate variables other than temperature, uncertainties in forcings such as aerosols, and limits in process understanding continue to hamper attribution of changes in many aspects of the climate system. {10.1, 10.3, 10.7}
- Changes in the water cycle remain less reliably modelled in both their changes and their internal variability, limiting confidence in attribution assessments. Observational uncertainties and the large effect of internal variability on observed precipitation also precludes a more confident assessment of the causes of precipitation changes. {2.5.1, 2.5.4, 10.3.2}
- Modelling uncertainties related to model resolution and incorporation of relevant processes become more important at regional scales, and the effects of internal variability become more significant. Therefore, challenges persist in attributing observed change to external forcing at regional scales. {2.4.1, 10.3.1}
- The ability to simulate changes in frequency and intensity of extreme events is limited by the ability of models to reliably simulate mean changes in key features. {10.6.1}
- In some aspects of the climate system, including changes in drought, changes in tropical cyclone activity, Antarctic warming, Antarctic sea ice extent, and Antarctic mass balance *confidence* in attribution to human influence remains *low* due to modelling uncertainties and low agreement between scientific studies. {10.3.1, 10.5.2, 10.6.1}

TS.6.4 Key Uncertainties in Projections of Global and Regional Climate Change

- Based on model results there is *medium confidence* in the predictability of yearly to decadal averages of temperature both for the global average and for some geographical regions. Multi-model results for precipitation indicate a generally low predictability. Short-term climate projection is also limited by the *low confidence* in projections of natural forcing. {11.1, 11.2.2, 11.3.1; Box 11.1}
- There is *low confidence* in projections for a poleward shift of the position and strength of Northern Hemisphere storm tracks. {11.3.2, 12.4.4}
- There is generally *low confidence* in basin-scale projections of significant trends in tropical cyclone frequency and intensity in the 21st century. {11.3.2, 14.6.1}
- Projected changes in soil moisture and surface run off are not robust in many regions. {11.3.2, 12.4.5}
- Several components or phenomena in the climate system could potentially exhibit abrupt or nonlinear changes, but for many phenomena there is *low confidence* and little consensus on the likelihood of such events over the 21st century. {12.5.5}
- There is *low confidence* on magnitude of carbon losses through CO₂ or CH₄ emissions to the atmosphere from thawing permafrost. There is *limited confidence* in projected future methane emissions from natural sources due to changes in wetlands and gas hydrate release from the sea floor. {6.4.3}
- There is *medium confidence* in the projected contributions to sea level rise by models of ice sheet dynamics for the 21st century, and *low confidence* in their projections beyond 2100. {13.3.3}
- There is *low confidence* in semi-empirical model projections of global mean sea level rise, and no consensus in the scientific community about their reliability. {13.5.2, 13.5.3}
- There is *low confidence* in projections of many aspects of climate phenomena that influence regional climate change, including changes in amplitude and spatial pattern of modes of climate variability. {9.5.3, 14.2–14.7}

Tables

Table TS.1: Projected change in global mean surface air temperature and global mean sea level rise for the mid- and late 21st century. {12.4.1; Table 12.2, Table 13.5}

Variable	Scenario	2046–2065		2081–2100	
		mean	likely range ^c	mean	likely range ^c
Global Mean Surface Temperature Change (°C) ^a	RCP2.6	1.0	0.4 to 1.6	1.0	0.3 to 1.7
	RCP4.5	1.4	0.9 to 2.0	1.8	1.1 to 2.6
	RCP6.0	1.3	0.8 to 1.8	2.2	1.4 to 3.1
	RCP8.5	2.0	1.4 to 2.6	3.7	2.6 to 4.8
		mean	likely range ^d	mean	likely range ^d
Global Mean Sea Level Rise (m) ^b	RCP2.6	0.24	0.17 to 0.31	0.40	0.26 to 0.54
	RCP4.5	0.26	0.19 to 0.33	0.47	0.32 to 0.62
	RCP6.0	0.25	0.18 to 0.32	0.47	0.33 to 0.62
	RCP8.5	0.29	0.22 to 0.37	0.62	0.45 to 0.81

Notes:

- (a) Based on the CMIP5 ensemble; anomalies calculated with respect to 1986–2005. Using HadCRUT4 and its uncertainty estimate (5–95% confidence interval), the observed warming to the reference period 1986–2005 used for projections is 0.61 [0.55 to 0.67] °C for 1850–1900, 0.30 [0.27 to 0.33] °C for 1961–1990, and 0.11 [0.09 to 0.13] °C for 1980–1999. {2.4.3, Tables 12.2 and 12.3}
- (b) Based on 21 CMIP5 models; anomalies calculated with respect to 1986–2005. Where CMIP5 results were not available for a particular AOGCM and scenario, they were estimated as explained in Chapter 13, Table 13.5. The contributions from ice sheet rapid dynamical change and anthropogenic land water storage are treated as having uniform probability distributions, and as largely independent of scenario. This treatment does not imply that the contributions concerned will not depend on the scenario followed, only that the current state of knowledge does not permit a quantitative assessment of the dependence. Based on current understanding, only the collapse of marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause global mean sea level to rise substantially above the *likely* range during the 21st century. There is *medium confidence* that this additional contribution would not exceed several tenths of a meter of sea level rise during the 21st century.
- (c) Calculated from projections as 5–95% model ranges. These ranges are then assessed to be *likely* ranges after accounting for additional uncertainties or different levels of confidence in models. For projections of global mean surface temperature change in 2046–2065 *confidence* is *medium*, because contributions of radiative forcing and initial conditions to the temperature response uncertainty are larger than for 2081–2100. The likely ranges for 2046–2065 do not take into account the possible influence of factors that lead to near-term (2016–2035) projections of global mean surface temperature that are lower than the 5–95% model ranges, because the influence of these factors on longer term projections has not been quantified because of insufficient scientific understanding. {11.3.6}
- (d) Calculated from projections as 5–95% model ranges. These ranges are then assessed to be *likely* ranges after accounting for additional uncertainties or different levels of confidence in models. For projections of global mean sea level rise *confidence* is *medium* for both time horizons.

Table TS.2: Overview of projected regional changes and their relation to major climate phenomena. A phenomenon is considered relevant when there is both sufficient confidence that it has an influence on the given region, and when there is sufficient confidence that the phenomenon will change, particularly under the RCP4.5 or higher end scenarios. See Section 14.8 and Table 14.2 for full assessment of the confidence in these changes, and their relevance for regional climate. {14.8; Table 14.2}

Regions	Projected Major Changes in Relation to Phenomena
Arctic {14.8.2}	Wintertime changes in temperature and precipitation resulting from the small projected increase in NAO; Enhanced warming and sea ice melting; Significant increase in precipitation by mid-century due mostly to enhanced precipitation in Extratropical Cyclones.
North America {14.8.3}	Monsoon precipitation will shift later in the annual cycle; increased precipitation in extra-tropical cyclones will lead to large increases in wintertime precipitation over the northern third of the continent; extreme precipitation increases in tropical cyclones making landfall along the western coast of US and Mexico, the Gulf Mexico, and the eastern coast of US and Canada.
Central America and Caribbean {14.8.4}	Projected reduction in mean precipitation and increase in extreme precipitation; more extreme precipitation in tropical cyclones making landfall along the eastern and western coasts.
South America {14.8.5}	A southward displaced South Atlantic Convergence Zone increases precipitation in the southeast; positive trend in the Southern Annular Mode displaces the extratropical storm track southward, decreasing precipitation in central Chile and increasing it at the southern tip of South America.
Europe and Mediterranean {14.8.6}	Enhanced extremes of storm-related precipitation and decreased frequency of storm-related precipitation over the E. Mediterranean.
Africa {14.8.7}	Enhanced summer monsoon precipitation in West Africa; increased short rain in East Africa due to the pattern of Indian Ocean warming; increased rainfall extremes of landfall cyclones on the east coast (including Madagascar).
Central and North Asia {14.8.8}	Enhanced summer precipitation; enhanced winter warming over North Asia.
East Asia {14.8.9}	Enhanced summer monsoon precipitation; increased rainfall extremes of landfall typhoons on the coast; reduction in the midwinter suppression of extratropical cyclones.
West Asia {14.8.10}	Increased rainfall extremes of landfall cyclones on the Arabian Peninsula; decreased precipitation in NW Asia due to a northward shift of extratropical storm tracks.
South Asia {14.8.11}	Enhanced summer monsoon precipitation; increased rainfall extremes of landfall cyclones on the coasts of the Bay of Bengal and Arabian Sea.
Southeast Asia {14.8.12}	Reduced precipitation in Indonesia during Jul-Oct. due to the pattern of Indian Ocean warming; increased rainfall extremes of landfall cyclones on the coasts of the South China Sea, Gulf of Thailand, and Andaman Sea.
Australia and New Zealand {14.8.13}	Summer monsoon precipitation may increase over northern Australia; More frequent episodes of the zonal South Pacific Convergence Zone may reduce precipitation in northeastern Australia; increased warming and reduced precipitation in New Zealand and southern Australia due to projected positive trend in the Southern Annular Mode; increased extreme precipitation associated with tropical and extratropical storms
Pacific Islands {14.8.14}	Tropical convergence zone changes affect rainfall and its extremes; more extreme precipitation associated with tropical cyclones
Antarctica {14.8.15}	Increased warming over Antarctic Peninsula and west Antarctic related to the positive trend in the Southern Annular Mode; increased precipitation in coastal areas due to a poleward shift of storm track.

TFE9, Table 1: Extreme weather and climate events: Global-scale assessment of recent observed changes, human contribution to the changes, and projected further changes for the early (2016–2035) and late (2081–2100) 21st century. Bold indicates where the AR5 (black) provides a revised* global-scale assessment from the SREX (blue) or AR4 (red). Projections for early 21st century were not provided in previous assessment reports. Projections in the AR5 are relative to the reference period of 1986–2005, and use the new RCP scenarios.

Phenomenon and direction of trend	Assessment that changes occurred (typically since 1950 unless otherwise indicated)	Assessment of a human contribution to observed changes	Likelihood of further changes	
			Early 21st century	Late 21st century
Warmer and/or fewer cold days and nights over most land areas	<i>Very likely</i> [2.6.1] <i>Very likely</i> <i>Very likely</i>	Very likely [10.6.1] <i>Likely</i> <i>Likely</i>	<i>Likely</i> [11.3.2] – –	<i>Virtually certain</i> [12.4.3] <i>Virtually certain</i> <i>Virtually certain</i>
Warmer and/or more frequent hot days and nights over most land areas	<i>Very likely</i> [2.6.1] <i>Very likely</i> <i>Very likely</i>	Very likely [10.6.1] <i>Likely</i> <i>Likely (nights only)</i>	<i>Likely</i> [11.3.2] – –	<i>Virtually certain</i> [12.4.3] <i>Virtually certain</i> <i>Virtually certain</i>
Warm spells/heat waves. Frequency and/or duration increases over most land areas	Medium confidence on a global scale <i>Likely</i> in some regions (a) [2.6.1] <i>Medium confidence in many (but not all) regions</i> <i>Likely</i>	Likely (b) [10.6.2] <i>Not formally assessed</i> <i>More likely than not</i>	Not formally assessed (c) [11.3.2] – –	<i>Very likely</i> [12.4.3] <i>Very likely</i> <i>Very likely</i>
Heavy precipitation events. Increase in the frequency, intensity, and/or amount of heavy precipitation.	<i>Likely</i> more land areas with increases than decreases <i>Very likely</i> in central North America [2.6.2] <i>Likely</i> more land areas with increases than decreases <i>Likely over most land areas</i>	Medium confidence [7.6.5, 10.6.1] <i>Medium confidence</i> <i>More likely than not</i>	<i>Likely</i> over many land areas [11.3.2] – –	Very likely in some areas (d) [12.4.5] <i>Likely</i> over many areas <i>Very likely over most land areas</i>
Increases in intensity and/or duration of drought	Low confidence on a global scale <i>Likely</i> changes in some regions (e) [2.6.2] <i>Medium confidence in some regions</i> <i>Likely in many regions, since 1970 (f)</i>	Low confidence [10.6.1] <i>Medium confidence</i> <i>More likely than not</i>	<i>Low confidence</i> (g) [11.3.2] – –	Likely (medium confidence) on a regional to global scale (h) [12.4.5] <i>Medium confidence in some regions</i> <i>Likely (f)</i>
Increases in intense tropical cyclone activity	Low confidence in long term (centennial) changes <i>Virtually certain</i> in North Atlantic since 1970 [2.6.3] <i>Low confidence</i> <i>Likely (in some regions, since 1970)</i>	Low confidence [10.6.1] <i>Low confidence</i> <i>More likely than not</i>	<i>Low confidence</i> [11.3.2] – –	More likely than not in some basins [14.6] <i>More likely than not</i> in some basins <i>Likely</i>
Increased incidence and/or magnitude of extreme high sea level	<i>Likely</i> (since 1970) [3.7.5] <i>Likely</i> (late 20th century) <i>Likely</i>	Not assessed <i>Likely (i)</i> <i>More likely than not (i)</i>	Not assessed – –	Very likely [13.7.2] <i>Very likely (j)</i> <i>Likely</i>

* The direct comparison of assessment findings between reports is difficult. For some climate variables, different aspects have been assessed, and the revised guidance note on uncertainties has been used for the SREX and AR5. The availability of new information, improved scientific understanding, continued analyses of data and models, and specific differences in methodologies applied in the assessed studies, all contribute to revised assessment findings.

Notes:

- (a) *Likely* that heat wave frequency has increased in large parts of Europe, Asia and Australia.
- (b) Attribution is based on available case studies. It is *likely* that human influence has substantially increased the probability of occurrence of some observed heat waves in some locations.
- (c) Models project near-term increases in the duration, intensity and spatial extent of heat waves and warm spells.
- (d) *Very likely* over most of the mid-latitude land-masses and over wet tropical regions.
- (e) The frequency and intensity of drought has *likely* increased in the Mediterranean and West Africa and *likely* decreased in central North America and north-west Australia.
- (f) AR4 assessed the area affected by drought.
- (g) There is *low confidence* in projected changes in soil moisture.
- (h) Regional to global-scale projected decreases in soil moisture and increased agricultural drought are *likely (medium confidence)* in presently dry regions by the end of this century under the RCP8.5 scenario. Soil moisture drying in the Mediterranean, Southwest US and southern African regions is consistent with projected changes in Hadley circulation and increased surface temperatures, so there is *high confidence* in *likely* surface drying in these regions by the end of this century under the RCP8.5 scenario.
- (i) Attribution is based on the close relationship between observed changes in extreme and mean sea level.
- (j) SREX assessed it to be *very likely* that mean sea level rise will contribute to future upward trends in extreme coastal high water levels.

Date of Draft: 7 June 2013

Figures

Box TS.1, Figure 1: A depiction of evidence and agreement statements and their relationship to confidence. Confidence increases toward the top-right corner as suggested by the increasing strength of shading. Generally, evidence is most robust when there are multiple, consistent independent lines of high-quality. {Figure 1.11}

Figure TS.1: Multiple complementary indicators of a changing global climate. Each line represents an independently-derived estimate of change in the climate element. The times series presented are assessed in chapters 2, 3, and 4. In each panel all datasets have been normalized to a common period of record. A full detailing of which source datasets go into which panel is given in Chapter 2, Supplementary Material 2.SM.5 and in the respective chapters (See also FAQ 2.1, Figure 1). {2.4, 2.5, 3.2, 3.7, 4.5.2, 4.5.3}

Figure TS.2: Change in surface temperature over 1901-2012 as determined by linear trend for three data sets. White areas indicate incomplete or missing data. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in the first and last 10% of the time period. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). Differences in coverage primarily reflect the degree of interpolation to account for data void regions undertaken by the dataset providers ranging from none beyond grid box averaging (HadCRUT4) to substantial (GISS). {Figure 2.21}

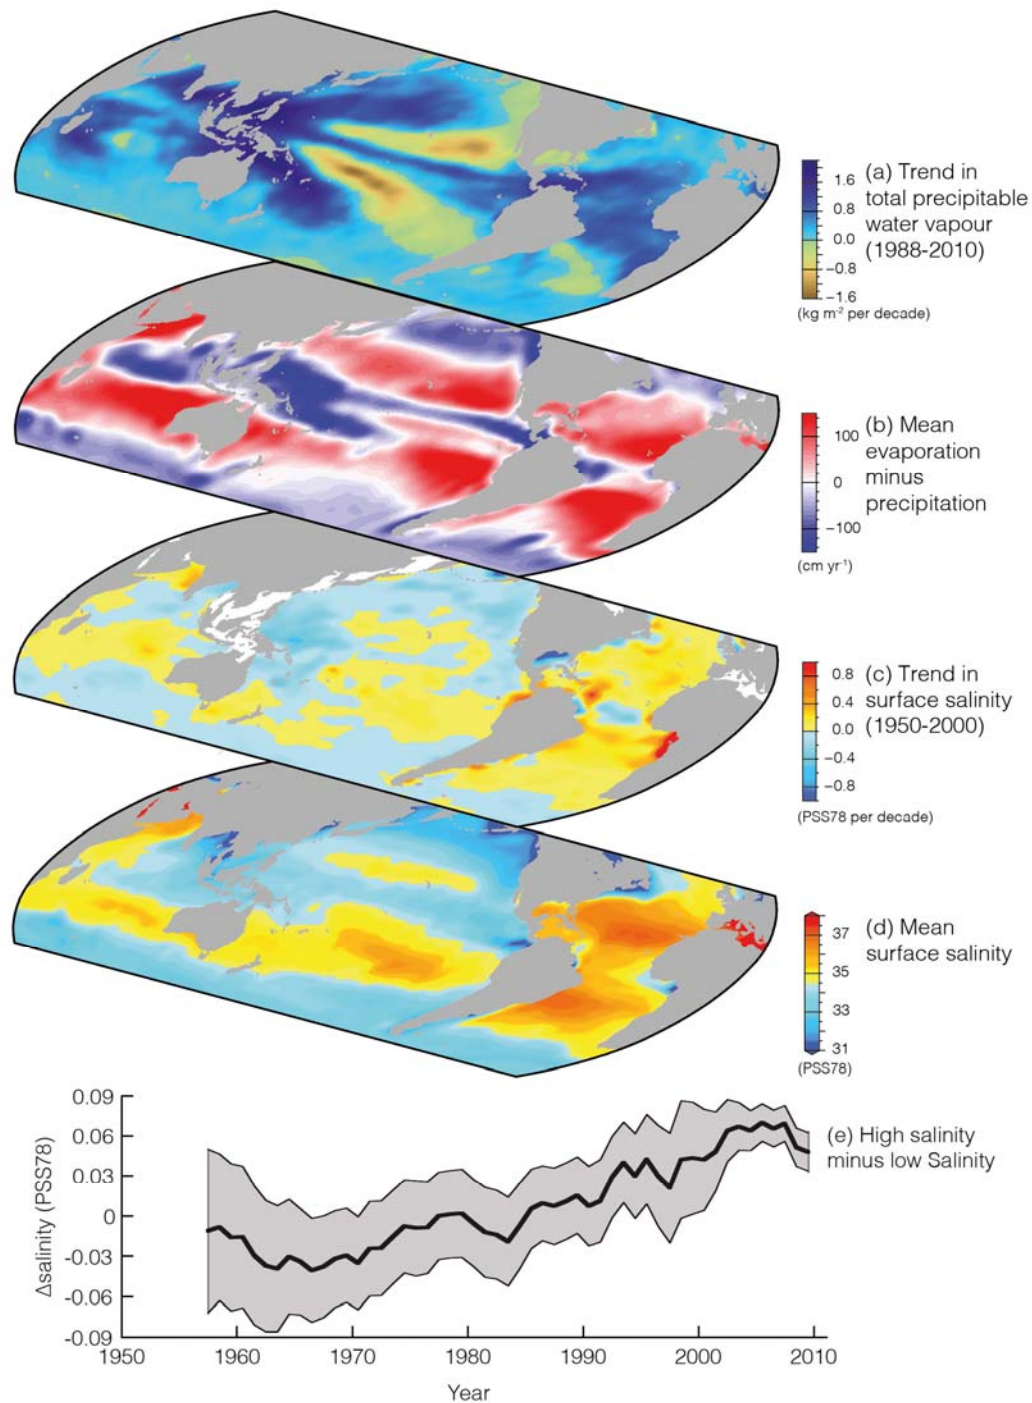

Figure TS.3: Upper panels: distribution of ice loss determined from GRACE time-variable gravity for (a) Antarctica and (b) Greenland, shown in centimetres of water per year ($\text{cm of water yr}^{-1}$) for the period 2003 to 2012. Lower panel: the assessment of the total loss of ice from glaciers and ice sheets in terms of sea level equivalent (in mm). The contribution from glaciers excludes those on the periphery of the ice sheets. {4.3.4; Figures 4.12, 4.13, 4.14, 4.16, 4.17}

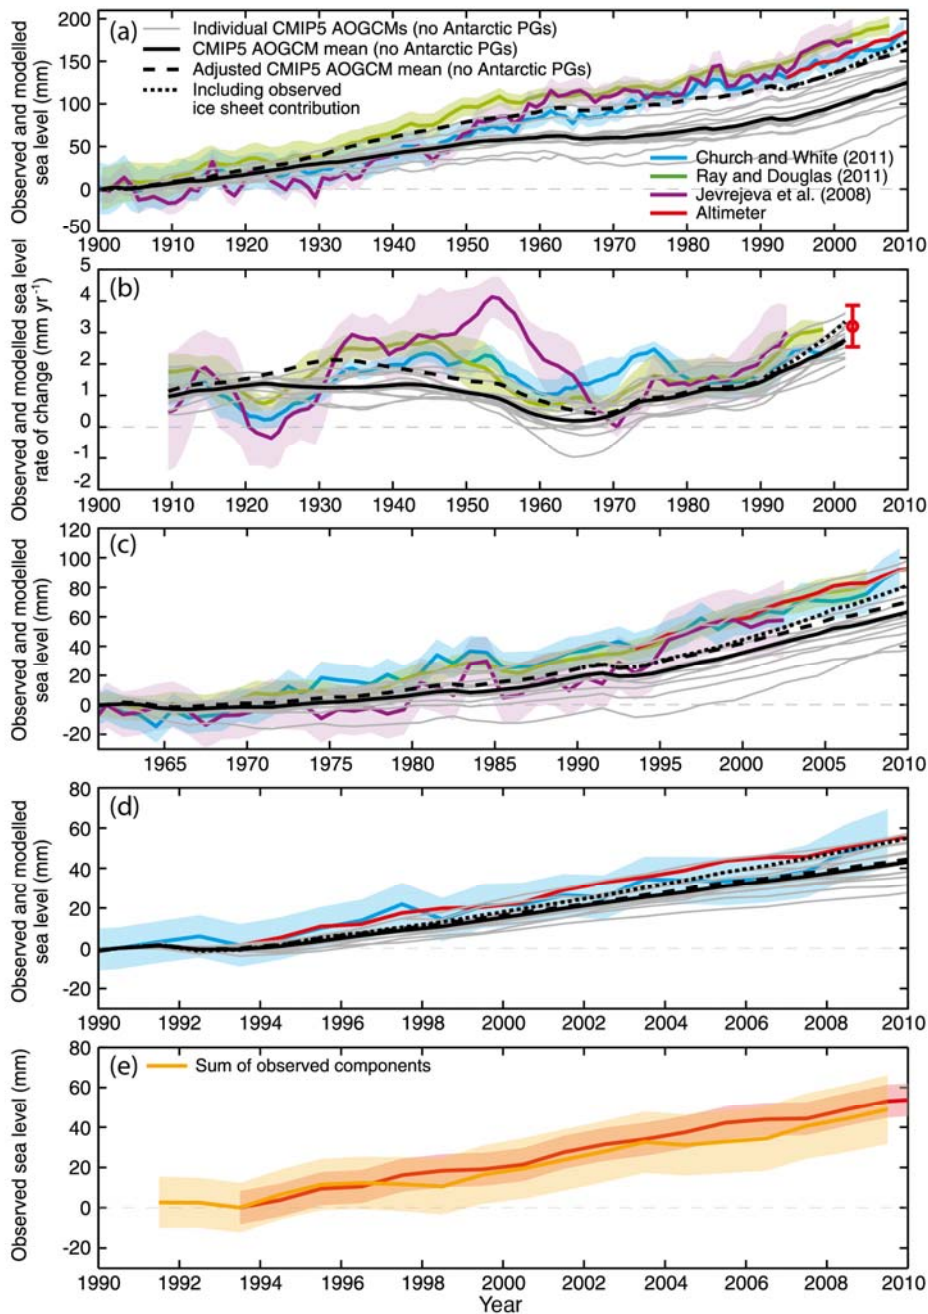

TFE.1, Figure 1: Changes in sea surface salinity are related to the atmospheric patterns of Evaporation minus Precipitation (E-P) and trends in total precipitable water: (a) Linear trend (1988 to 2010) in total precipitable water (water vapor integrated from Earth's surface up through the entire atmosphere) (kg m⁻² per decade) from satellite observations. (b) The 1979–2005 climatological mean net evaporation minus precipitation (cm yr⁻¹) from meteorological reanalysis data. (c) Trend (1950 to 2000) in surface salinity (PSS78 per 50years). (d) The climatological-mean surface salinity (PSS78) (blues <35; yellows-reds >35). (e) Global difference between salinity averaged over regions where the sea surface salinity is greater than the global mean sea surface salinity ("High Salinity") and salinity averaged over regions values below the global mean ("Low Salinity"). Details of data sources: see Figure 3.21 and FAQ 3.3, Figure 1. {3.9}

Annual mean hydrological cycle change (RCP8.5: 2081-2100)

TFE.1, Figure 2: Annual mean changes in precipitation (P), evaporation (E), relative humidity, E-P, runoff and soil moisture, for 2081–2100 relative to 1986–2005 under the RCP8.5 scenario (see Box TS.6). The number of CMIP5 models to calculate the multi-model mean is indicated in the upper right corner of each panel. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). {Figures 12.25–12.27}

TFE.2, Figure 1: Comparison of the observed global mean sea level rise from the sum of the modelled contributions from ocean thermal expansion, glaciers (excluding glaciers peripheral to the Antarctic ice sheet, PGs) and changes in land-water storage. In panels (a)-(d): the grey lines are results for individual CMIP5 AOGCMs; the black line is the model mean plus a correction for the omission of volcanic forcing in the AOGCM control experiments; the adjusted model mean (dashed black line) is the sum of the corrected model mean thermal expansion, the change in land-water storage, the glacier estimate using observed (rather than modelled) climate, and an illustrative long-term ice-sheet contribution (of 0.1 mm yr^{-1}); the adjusted model mean including the observed ice sheet contribution (dotted black line) begins in 1993 and includes the ice-sheet contributions, but excludes the glaciers peripheral to both the Greenland Ice Sheet and the Antarctic Ice Sheet, to avoid double counting because the observational ice-sheet estimates include the peripheral glaciers; three estimates of global mean sea level, with the shading indicating the uncertainty estimates (two standard deviations) are shown; the satellite altimetry data since 1993 are shown in red. The modelled sea level is given (a) for the period 1900 to 2010, (b) the rates of sea level change for the same period, with the satellite altimetry data shown as a red dot for the rate, (c) for 1961 to 2010 and (d) for 1990 to 2010. Panel (e) compares the sum of the observed contributions (orange) and the observed sea level from the satellite altimetry data (red). {13.3; Figure 13.7}

TFE.2, Figure 2: Compilation of paleo sea level data (purple), tide gauge data (blue, red and green), altimeter data (light blue), and central estimates and likely ranges for projections of global-mean sea level rise from the combination of CMIP5 and process-based models for RCP2.6 (blue) and RCP8.5 (red) scenarios, all relative to pre-industrial values. {Figures 13.3, 13.11, 13.27}

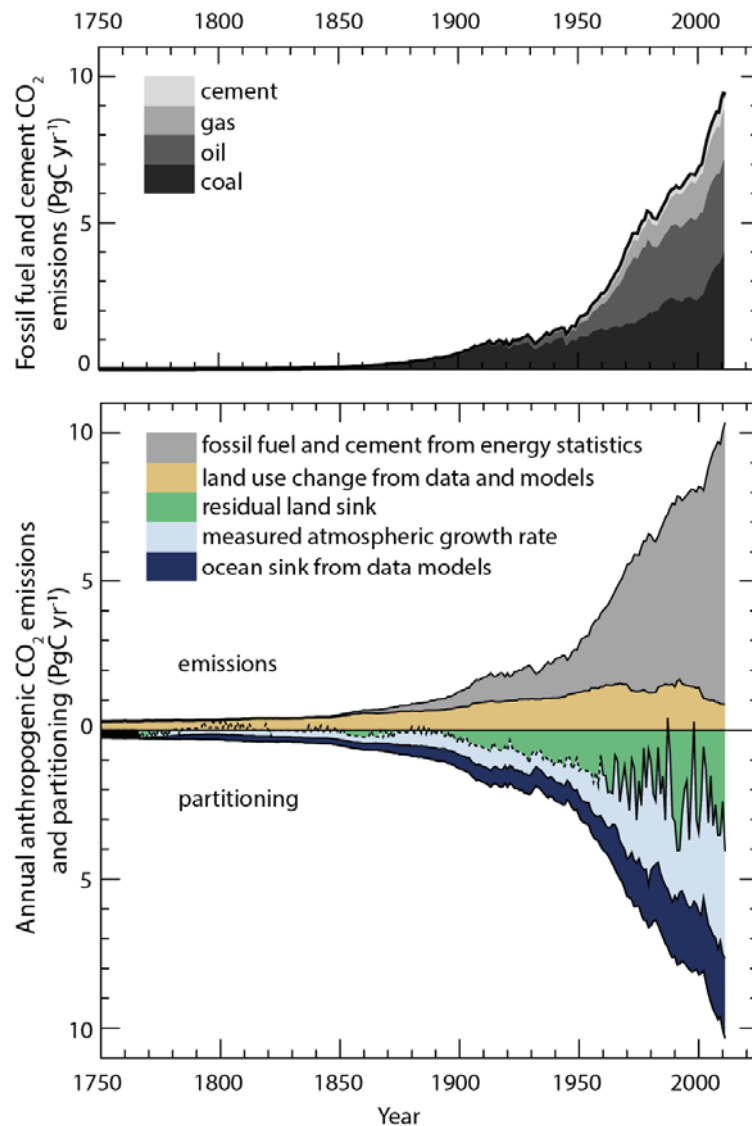

Figure TS.4: Annual anthropogenic CO₂ emissions and their partitioning among the atmosphere, land and ocean (PgC yr⁻¹) from 1750 to 2011. (Top) Fossil fuel and cement CO₂ emissions by category, estimated by the Carbon Dioxide Information Analysis Center (CDIAC). (Bottom) Fossil fuel and cement CO₂ emissions as above. CO₂ emissions from net land use change, mainly deforestation, are based on land cover change data (see Table 6.2). The atmospheric CO₂ growth rate prior to 1959 is based on a spline fit to ice core observations and a synthesis of atmospheric measurements from 1959. The fit to ice core observations does not capture the large interannual variability in atmospheric CO₂ and is represented with a dashed line. The ocean CO₂ sink is from a combination of models and observations. The residual terrestrial sink (term in green in the figure) is computed from the residual of the other terms. The emissions and their partitioning only include the fluxes that have changed since 1750, and not the natural CO₂ fluxes (e.g., atmospheric CO₂ uptake from weathering, outgassing of CO₂ from lakes and rivers, and outgassing of CO₂ by the ocean from carbon delivered by rivers; see Figure 6.1) between the atmosphere, land and ocean reservoirs that existed before that time and still exist today. The uncertainties in the various terms are discussed in chapter 6 and reported in Table 6.1 for decadal mean values. {Figure 6.8}

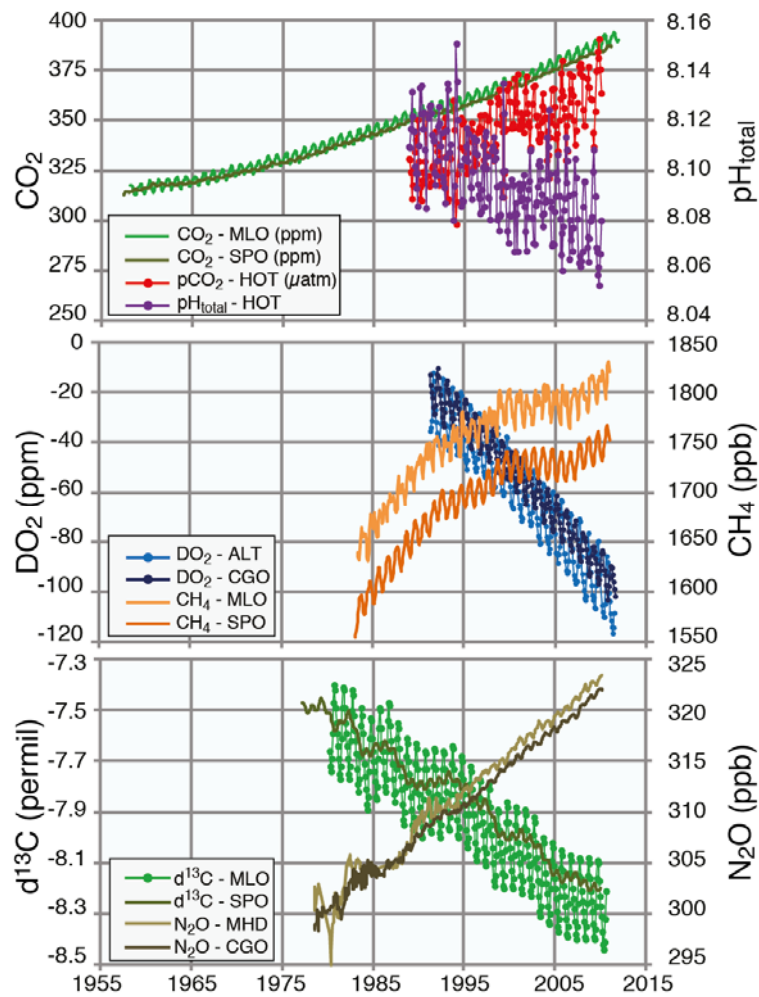

Figure TS.5: Atmospheric concentration of CO₂, oxygen, ¹³C/¹²C stable isotope ratio in CO₂, as well as CH₄ and N₂O atmospheric concentrations and oceanic surface observations of pCO₂ and pH, recorded at representative time series stations in the Northern and the Southern Hemispheres. MLO: Mauna Loa Observatory, Hawaii; SPO: South Pole; HOT: Hawaii Ocean Time-Series station; MHD: Mace Head, Ireland; CGO: Cape Grim, Tasmania; ALT: Alert, Northwest Territories, Canada. {Figure 6.3, FAQ 3.2, Figure 1}

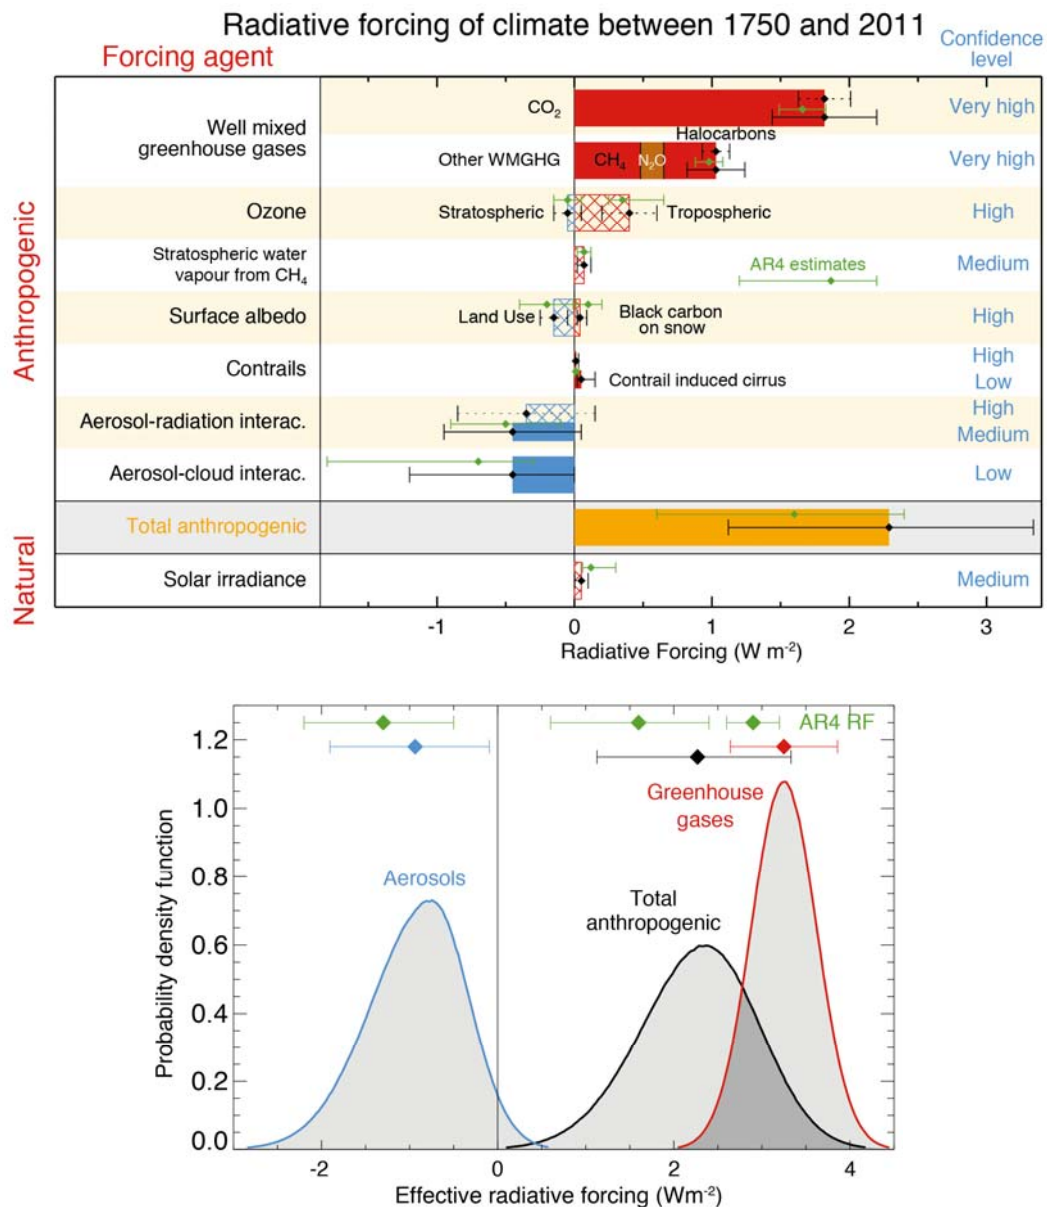

Figure TS.6: Radiative Forcing (RF) and Effective Radiative Forcing (ERF) of climate change during the industrial era. Top: Forcing by concentration change between 1750 and 2011 with associated uncertainty range (solid bars are ERF, hatched bars are RF, green diamonds and associated uncertainties are for RF assessed in AR4). Bottom: Probability Density Functions for the ERF, for the aerosol, well-mixed greenhouse gas (WMGHG) and total. The green lines show the AR4 RF 90% confidence intervals and can be compared with the red, blue and black lines which show the AR5 ERF 90% confidence intervals (although RF and ERF differ, especially for aerosols). The ERF from surface albedo changes and combined contrails and contrail induced cirrus is included in the total anthropogenic forcing, but not shown as a separate probability density function. For some forcing mechanisms (ozone, land use, solar) the RF is assumed to be representative of the ERF but an additional uncertainty of 17% is added in quadrature to the RF uncertainty. {Figures 8.15, 8.16}

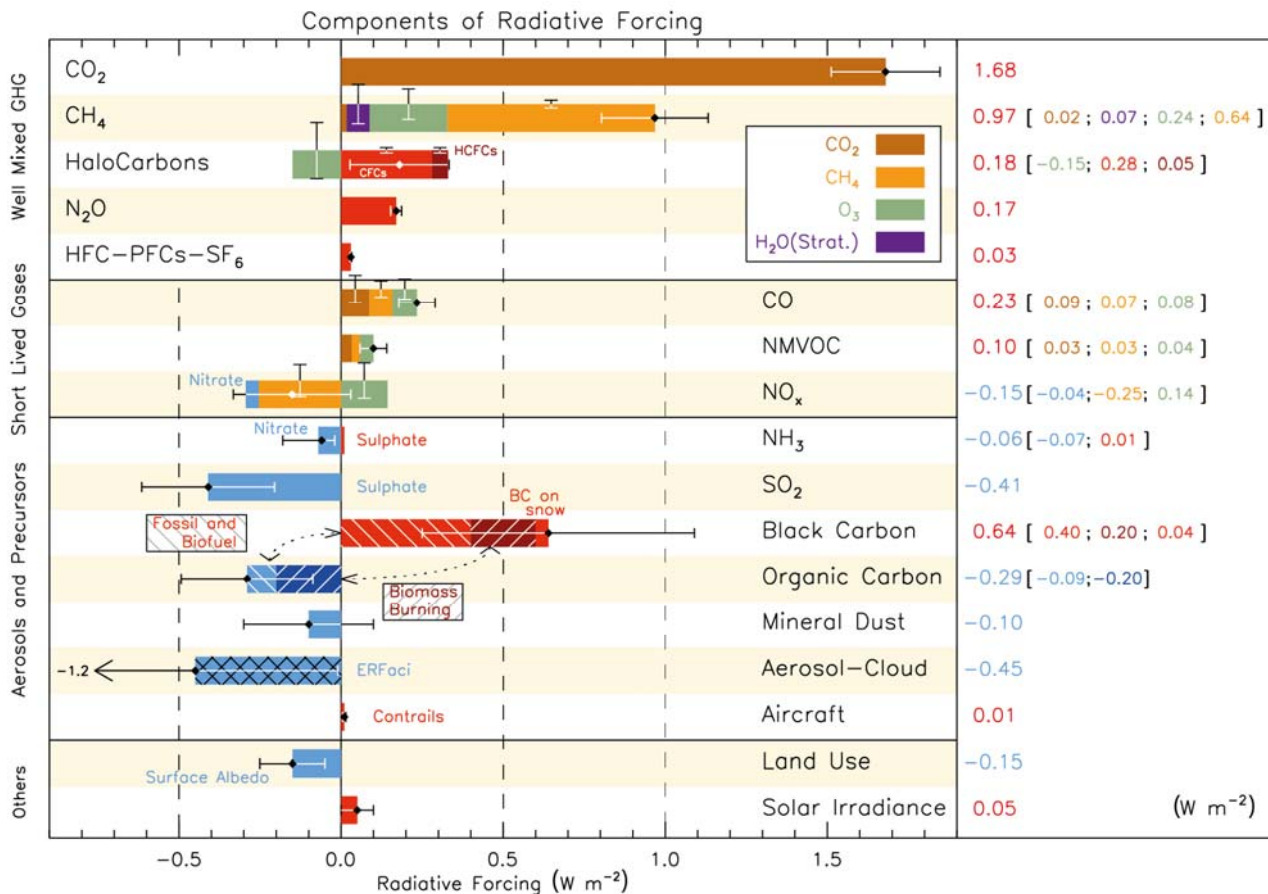

Figure TS.7: Radiative forcing of climate change during the industrial era shown by emitted components from 1750 to 2011. The horizontal bars indicate the overall uncertainty, while the vertical bars are for the individual components (vertical bar lengths proportional to the relative uncertainty, with a total length equal to the bar width for a $\pm 50\%$ uncertainty). Best estimates for the totals and individual components (from left to right) of the response are given in the right column. Values are RF except for the ERF of aerosol-cloud interactions (ERF_{aci}). An additional rapid adjustment to aerosol-radiation interactions of -0.1 [-0.3 to $+0.1$] $W m^{-2}$ is attributable primarily to black carbon (ERF_{ari}-RF_{ari} in Figure TS.6). CFCs= Chlorofluorocarbons, HCFCs= Hydrochlorofluorocarbons, HFCs=Hydrofluorocarbons, PFCs= Perfluorocarbons, NMVOC= Non-Methane Volatile Organic Compounds, BC= Black Carbon. {Figure 8.17}

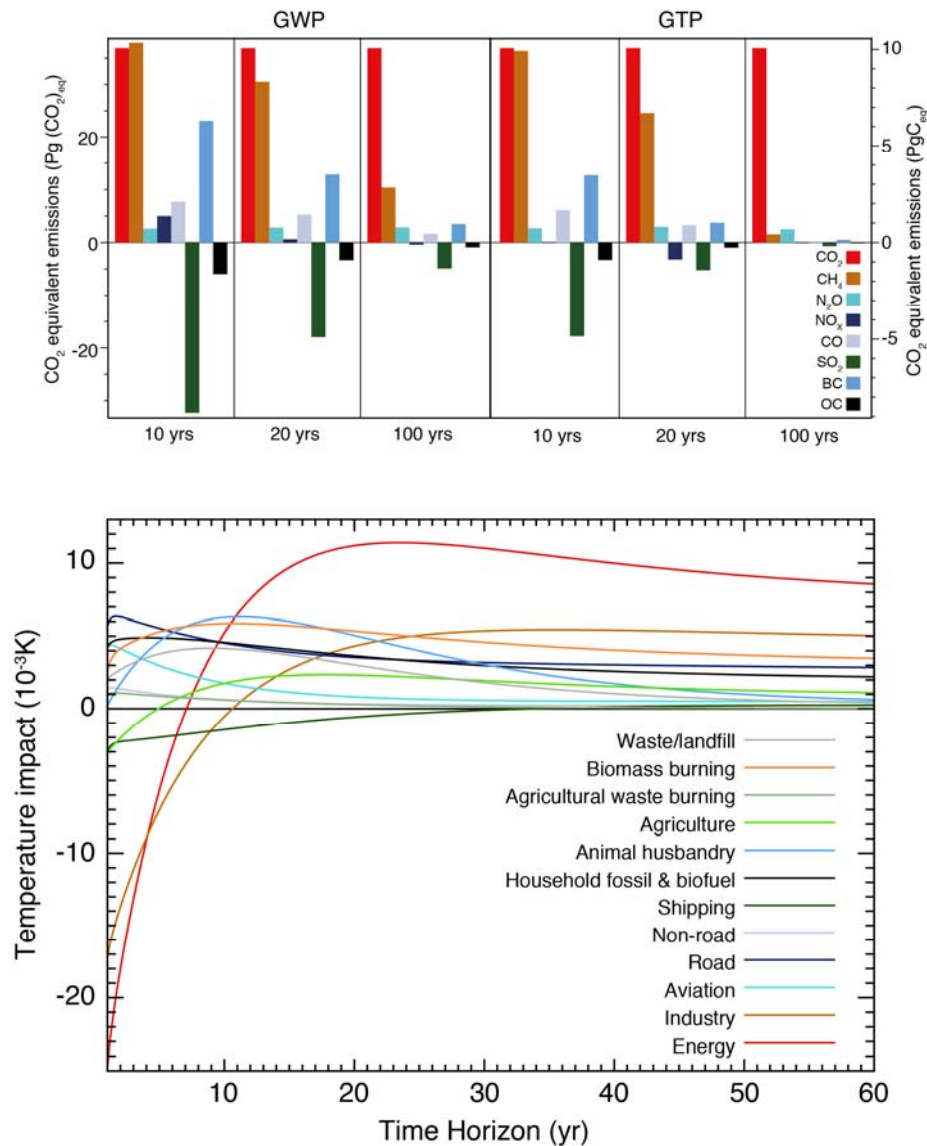

Figure TS.8: (Upper Panel) Global anthropogenic present-day emissions weighted by the Global Warming Potential (GWP) and the Global Temperature change Potential (GTP) for the chosen time horizons. Year 2008 (single-year pulse) emissions weighted by GWP, which is the global mean radiative forcing per unit mass emitted integrated over the indicated number of years relative to the forcing from CO₂ emissions, and GTP which estimates the impact on global mean temperature based on the temporal evolution of both radiative forcing and climate response per unit mass emitted relative to the impact of CO₂ emissions. The units are “CO₂ equivalents” which reflects equivalence only in the impact parameter of the chosen metric (integrated RF over the chosen time horizon for GWP; temperature change at the chosen point in time for GTP), given as Pg(CO₂)eq (left axis) and PgCeq (right axis) (see footnote 5). (Bottom Panel) The Absolute GTP (AGTP) as a function of time multiplied by the present-day emissions of all compounds from the indicated sectors is used to estimate global mean temperature response (AGTP is the same as GTP, except is not normalized by the impact of CO₂ emissions). There is little change in the relative values for the sectors over the 60–100 year time horizon. The effects of aerosol-cloud interactions and aviation-induced cirrus are not included in the upper panel. {Figures 8.32, 8.33}

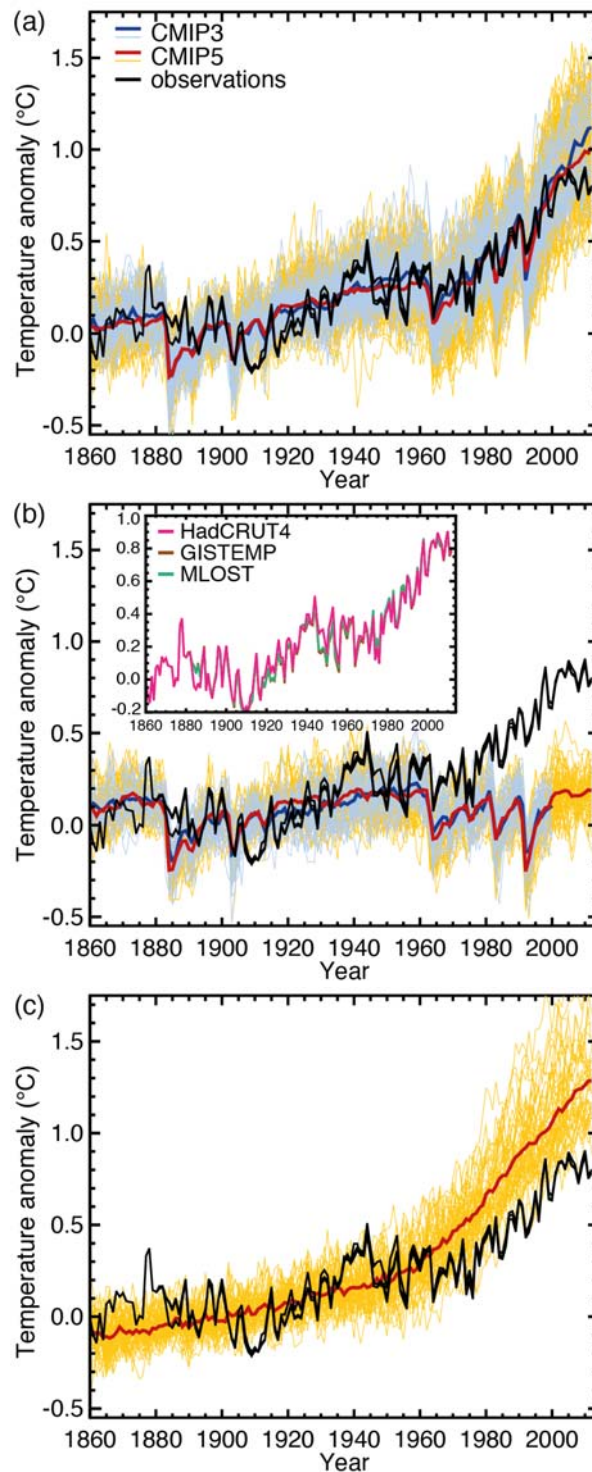

Figure TS.9: Three observational estimates of global mean surface temperature (black lines) from HadCRUT4, GISTEMP, and MLOST, compared to model simulations (CMIP3 models – thin blue lines and CMIP5 models – thin yellow lines) with anthropogenic and natural forcings (a), natural forcings only (b) and greenhouse gas forcing only (c). Thick red and blue lines are averages across all available CMIP5 and CMIP3 simulations respectively. All simulated and observed data were masked using the HadCRUT4 coverage (since this dataset has the most restricted spatial coverage), and global average anomalies are shown with respect to 1880–1919, where all data are first calculated as anomalies relative to 1961–1990 in each grid box. Inset to (b) shows the three observational datasets distinguished by different colours. {Figure 10.1}

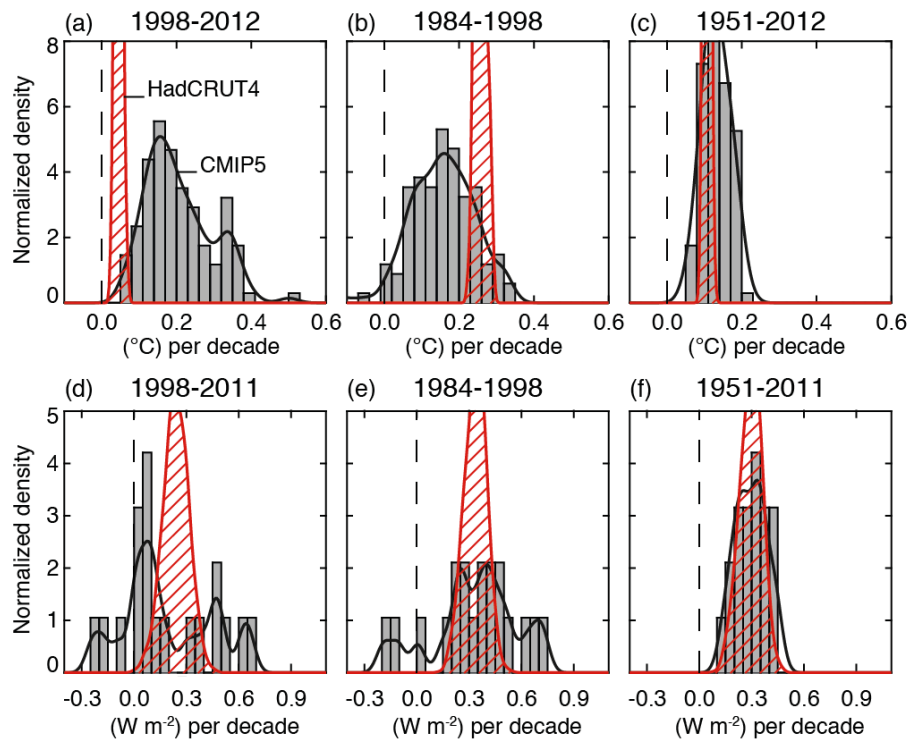

Figure TS.10: Assessed *likely* ranges (whiskers) and their midpoints (bars) for warming trends over the 1951–2010 period due to well-mixed greenhouse gases (GHG), anthropogenic forcings (ANT), anthropogenic forcings other than well-mixed greenhouse gases (OA), natural forcings (NAT), and internal variability. The trend in the HadCRUT4 observations is shown in black with its 5 to 95% uncertainty range due only to observational uncertainty in this record. {Figure 10.5}

Box TS.3, Figure 1: Top: Observed and simulated GMST trends in $^{\circ}\text{C}$ per decade, over the periods 1998–2012 (a), 1984–1998 (b), and 1951–2012 (c). For the observations, 100 realisations of the HadCRUT4 ensemble are shown (red, hatched). The uncertainty displayed by the ensemble width is that of the statistical construction of the global average only, in contrast to the trend uncertainties quoted in Section 2.4.3, which include an estimate of internal climate variability. Here, by contrast, internal variability is characterised through the width of the model ensemble. For the models, all 114 available CMIP5 historical realisations are shown, extended after 2005 with the RCP4.5 scenario and through 2012 (grey, shaded). Bottom: Trends in effective radiative forcing (ERF, in W m^{-2} per decade) over the periods 1998–2011 (d), 1984–1998 (e), and 1951–2011 (f). The figure shows AR5 best-estimate ERF trends (red, hatched) and CMIP5 ERF (grey, shaded). Black lines are smoothed versions of the histograms. Each histogram is normalised so that its area sums up to one. {2.4.3, 8.5.2; Box 9.2; Figure 8.18, Box 9.2, Figure 1}

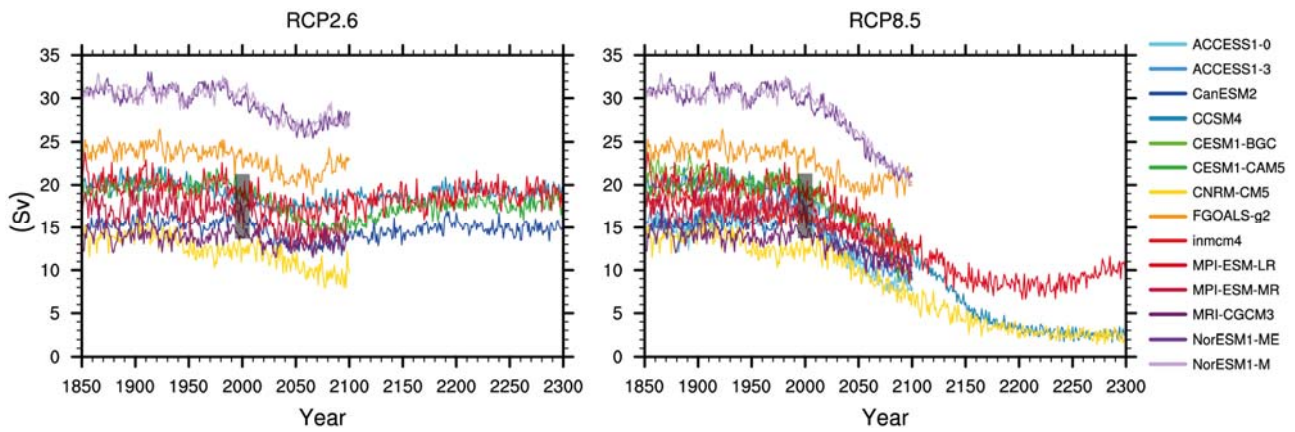

TFE.3, Figure 1: (top: left) Observed globally and annually averaged CO₂ concentrations in parts per million (ppm) since 1950 compared with projections from the previous IPCC assessments. Observed global annual CO₂ concentrations are shown in dark blue. The shading shows the largest model projected range of global annual CO₂ concentrations from 1950 to 2035 from FAR (First Assessment Report; Figure A.3 in the Summary for Policymakers (SPM) of IPCC 1990), SAR (Second Assessment Report; Figure 5b in the TS of IPCC 1996), TAR (Third Assessment Report; Appendix II of IPCC 2001), and for the A2, A1B and B1 scenario presented in the AR4 (Fourth Assessment Report; Figure 10.26). (top: right) Same observed globally averaged CO₂ concentrations and the projections from this report. Only RCP8.5 has a range of values since the emission driven scenarios were only carried out for this RCP. For the other RCPs the best estimate is given. (middle: left) Estimated changes in the observed globally and annually averaged surface temperature anomaly relative to 1961–1990 (in °C) since 1950 compared with the range of projections from the previous IPCC assessments. Values are harmonized to start from the same value at 1990. Observed global annual temperature anomaly, relative to 1961–1990, from three datasets is shown as squares (NASA (dark blue), NOAA (warm mustard), and the UK Hadley Centre (bright green) data sets). The coloured shading shows the projected range of global annual mean near surface temperature change from 1990 to 2035 for models used in FAR (Figure 6.11), SAR (Figure 19 in the TS of IPCC 1996), TAR (full range of TAR, Figure 9.13(b)). TAR results are based on the simple climate model analyses presented in this assessment and not on the individual full three-dimensional climate model simulations. For the AR4 results are presented as single model runs of the CMIP3 ensemble for the historical

period from 1950-2000 (light grey lines) and for three scenarios (A2, A1B and B1) from 2001-2035. For the three SRES scenarios the bars show the CMIP3 ensemble mean and the likely range given by -40 % to +60% of the mean as assessed in Meehl et al. (2007). The publication years of the assessment reports are shown. (middle; right) Projections of annual mean global mean surface air temperature (GMST) for 1950–2035 (anomalies relative to 1961–1990) under different RCPs from CMIP5 models (light grey and coloured lines, one ensemble member per model), and observational estimates the same as the middle left panel. The grey shaded region shows the indicative likely range for annual mean GMST during the period 2016–2035 for all RCPs (see Figure TS.14 for more details). The grey bar shows this same indicative likely range for the year 2035. (bottom: left) Estimated changes in the observed global annual mean sea level (GMSL) since 1950. Different estimates of changes in global annual sea level anomalies from tide gauge data (dark blue, warm mustard, dark green) and based on annual averages of altimeter data (light blue) starting in 1993 (the values have been aligned to fit the 1993 value of the tide gauge data). Squares indicate annual mean values, solid lines smoothed values. The shading shows the largest model projected range of global annual sea level rise from 1950 to 2035 for FAR (Figures 9.6 and 9.7), SAR (Figure 21 in TS of IPCC, 1996), TAR (Appendix II of IPCC, 2001; updated) based on the Coupled Model Intercomparison Project Phase 3 (CMIP3) model results available at the time of AR4 using the SRES A1B scenario. Note that in the AR4 no full range was given for the sea level projections for this period. Therefore, the figure shows results only for the SRES-A1B scenario that have been published subsequent to the AR4. The bars at the right hand side of each graph show the full range given for 2035 for each assessment report. The publication years of the assessment reports are shown. Appendix 1.A for details on the data and calculations used to create these figures. (bottom: right) Same observational estimate as bottom left. The bars are the "likely ranges (medium confidence) for global mean sea level rise at 2081-2100 with respect to 1986-2005 following the four RCPs. See Chapters 1, 11 and 13 for more details. {Figures 1.4, 1.5, 1.10, 11.9, 11.19, 11.25, 13.11}

TFE.4, Figure 1: The Earth's energy budget from 1970 through 2011. (a) The cumulative energy inflow into the Earth system from changes in well-mixed and short-lived greenhouse gases, solar forcing, tropospheric aerosol forcing, volcanic forcing, and changes in surface albedo due to land-use change (all relative to 1860-1879) are shown by the coloured lines; these contributions are added to give the total energy inflow (black; contributions from black carbon on snow and contrails as well as contrail-induced cirrus are included but not shown separately). (b) The cumulative total energy inflow from (a, black) is balanced by the sum of the energy uptake of the Earth system (blue; energy absorbed in warming the ocean, the atmosphere, and the land, as well as in the melting of ice) and an increase in outgoing radiation inferred from changes in the global-mean surface temperature. The sum of these two terms is given for a climate feedback parameter α of 2.47, 1.23, and $0.82 \text{ W m}^{-2} \text{ } ^\circ\text{C}^{-1}$, corresponding to an equilibrium climate sensitivity of 1.5°C , 3.0°C , and 4.5°C , respectively; 1.5°C – 4.5°C is assessed to be the *likely* range of equilibrium climate sensitivity. The energy budget would be closed for a particular value of α if the corresponding line coincided with the total energy inflow. For clarity, all uncertainties (shading) shown are *likely* ranges. {Box 12.2; Box 13.1, Figure 1}

TFE.5, Figure 1: Atlantic Meridional Overturning Circulation strength at 30°N (Sv) as a function of year, from 1850 to 2300 as simulated by different AOGCMs in response to scenario RCP2.6 (left) and RCP8.5 (right). The vertical black bar shows the range of AMOC strength measured at 26°N, from 2004 to 2011 {Figure 3.11, 12.35}

Figure TS.11: Simulated and observed 1951–2011 trends in the Southern Annular Mode (SAM) index by season. The SAM index is a difference between zonal mean sea level pressure (SLP) at 40°S and 65°S. The SAM index is defined without normalization, so that the magnitudes of simulated and observed trends can be compared. Black lines show observed trends from the HadSLP2r dataset (solid), and the 20th century Reanalysis (dotted). Grey bars show 5th–95th percentile ranges of control trends, and red boxes show the 5th–95th percentile range of trends in historical simulations including anthropogenic and natural forcings. Coloured bars show ensemble mean trends and their associated 5–95% confidence ranges simulated in response to greenhouse gas (light green), aerosol (dark green), ozone (magenta) and natural forcing changes (blue) in CMIP5 individual-forcing simulations. {Figure 10.13b}

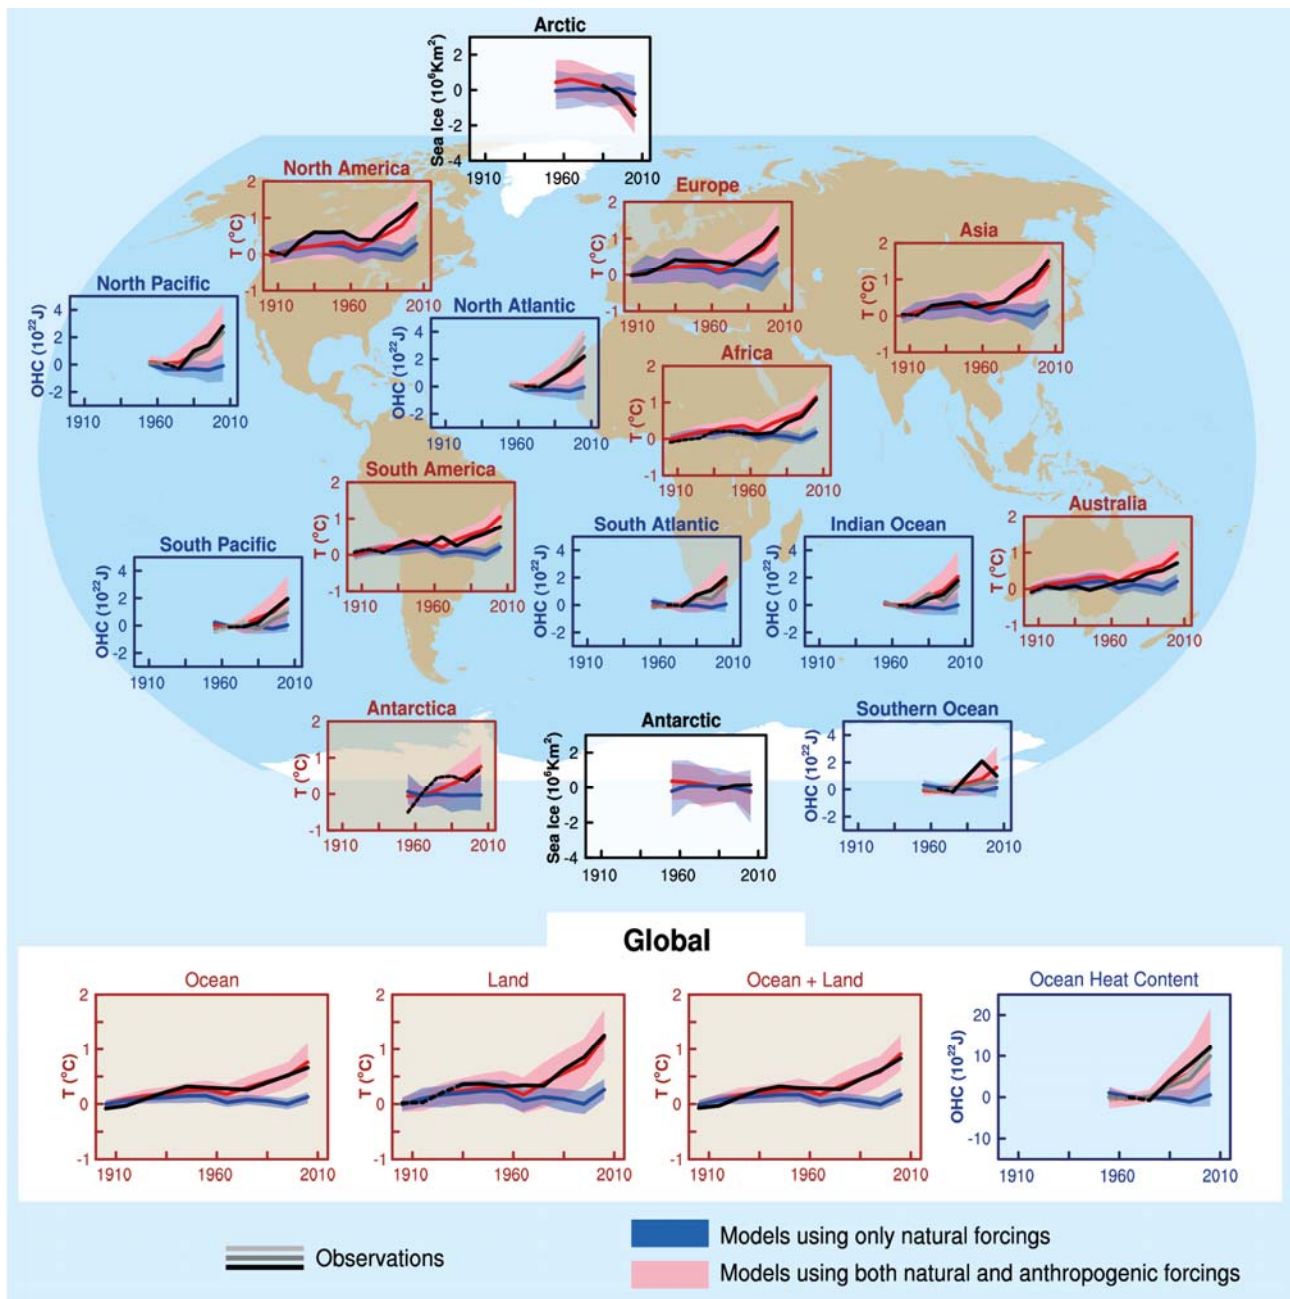

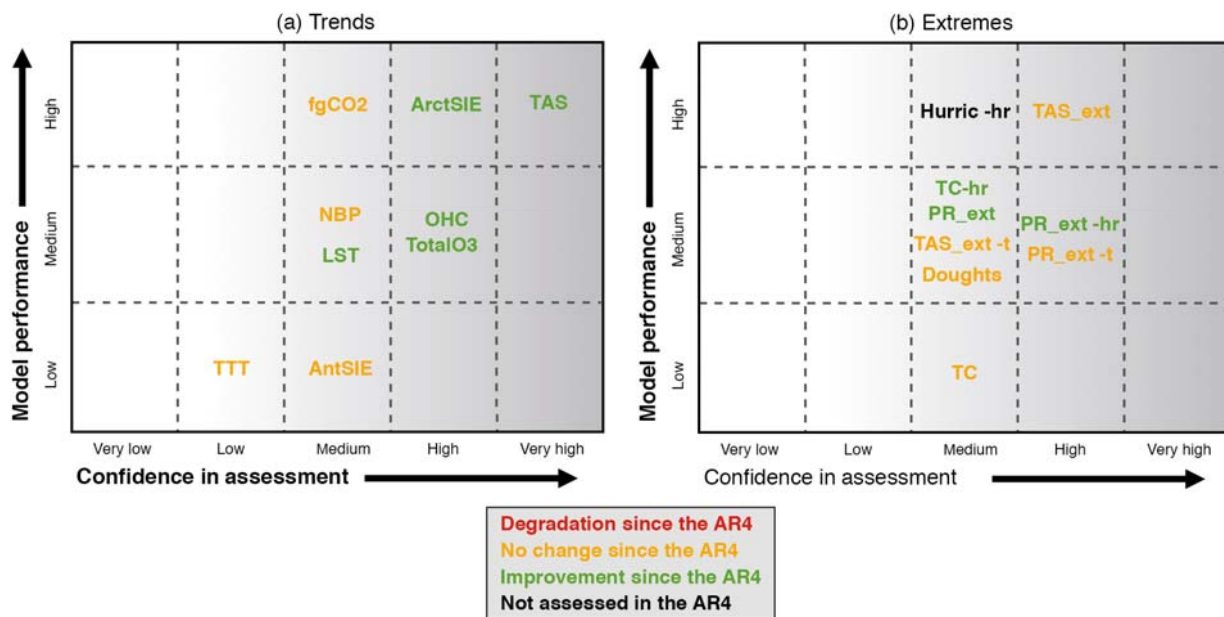

Figure TS.12: Detection and attribution signals (decadal averages) in the climate system, at regional scales (top panels) and global scales (bottom 4 panels). Brown panels are land surface temperature time series, blue panels are ocean heat content time series, and white panels are sea-ice time series. Each panel shows observations (black or black and shades of grey), and the 5–95% range of the simulated response to natural forcings (blue shading) and natural and anthropogenic forcings (pink shading), together with the corresponding ensemble means (dark blue and dark red respectively). The observed surface temperature is from HadCRUT4. Three observed records of ocean heat content (OHC) are shown. Sea-ice anomalies (rather than absolute values) are plotted and based on models in Figure 10.16. The observations are either solid or dashed and indicate the quality of the observations and estimates. For land and ocean surface temperatures panels and precipitation panels, solid observation lines indicate where spatial coverage of areas being examined, is above 50% coverage and dashed observation lines where coverage is below 50%. For example, data coverage of Antarctica never goes above 50% of the land area of the continent. For ocean heat content and sea-ice panels the solid observations line is where the coverage of data is good and higher in quality, and the dashed line is where the data coverage is only adequate. This figure is based in Figure 10.21 except presented as decadal averages rather than yearly averages. {Figure 10.21}

Box TS.4, Figure 1: Summary of how well the current-generation climate models simulate important features of the climate of the 20th century. Confidence in the assessment increases towards the right as suggested by the increasing strength of shading. Model quality increases from bottom to top. The colour coding indicates improvements from the models available at the time of the AR4 to the current assessment. There have been a number of improvements since the AR4, and some some modelled quantities are not better simulated. The major climate quantities are listed in this summary and none shows degradation. The assessment is mostly based on the multi-model mean, not excluding that deviations for individual models could exist. Assessed model quality is simplified for representation in this figure; details of each assessment are found in Chapter 9. {9.8.1; Figure 9.44}

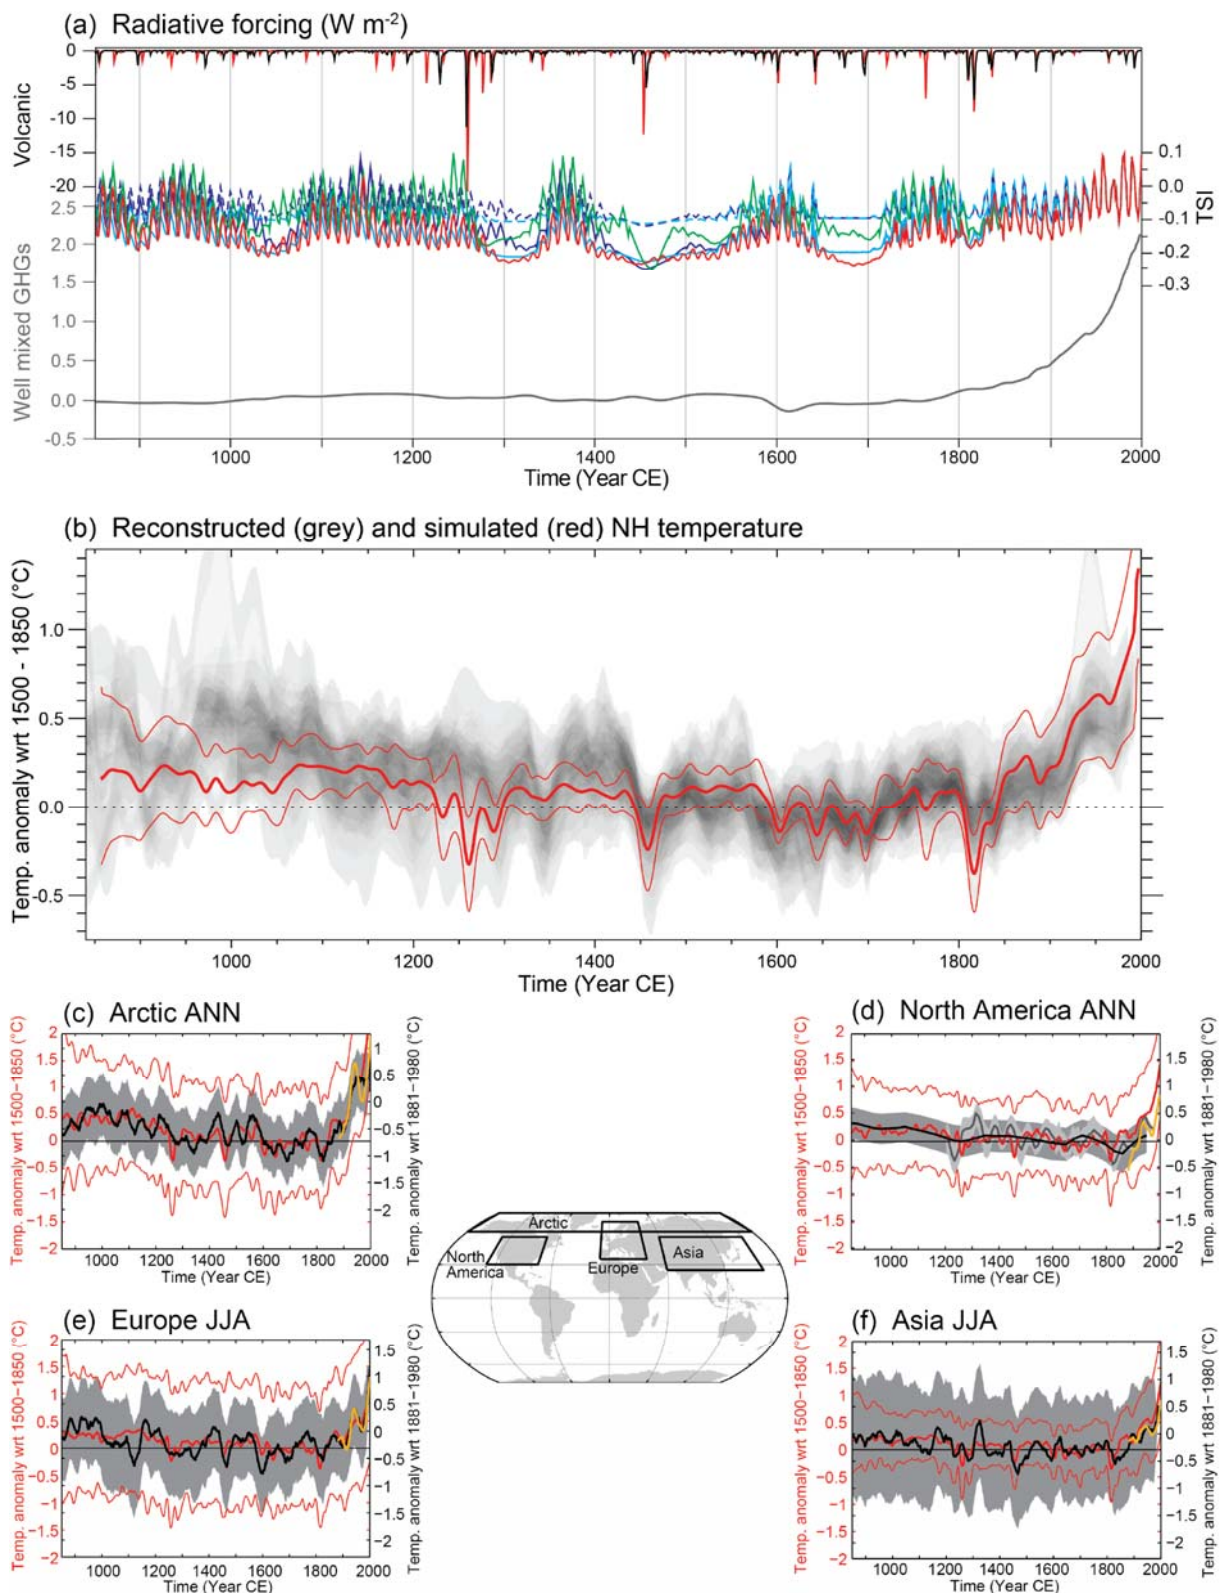

The figure highlights the following key features, with the sections that back up the assessment added in brackets:

(a) Trends in:

AntSIE:	Antarctic sea-ice extent {9.4.3}
ArctSIE:	Arctic sea-ice extent {9.4.3}
fgCO2:	Global ocean carbon sink {9.4.5}
LST:	Lower-stratospheric temperature {9.4.1.}
NBP:	Global land carbon sink {9.4.5}
OHC:	Global ocean heat content {9.4.2}
TotalO3:	Total-column ozone {9.4.1}
TAS:	Surface air temperature {9.4.1}
TTT:	Tropical tropospheric temperature {9.4.1}

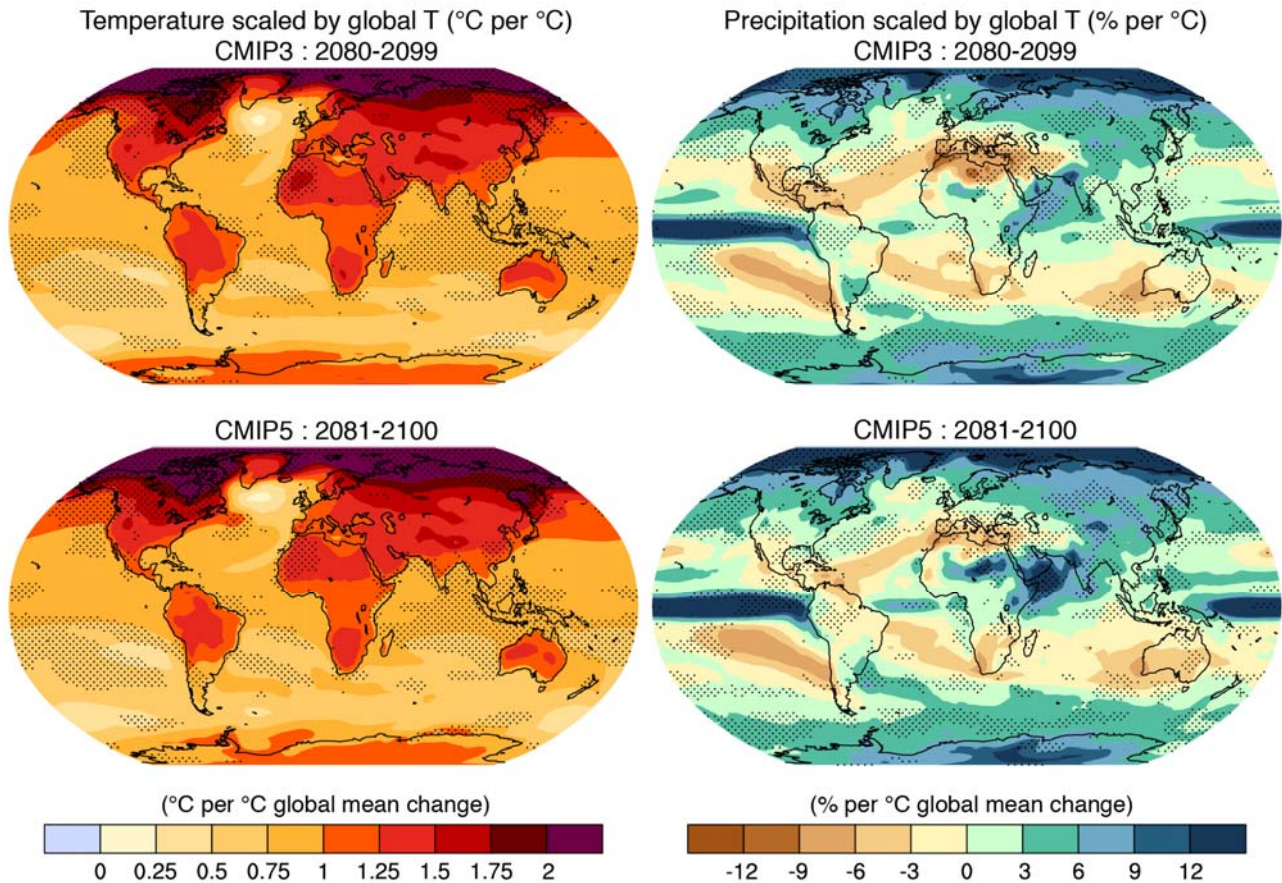

(b) Extremes:

Droughts	Droughts {9.5.4}
Hurric-hr	Year-to-year count of Atlantic hurricanes in high-resolution AGCMs {9.5.4}
PR_ext	Global distribution of precipitation extremes {9.5.4}
PR_ext-hr	Global distribution of precipitation extremes in high-resolution AGCMs {9.5.4}
PR_ext-t	Global trends in precipitation extremes {9.5.4}
TAS_ext	Global distributions of surface air temperature extremes {9.5.4}
TAS_ext-t	Global trends in surface air temperature extremes {9.5.4}
TC	Tropical cyclone tracks and intensity {9.5.4}
TC-hr	Tropical cyclone tracks and intensity in high-resolution AGCMs {9.5.4}

Box TS.5, Figure 1: Last-millennium simulations and reconstructions. (a) 850–2000 PMIP3/CMIP5 radiative forcing due to volcanic, solar and well mixed greenhouse gas. Different colors illustrate the two existing datasets for volcanic forcing (CEA and GRA) and the four estimates of solar forcing (DB, MEA, SBF and VSK). For solar forcing, solid (dashed) lines stand for reconstruction variants in which background changes in irradiance are (not) considered; (b) 850–2000 PMIP3/CMIP5 simulated (red) and reconstructed (shading) NH temperature changes. The thick red line depicts the multi-model mean while the thin red lines show the multi-model 90% range. The overlap of reconstructed temperatures is shown by grey shading; all data are expressed as anomalies from their 1500–1850 mean and smoothed

with a 30-year filter. Note that some reconstructions represent a smaller spatial domain than the full NH or a specific season, while annual temperatures for the full NH mean are shown for the simulations. (c), (d), (e) and (f) Arctic and North America annual mean temperature, and Europe and Asia June-July-August (JJA) temperature, from 950 to 2000 from reconstructions (black line), and PMIP3/CMIP5 simulations (thick red, multi-model mean; thin red 90% multi-model range). All red curves are expressed as anomalies from their 1500–1850 mean and smoothed with a 30-year filter. The shaded envelope depicts the uncertainties from each reconstruction (Arctic: 90% confidence bands, North American: ± 2 standard deviation, Asia: ± 2 root mean square error, Europe: 95% confidence bands). For comparison with instrumental record, the CRUTEM4 dataset is shown (yellow line). All lines are smoothed by applying a 30 year moving average. Map shows the individual regions for each reconstruction. {5.3.5; Table 5.A.1; Figures 5.1, 5.8, 5.12}

Box TS.6, Figure 1: Patterns of temperature (left column) and percent precipitation change (right column) for the CMIP3 models average (first row) and CMIP5 models average (second row), scaled by the corresponding global average temperature changes. The patterns are computed in both cases by taking the difference between the averages over the last twenty years of the 21st century experiments (2080–2099 for CMIP3 and 2081–2100 for CMIP5) and the last twenty years of the historic experiments (1980–1999 for CMIP3, 1986–2005 for CMIP5) and rescaling each difference by the corresponding change in global average temperature. This is done first for each individual model, then the results are averaged across models. Stippling indicates a measure of significance of the difference between the two corresponding patterns obtained by a bootstrap exercise. Two subsets of the pooled set of CMIP3 and CMIP5 ensemble members of the same size as the original ensembles, but without distinguishing CMIP3 from CMIP5 members, were randomly sampled 500 times. For each random sample the corresponding patterns and their difference are computed, then the true difference is compared, grid-point by grid-point, to the distribution of the bootstrapped differences, and only grid-points at which the value of the difference falls in the tails of the bootstrapped distribution (less than the 2.5 percentiles or the 97.5 percentiles) are stippled. {Figure 12.41}

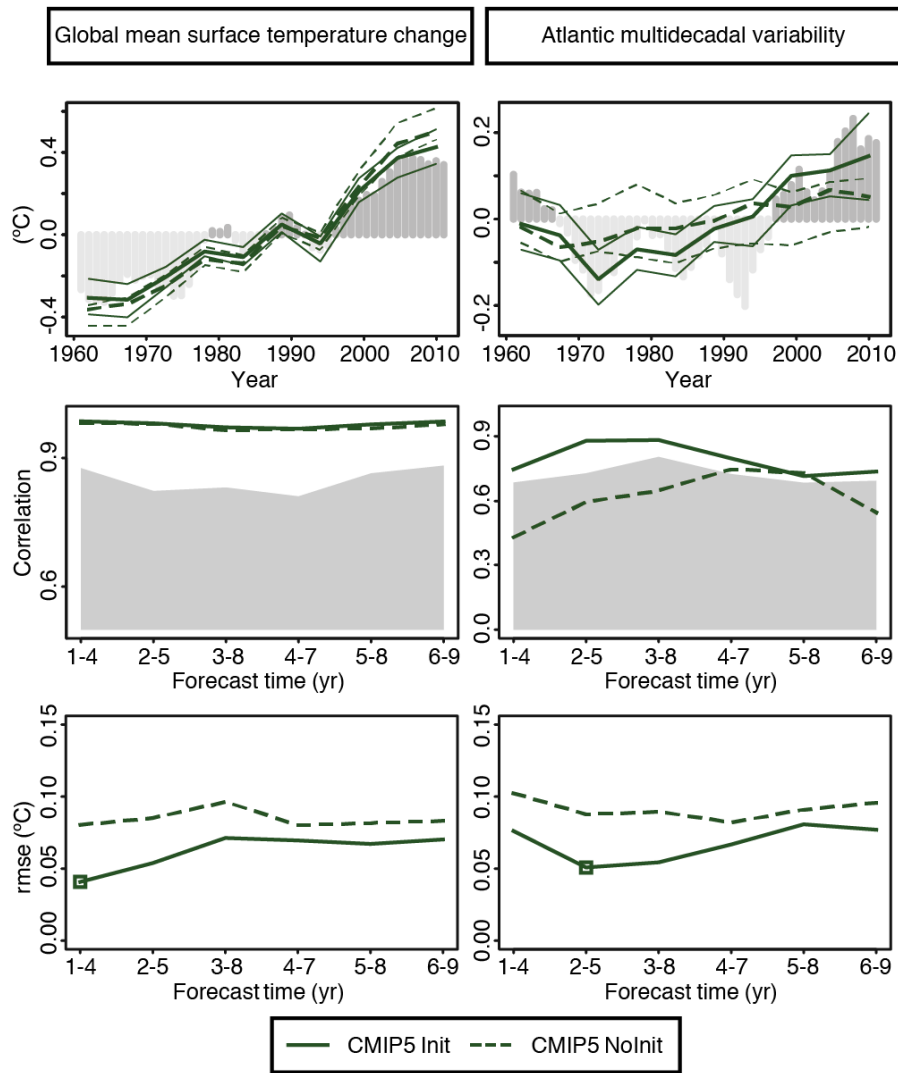

Figure TS.13: Decadal prediction forecast quality of several climate indices. Top row: Time series of the 2–5 year average ensemble-mean initialized hindcast anomalies and the corresponding non-initialized experiments for three climate indices: Global Mean Surface Temperature (GMST, left) and the Atlantic Multidecadal Variability (AMV, right). The observational time series, GISS global-mean temperature and ERSST for the AMV, are represented with dark grey (positive anomalies) and light grey (negative anomalies) vertical bars, where a four-year running mean has been applied for consistency with the time averaging of the predictions. Predicted time series are shown for the CMIP5 Init (solid) and NoInit (dotted) simulations with hindcasts started every five years over the period 1960–2005. The lower and upper quartile of the multi-model ensemble are plotted using thin lines. The AMV index was computed as the sea surface temperature anomalies averaged over the region Equator–60°N and 80°W–0°W minus the sea surface temperature anomalies averaged over 60°S–60°N. Note that the vertical axes are different for each time series. Middle row: Correlation of the ensemble-mean prediction with the observational reference along the forecast time for four-year averages of the three sets of CMIP5 hindcasts for Init (solid) and NoInit (dashed). The one-sided 95% confidence level with a t distribution is represented in grey. The effective sample size has been computed taking into account the autocorrelation of the observational time series. A two-sided t test (where the effective sample size has been computed taking into account the autocorrelation of the observational time series) has been used to test the differences between the correlation of the initialized and non-initialized experiments, but no differences were found statistically significant with a confidence equal or higher than 90%. Bottom row: Root mean square error (RMSE) of the ensemble-mean prediction along the forecast time for four-year averages of the CMIP5 hindcasts for Init (solid) and NoInit (dashed). A two-sided F test (where the effective sample size has been computed taking into account the autocorrelation of the observational time series) has been used to test the ratio between the RMSE of the Init and NoInit, and those forecast times with differences statistically significant with a confidence equal or higher than 90% are indicated with an open square. {Figure 11.3}

Global mean temperature near-term projections relative to 1986–2005

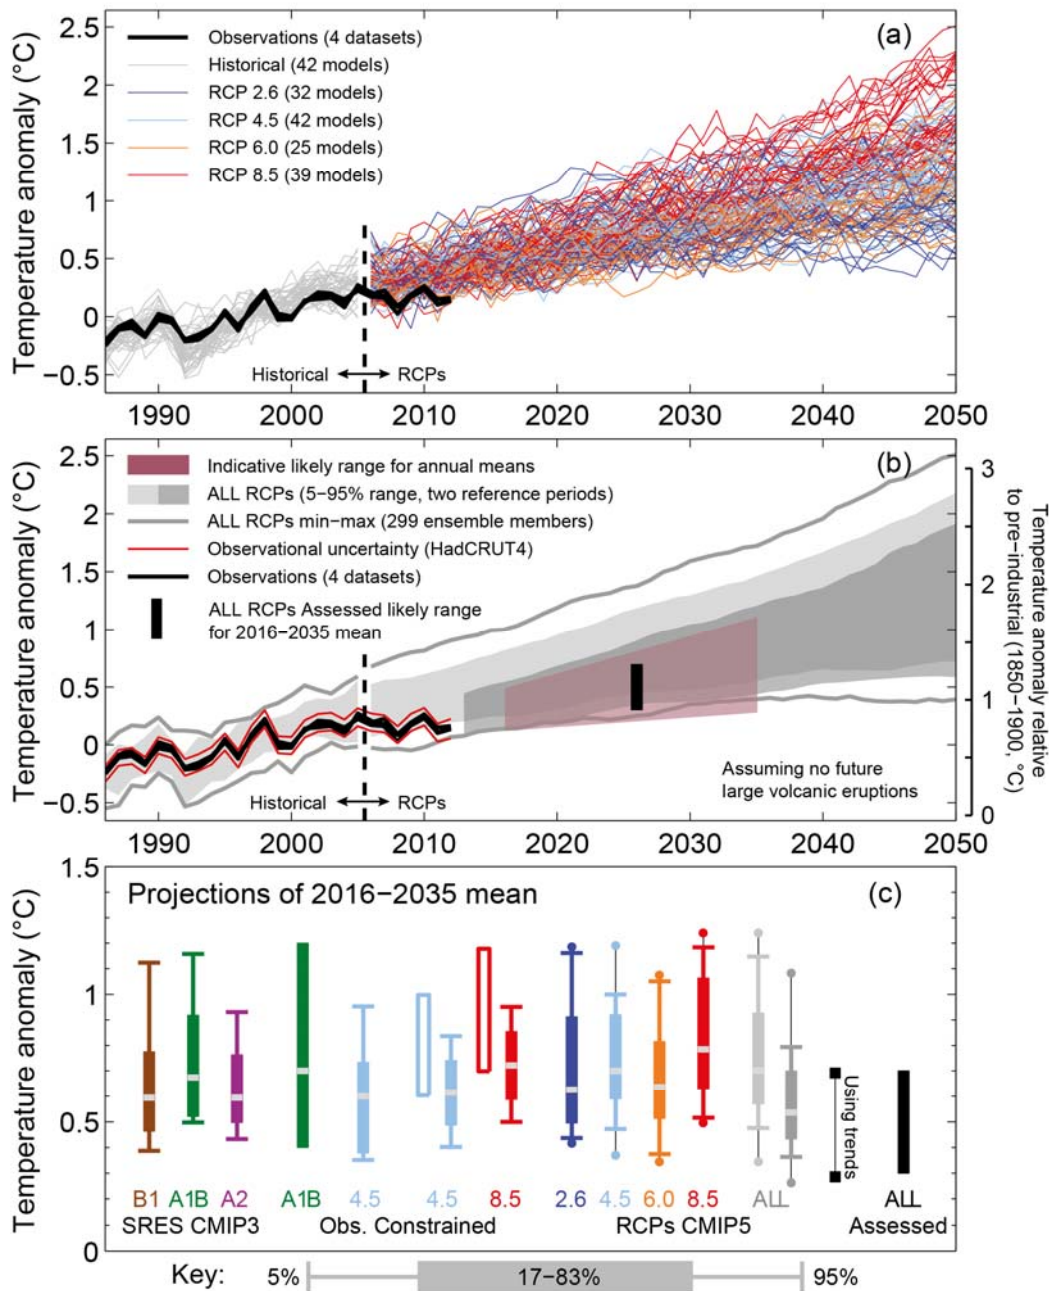

Figure TS.14: Synthesis of near-term projections of global mean surface air temperature (GMST). (a) Projections of annual mean GMST 1986–2050 (anomalies relative to 1986–2005) under all RCPs from CMIP5 models (grey and coloured lines, one ensemble member per model), with four observational estimates (HadCRUT4, ERA-Interim, GISTEMP, NOAA) for the period 1986–2012 (black lines). (b) as (a) but showing the 5–95% range of annual mean CMIP5 projections (using one ensemble member per model) for all RCPs using a reference period of 1986–2005 (light grey shade) and all RCPs using a reference period of 2006–2012, together with the observed anomaly for (2006–2012)–(1986–2005) of 0.16°C (dark grey shade). The percentiles for 2006 onwards have been smoothed with a 5 year running mean for clarity. The maximum and minimum values from CMIP5 using all ensemble members and the 1986–2005 reference period are shown by the grey lines (also smoothed). Black lines show annual mean observational estimates. The red shaded region shows the indicative likely range for annual mean GMST during the period 2016–2035 based on the “ALL RCPs Assessed” likely range for the 20 year mean GMST anomaly for 2016–2035, which is shown as a black bar in both panels (b) and (c) (see text for details). The temperature scale relative to pre-industrial climate on the right hand side assumes a warming of GMST prior to 1986–2005 of 0.61°C estimated from HadCRUT4. (c) A synthesis of projections for the mean GMST anomaly for 2016–2035 relative to 1986–2005. The box and whiskers represent the 66% and 90% ranges. Shown are: unconstrained SRES CMIP3 and RCP CMIP5 projections; observationally

constrained projections for the SRES A1B and, the RCP4.5 and 8.5 scenarios; unconstrained projections for all four RCP scenarios using two reference periods as in panel (b) (light grey and dark grey shades), consistent with panel (b); 90% range estimated using CMIP5 trends for the period 2012–2035 and the observed GMST anomaly for 2012; an overall *likely* (>66%) assessed range for all RCP scenarios. The dots for the CMIP5 estimates show the maximum and minimum values using all ensemble members. The medians (or maximum likelihood estimate; green filled bar) are indicated by a grey band. Adapted from Figure 11.25. See Chapter 11, Section 11.3.6 for details. {Figure 11.25}

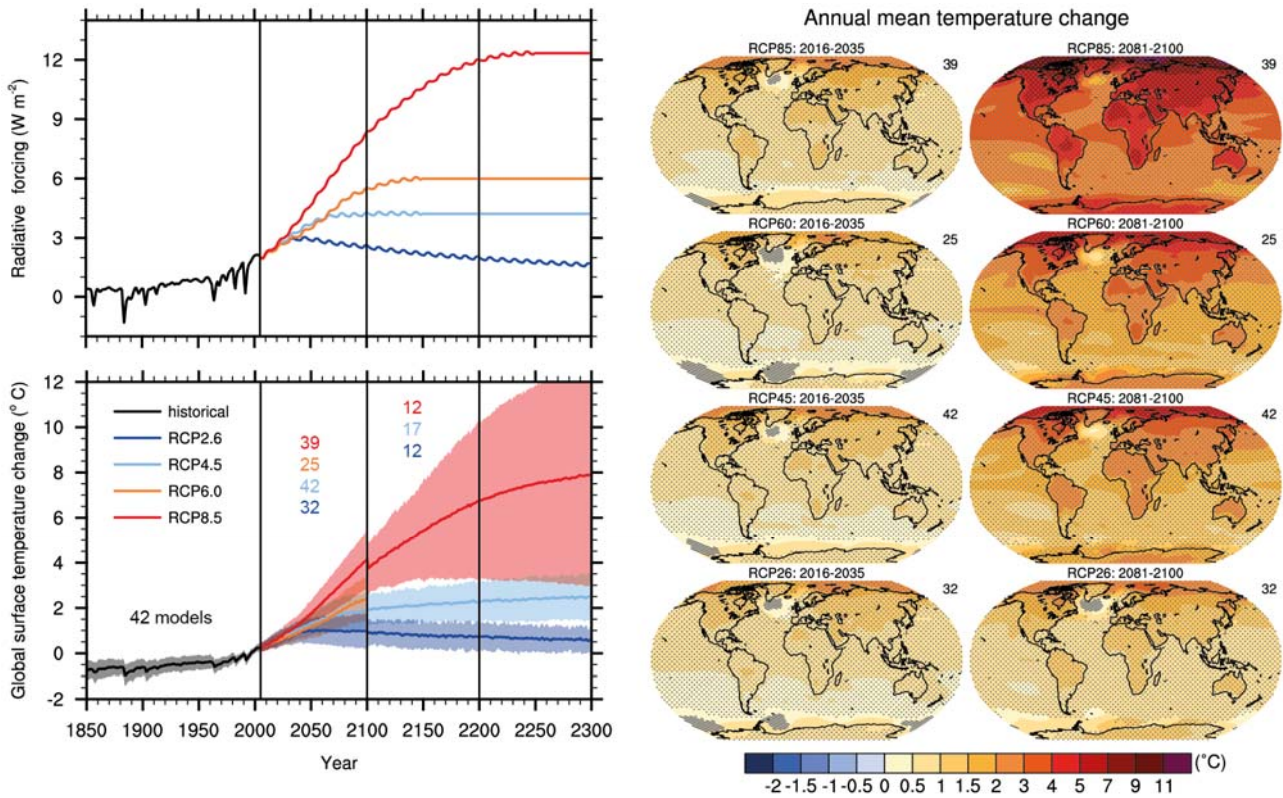

Figure TS.15: Top left: Total global mean radiative forcing for the 4 RCP scenarios based on the MAGICC energy balance model. Note that the actual forcing simulated by the CMIP5 models differs slightly between models. Bottom left: Time series of global annual mean surface air temperature anomalies (relative to 1986–2005) from CMIP5 concentration-driven experiments. Projections are shown for each RCP for the multimodel mean (solid lines) and ± 1.64 standard deviation (5–95%) across the distribution of individual models (shading). Those ranges are interpreted as “likely” changes at the end of the 21st century. Discontinuities at 2100 are due to different numbers of models performing the extension runs beyond the 21st century and have no physical meaning. Numbers in the same colours as the lines indicate the number of different models contributing to the different time periods. Maps: Multimodel ensemble average of annual mean surface air temperature change (compared to 1986–2005 base period) for 2016–2035 and 2081–2100, for RCP2.6, 4.5, 6.0 and 8.5. Hatching indicates regions where the multi model mean signal is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean signal is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change. The number of CMIP5 models used is indicated in the upper right corner of each panel. {Box 12.1; Figures 12.4, 12.5, 12.11; Annex I}

Annual mean precipitation change (2081-2100)

Figure TS.16: Maps of multi-model results for the scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5 in 2081–2100 of average percent change in mean precipitation. Changes are shown relative to 1986–2005. The number of CMIP5 models to calculate the multi-model mean is indicated in the upper right corner of each panel. Hatching indicates regions where the multi model mean signal is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean signal is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). {Figure 12.22; Annex I}

Figure TS.17: Northern Hemisphere sea-ice extent in September over the late 20th century and the whole 21st century for the scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5 in the CMIP5 models, and corresponding maps of multi-model results in 2081–2100 of Northern Hemisphere September sea ice extent. In the time series, the number of CMIP5 models to calculate the multi-model mean is indicated (subset in brackets). Time series are given as 5 year running means. The projected mean sea ice extent of a subset of models that most closely reproduce the climatological mean state and 1979–2012 trend of the Arctic sea ice is given (solid lines), with the min-max range of the subset indicated with shading. Black (grey shading) is the modelled historical evolution using historical reconstructed forcings. The CMIP5 multi-model mean is indicated with dashed lines. In the maps, the CMIP5 multi-model mean is given in white color, the results for the subset in grey colour. Filled areas mark the averages over the 2081–2100 period, lines mark the sea ice extent averaged over the 1986–2005 period. The observed sea ice extent is given in pink as a time series and averaged over 1986–2005 as a pink line in the map. {Figures 12.18, 12.29, 12.31}

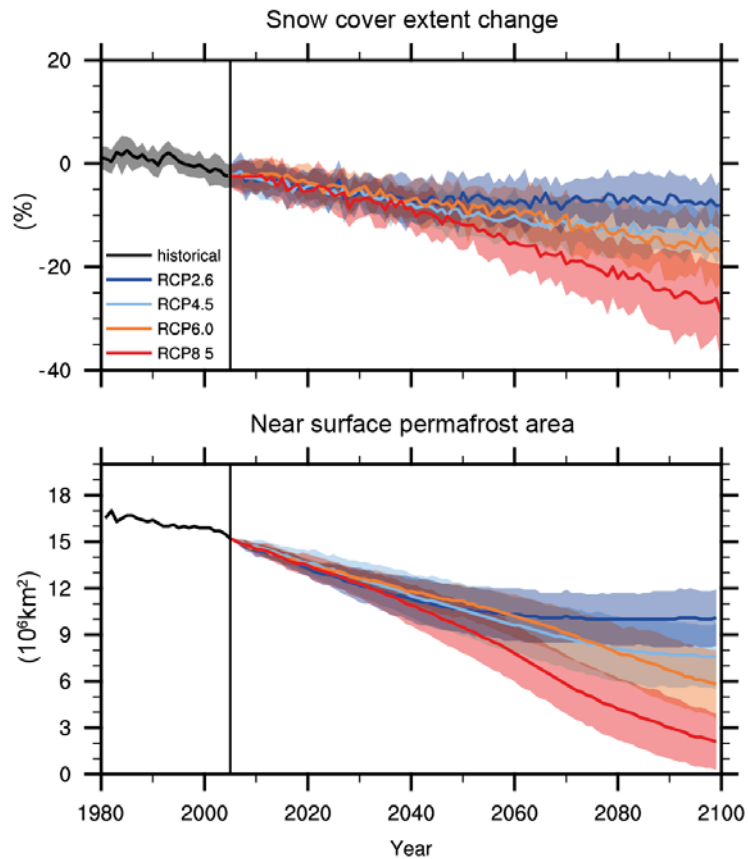

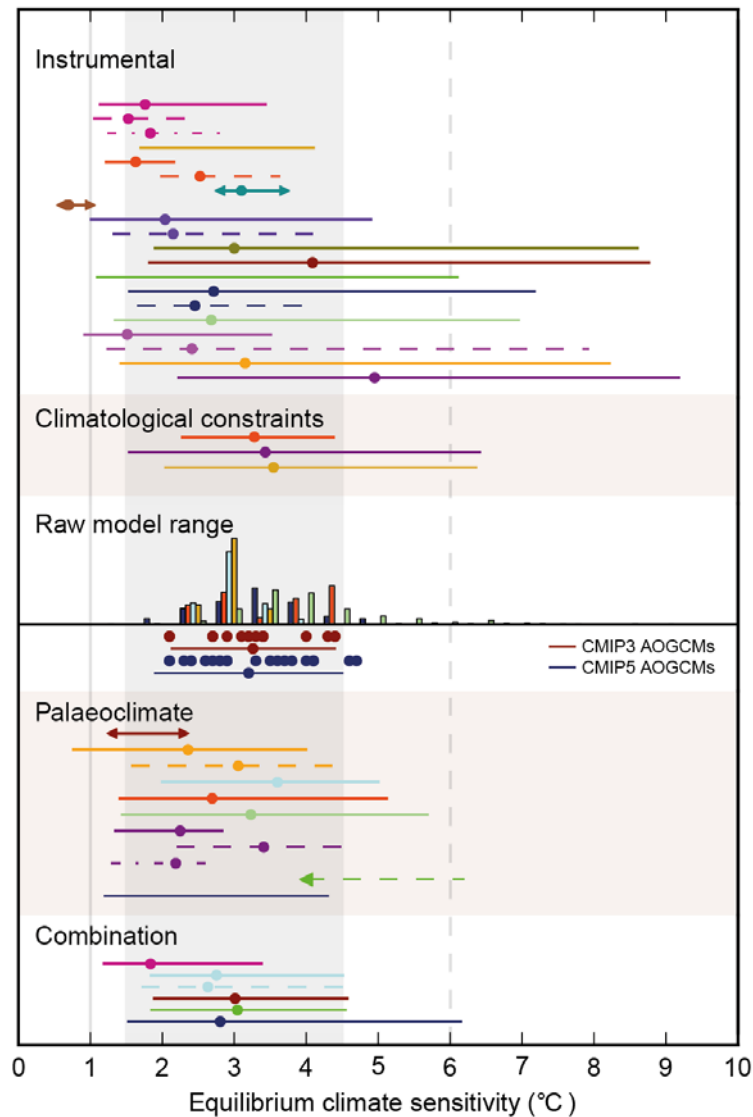

Figure TS.18: Top: Northern Hemisphere spring (March to April average) relative snow covered area (RSCA) in CMIP5, obtained by dividing the simulated 5-year box smoothed spring snow covered area (SCA) by the simulated average spring SCA of 1986–2005 reference period. Bottom: Northern hemisphere diagnosed near-surface permafrost area in CMIP5, using 20-year average monthly surface air temperatures and snow depths. Lines indicate the multi model average, shading indicates the inter-model spread (one standard deviation). {Figures 12.32, 12.33}

TFE.6, Figure 1: Probability density functions, distributions and ranges for equilibrium climate sensitivity, based on Figure 10.20b plus climatological constraints shown in IPCC AR4 (Box AR4 10.2 Figure 1), and results from CMIP5 (see Table 9.5). The grey shaded range marks the *likely* 1.5°C to 4.5°C range, grey solid line the *extremely unlikely* less than 1°C, the grey dashed line the *very unlikely* greater than 6°C. Adapted from Box 12.2, Figure 1. See Figure 10.20b and Chapter 10 Supplementary Material for full caption and details. Labels refer to studies since AR4. {Box 12.2, Figure 1}

TFE.6, Figure 2: Probability density functions, distributions and ranges (5–95%) for the transient climate response from different studies, based on Figure 10.20a, and results from CMIP5 (black histogram, Table 9.5). The grey shaded range marks the *likely* 1°C to 2.5°C range, the grey solid line marks the *extremely unlikely* greater than 3°C. Adapted from Box 12.2, Figure 2. See Figure 10.20a and Chapter 10 Supplementary Material for full caption and details. {Box 12.2, Figure 2}

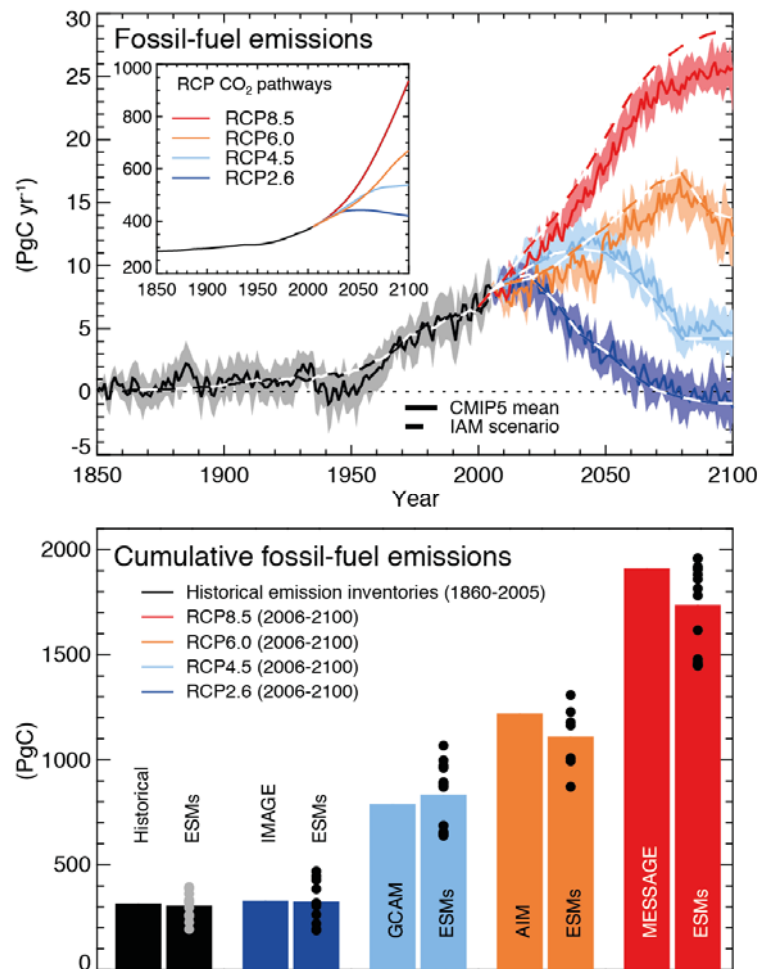

Figure TS.19: Compatible fossil fuel emissions simulated by the CMIP5 models for the four RCP scenarios. Top: timeseries of annual emission (PgC yr^{-1}). Dashed lines represent the historical estimates and RCP emissions calculated by the integrated assessment models (IAM) used to define the RCP scenarios, solid lines and plumes show results from CMIP5 ESMS (model mean, with 1 standard deviation shaded). Bottom: cumulative emissions for the historical period (1860–2005) and 21st century (defined in CMIP5 as 2006–2100) for historical estimates and RCP scenarios. Left bars are cumulative emissions from the IAMs, right bars are the CMIP5 ESMS multi-model mean estimate, and dots denote individual ESMS results. From the CMIP5 ESMS results, total carbon in the land-atmosphere-ocean system can be tracked and changes in this total must equal fossil fuel emissions to the system. Hence the compatible emissions are given by cumulative Emissions = $\Delta C_A + \Delta C_L + \Delta C_O$, while emission rate = $d/dt [C_A + C_L + C_O]$, where C_A , C_L , C_O are carbon stored in atmosphere, land and ocean respectively. Other sources and sinks of CO_2 such as from volcanism, sedimentation or rock weathering, which are very small on centennial timescales are not considered here. {Box 6.4; Figure 6.25}

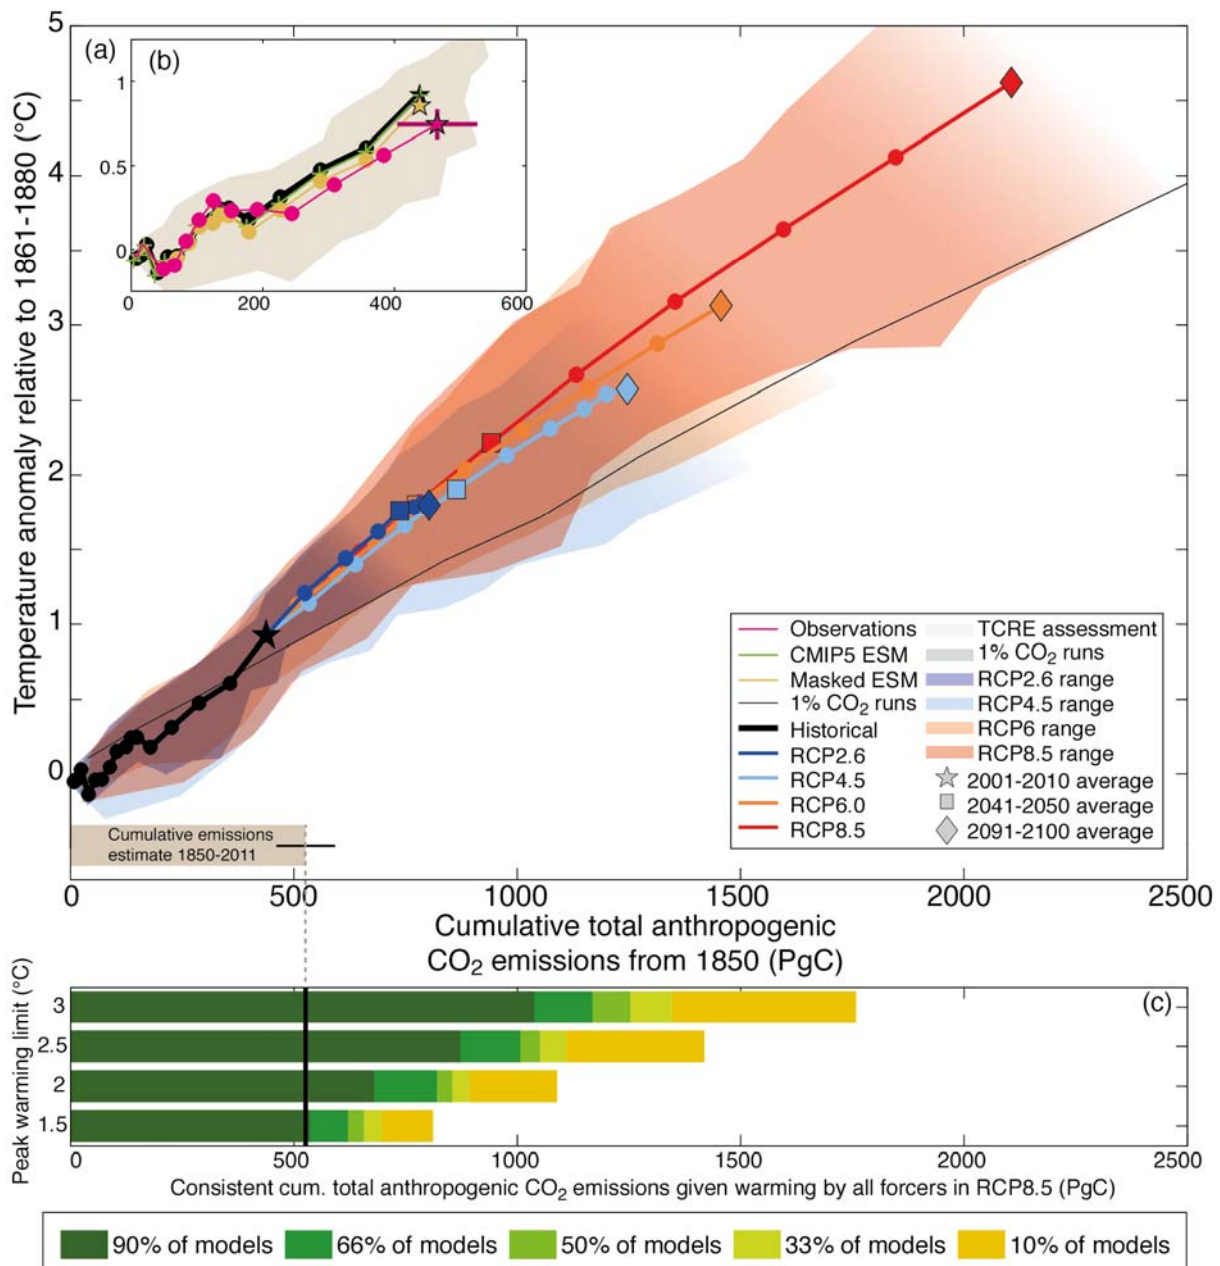

Figure TS.20: (a) Timeseries (model averages and min-max ranges) and (b) maps of multi-model surface ocean pH for the scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5 in 2081–2100. The maps in (b) show change in global ocean surface pH in 2081–2100 relative to 1886–2005. The number of CMIP5 models to calculate the multi-model mean is indicated in the upper right corner of each panel. {Figure 6.28}

TFE.7, Figure 1: Percentage of initial atmospheric CO₂ perturbation remaining in the atmosphere in response to an idealized instantaneous CO₂ emission pulse in year 0 as calculated by a range of coupled climate-carbon cycle models. Multi-model mean (blue line) and the uncertainty interval (± 2 standard deviations, shading) simulated during 100 years (left panel) and 1,000 years (right panel) following the instantaneous emission pulse of 100 PgC. (adapted from Box 6.1, Figure 1). {Box 6.1}

TFE.7, Figure 2: Comparison of carbon cycle feedback metrics between the ensemble of 7 GCMs and 4 EMICs at the time of AR4 (C⁴MIP) under the SRES-A2 scenario and the 8 CMIP5 models under the 140-year 1% CO₂ increase per year scenario. Black dots represent a single model simulation and coloured bars the mean of the multi-model results, grey dots are used for models with a coupled terrestrial nitrogen cycle. The comparison with C⁴MIP models is for context, but these metrics are known to be variable across different scenarios and rates of change (see Section 6.4.2.2). The SRES A2 scenario is closer in rate of change to a 0.5% CO₂ increase per year scenario and as such it should be expected that the CMIP5 climate-carbon sensitivity terms are comparable, but the concentration-carbon sensitivity terms are likely to be around 20% smaller for CMIP5 than for C⁴MIP due to lags in the ability of the land and ocean to respond to higher rates of CO₂ increase. This dependence on scenario reduces confidence in any quantitative statements of how CMIP5 carbon cycle feedbacks differ from C⁴MIP. {6.4.2}

TFE.8, Figure 1: Global mean temperature increase since 1861–1880 as a function of cumulative total global CO₂ emissions from various lines of evidence. (a) Decadal average results are shown over all CMIP5 EMIC and ESMs for each RCP respectively, with coloured lines (multi-model average), decadal markers (dots) and with three decades (2001–2010, 2041–2050 and 2091–2100) highlighted with a star, square and diamond, respectively. The historical time period up to decade 2001–2010 is taken from the CMIP5 historical runs prolonged by RCP8.5 for 2005–2010 and is indicated with a black thick line and black symbols. Coloured ranges illustrate the model spread (90% range) over all CMIP5 ESMs and EMICs and do not represent a formal uncertainty assessment. Ranges are filled as long as data of all models is available and until peak temperature. They are faded out for illustrative purposes afterward. CMIP5 simulations with 1% yr⁻¹ CO₂ increase only are illustrated by the dark grey area (range definition similar to RCPs above) and the black thin line (multi-model average). The light grey cone represents this report’s assessment of the transient climate response to emissions (TCRE) from CO₂ only. Estimated cumulative historical CO₂ emissions from 1850 to 2011 with associated uncertainties are illustrated by the grey bar at the bottom of panel a. (b) Comparison of historical model results with observations. The magenta line and uncertainty ranges are based on observed emissions from CDIAC extended by values of the Global Carbon project until 2010 and observed temperature estimates of HadCRUT4. The uncertainties in the last decade of observations are based on the assessment in this report. The black thick line is identical to the one in panel a. The thin green line with crosses is as the black line but for ESMs only. The yellow-brown line and range show these ESM results until 2010, when corrected for HadCRUT4’s incomplete geographical coverage over time. All values are given relative to the 1861–1880 base period. All time-series are derived

from decadal averages to illustrate the long-term trends. Note that observations are in addition subject to internal climate variability, adding an uncertainty of about 0.1°C. (c) Cumulative CO₂ emissions over the entire industrial era, consistent with four illustrative peak global temperature limits (1.5°C, 2°C, 2.5°C, and 3°C, respectively) when taking into account warming by all forcings. Horizontal bars indicate consistent cumulative emission budgets as a function of the fraction of models (CMIP5 ESMs and EMICs) that at least hold warming below a given temperature limit. Note that the fraction of models cannot be interpreted as a probability. The budgets are derived from the RCP8.5 runs, with relative high non-CO₂ forcing over the 21st century. If non-CO₂ are significantly reduced, the CO₂ emissions compatible with a specific temperature limit might be slightly higher, but only to a very limited degree, as illustrated by the other coloured lines in panel a, which assume significantly lower non-CO₂ forcing. {Figure 12.45}

Figure TS.21: Projections from process-based models with *likely* ranges and median values for global mean sea level rise and its contributions in 2081–2100 relative to 1986–2005 for the four RCP scenarios and scenario SRES A1B used in the AR4. The contributions from ice sheets include the contributions from ice-sheet rapid dynamical change, which are also shown separately. The contributions from ice-sheet rapid dynamics and anthropogenic land water storage are treated as having uniform probability distributions, and as independent of scenario (except that a higher rate of change is used for Greenland ice-sheet outflow under RCP8.5). This treatment does not imply that the contributions concerned will not depend on the scenario followed, only that the current state of knowledge does not permit a quantitative assessment of the dependence. See discussion in Sections 13.5.1 and 13.5.3 and Supplementary Material for methods. Based on current understanding, only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause global mean sea level to rise substantially above the *likely* range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter during the 21st century. {Figure 13.10}

Figure TS.22: Projections from process-based models of global mean sea level rise relative to 1986–2005 for the four emissions scenarios RCP2.6, RCP4.5, RCP6.0 and RCP8.5. The solid lines show the median projections, the dashed lines show the *likely* ranges for RCP4.5 and RCP6.0, and the shading the *likely* ranges for RCP2.6 and RCP8.5. The time means for 2081–2100 are shown as coloured vertical bars. See Sections 13.5.1 and 13.5.3 and Supplementary Material for methods. Based on current understanding, only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause global mean sea level to rise substantially above the *likely* range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter during the 21st century. {Table 13.5; Figures 13.10, 13.11}

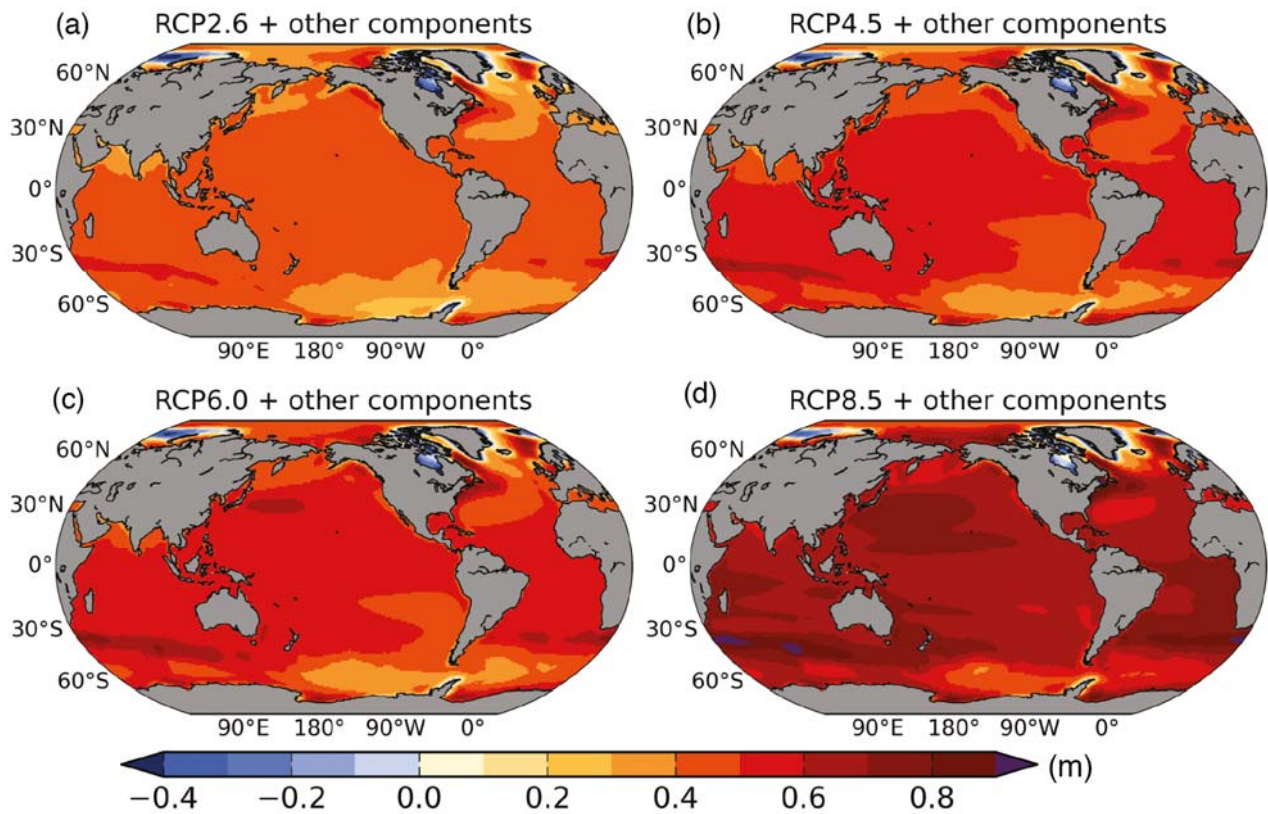

Figure TS.23: Ensemble mean net regional sea level change (m) evaluated from 21 CMIP5 models for the RCP scenarios (a) 2.6, (b) 4.5, (c) 6.0 and (d) 8.5 between 1986–2005 and 2081–2100. Each map includes effects of atmospheric loading, plus land-ice, GIA and terrestrial water sources. {Figure 13.20}

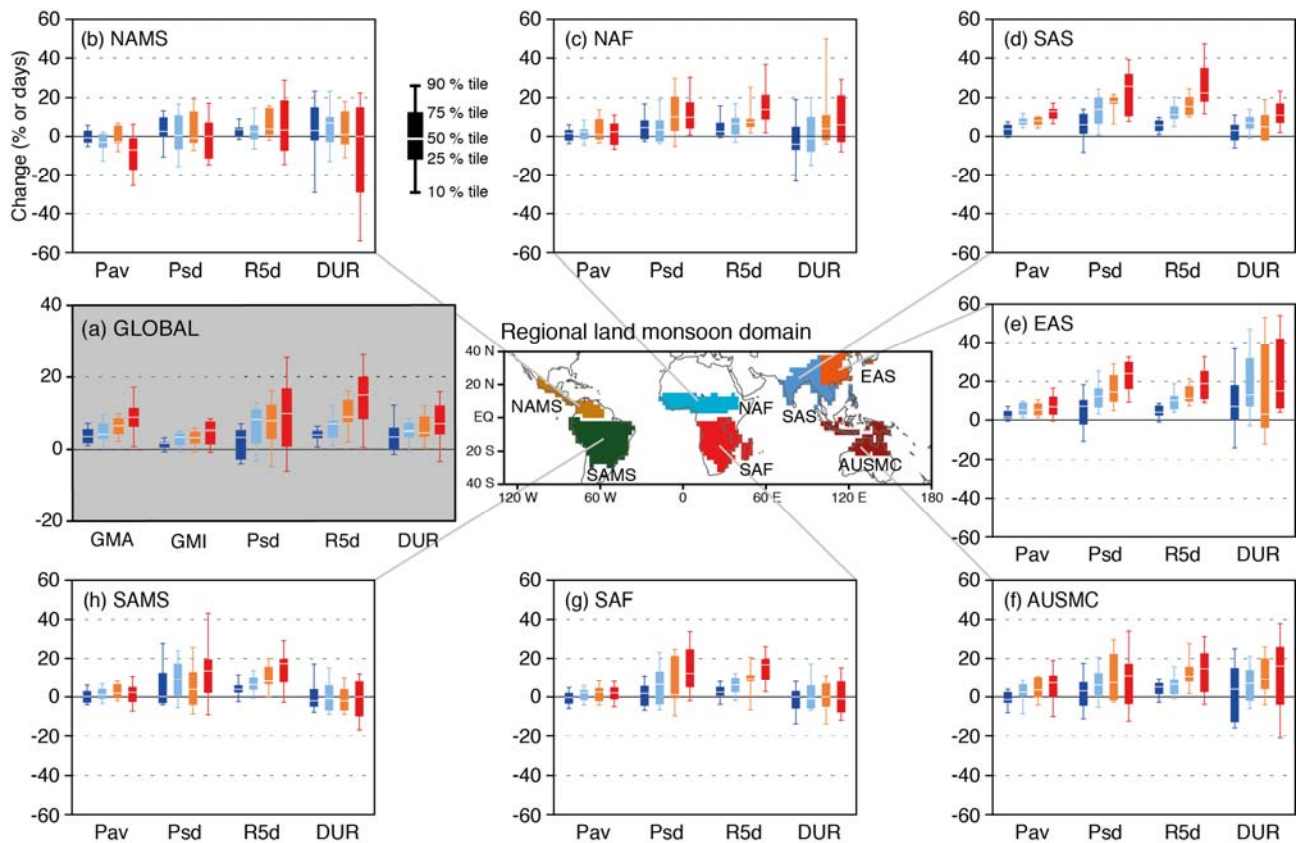

Figure TS.24: Future change in monsoon statistics between the present-day (1986–2005) and the future (2080–2099) based on CMIP5 ensemble from RCP2.6 (dark blue; 19 models), RCP4.5 (blue; 24), RCP6.0 (yellow; 14), and RCP8.5 (red; 24) simulations. (a) GLOBAL: Global monsoon area (GMA), global monsoon intensity (GMI), standard deviation of inter-annual variability in seasonal precipitation (Psd), seasonal maximum 5-day precipitation total (R5d), and monsoon season duration (DUR). Regional land monsoon domains determined by 24 multi-model mean precipitation in the present-day. (b)–(h) Future change in regional land monsoon statistics: seasonal average precipitation (Pav), Psd, R5d, and DUR in (b) North America (NAMS), (c) North Africa (NAF), (d) South Asia (SAS), (e) East Asia (EAS), (f) Australia-Maritime continent (AUSMC), (g) South Africa (SAF), and (h) South America (SAMS). Units are % except for DUR (days). Box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles. All the indices are calculated for the summer season (May–September for the Northern, and November–March for the Southern Hemisphere) over each model’s monsoon domains. {Figures 14.3, 14.4, 14.6, 14.7}

Figure TS.25: Standard deviation in CMIP5 multi-model ensembles of sea surface temperature variability over the eastern equatorial Pacific Ocean (Niño3 region: 5°S–5°N, 150°W–90°W), a measure of El Niño amplitude, for the pre-industrial (PI) control and 20th century (20C) simulations, and 21st century projections using RCP4.5 and RCP8.5. Open circles indicate multi-model ensemble means, and the red cross symbol is the observed standard deviation for the 20th century. Box-whisker plots show the 16th, 25th, 50th, 75th, and 84th percentiles. {Figure 14.14}

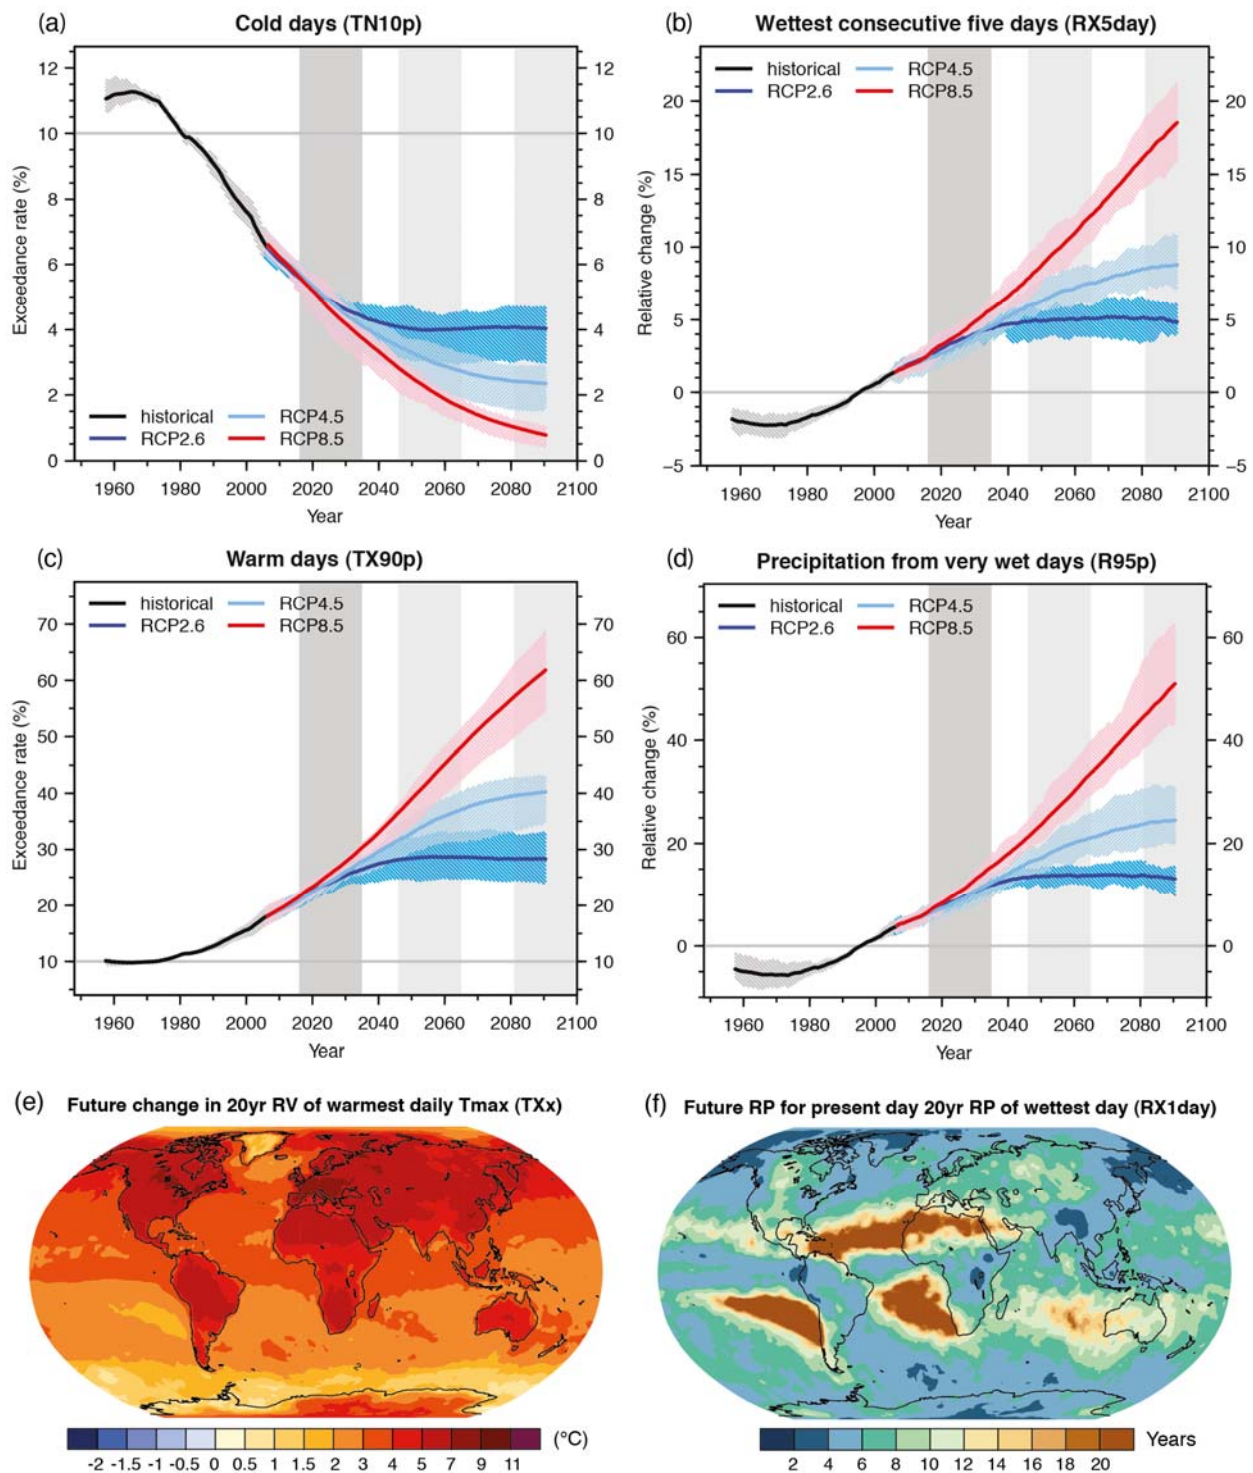

Figure TS.26: Projected changes in tropical cyclone statistics. All values represent expected percent change in the average over period 2081–2100 relative to 2000–2019, under an A1B-like scenario, based on expert judgment after subjective normalisation of the model projections. Four metrics were considered: the percent change in I) the total annual frequency of tropical storms, II) the annual frequency of Category 4 and 5 storms, III) the mean Lifetime Maximum Intensity (LMI; the maximum intensity achieved during a storm’s lifetime), and IV) the precipitation rate within 200 km of storm center at the time of LMI. For each metric plotted, the solid blue line is the best guess of the expected percent change, and the coloured bar provides the 67% (likely) confidence interval for this value (note that this interval ranges across –100% to +200% for the annual frequency of Category 4 and 5 storms in the North Atlantic). Where a metric is not plotted, there is insufficient data (denoted “X”) available to complete an assessment. A randomly drawn (and coloured) selection of historical storm tracks are underlaid to identify regions of tropical cyclone activity. See Section 14.6.1 for details. {14.6.1}

TFE.9, Figure 1: Global projections of the occurrence of (a) cold days (TN10p)- percentage of days annually with daily maximum surface air temperature (Tmax) below the 10th percentile of Tmax for 1961 to 1990, (b) wettest consecutive 5 days (RX5day) - percentage change in annual maximum consecutive 5-day precipitation totals, (c) warm days (TX90p)-percentage of days annually with daily maximum surface air temperature (Tmax) exceeding the 90th percentile of Tmax for 1961 to 1990 and (d) very wet day precipitation (R95p) - percentage change relative to 1986–2005 of annual precipitation from days >95th percentile. Results are shown from CMIP5 for the RCP2.6, RCP4.5 and RCP8.5 scenarios. Solid lines indicate the ensemble median and shading indicates the interquartile spread between individual projections (25th and 75th percentiles). Maps show (e) the change from 1986–2005 to 2081–2100 in twenty year return values (RV) of daily maximum temperatures, TXx, and (f) the 2081–2100 return period (RP) for rare daily precipitation values, RX1day, that have a 20 year return period during 1986–2005. Both maps are based on the CMIP5 RCP8.5 scenario. See Box 2.4, Table 1 for index definitions. {Figures 11.17, 12.13, 12.26}

Executive Summary

Human Effects on Climate

Human activities are continuing to affect the Earth's energy budget by changing the emissions and resulting atmospheric concentrations of radiatively important gases and aerosols and by changing land surface properties. Previous assessments have already shown through multiple lines of evidence that the climate is changing across our planet, largely as a result of human activities. The most compelling evidence of climate change derives from observations of the atmosphere, land, oceans, and cryosphere. Unequivocal evidence from in situ observations and ice core records shows that the atmospheric concentrations of important greenhouse gases such as carbon dioxide, methane, and nitrous oxides have increased over the last few centuries. [1.2.2, 1.2.3]

The processes affecting climate can exhibit considerable natural variability. Even in the absence of external forcing, periodic and chaotic variations on a vast range of spatial and temporal scales are observed. Much of this variability can be represented by simple (e.g., unimodal or power law) distributions, but many components of the climate system also exhibit multiple states – for instance, the glacial-interglacial cycles and certain modes of internal variability such as El Niño-Southern Oscillation (ENSO). Movement between states can occur as a result of natural variability, or in response to external forcing. The relationship between variability, forcing and response reveals the complexity of the dynamics of the climate system: the relationship between forcing and response for some parts of the system seems reasonably linear; in other cases this relationship is much more complex. [1.2.2]

Multiple Lines of Evidence for Climate Change

Global mean surface air temperatures over land and oceans have increased over the last 100 years. The temperature measurements in the oceans show a continuing increase in the heat content of the oceans. Analyses based on measurements of the Earth's radiative budget suggest a small positive energy imbalance that serves to increase the global heat content of the Earth system. Observations from satellites and in situ measurements show a trend of significant reductions in the mass balance of most land ice masses and in Arctic sea ice. The ocean's uptake of carbon dioxide is having a significant effect on the chemistry of sea water. Paleoclimatic reconstructions have helped place ongoing climate change in the perspective of natural climate variability. [1.2.3; Figure 1.3]

Observations of carbon dioxide (CO₂) concentrations, globally-averaged temperature and sea level rise are generally well within the range of the extent of the earlier IPCC projections. The recently observed increases in methane (CH₄) and nitrous oxide (N₂O) concentrations are smaller than those assumed in the scenarios in the previous assessments. Each IPCC assessment has used new projections of future climate change that have become more detailed as the models have become more advanced. Similarly, the scenarios themselves used in the IPCC assessments have changed over time to reflect the state of knowledge. The range of climate projections from model results provided and assessed in the first IPCC assessment in 1990 to those in the 2007 AR4 provides an opportunity to compare the projections with the actually observed changes, thereby examining the deviations of the projections from the observations over time. [1.3.1, 1.3.2, 1.3.4, Figure 1.4, Figure 1.5, Figure 1.6, Figure 1.7, Figure 1.10]

Climate change, whether driven by natural or human forcing, can lead to changes in the likelihood of the occurrence or strength of extreme weather and climate events or both. Since the AR4, the observational basis has increased substantially, so that some extremes are now examined over most land areas. Furthermore, more models with higher resolution and more regional models have been used in the simulations and projections of extremes. [1.3.3, Figure 1.9]

Treatment of Uncertainties

For AR5, the three IPCC Working Groups use two metrics to communicate the degree of certainty in key findings: (1) Confidence is a qualitative measure of the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, expert judgment) and the

degree of agreement¹; and, (2) Likelihood provides a quantified measure of uncertainty in a finding expressed probabilistically (e.g., based on statistical analysis of observations or model results)². [1.4, Figure 1.11]

Advances in Measurement and Modelling Capabilities

Over the last few decades, new observational systems, especially satellite-based systems, have increased the number of observations of the Earth's climate by orders of magnitude. Tools to analyse and process these data have been developed or enhanced to cope with this large increase in information, and more climate proxy data have been acquired to improve our knowledge of past changes in climate. Since the Earth's climate system is characterized on multiple spatial and temporal scales, new observations may reduce the uncertainties surrounding the understanding of short timescale processes quite rapidly. However, processes that occur over longer timescales may require very long observational baselines before much progress can be made. [1.5.1, Figure 1.12]

Increases in computing speed and memory have led to the development of more sophisticated models, which describe physical, chemical, and biological processes in greater detail. Modelling strategies have been extended to provide better estimates of the uncertainty in climate change projections. The model comparisons with observations have pushed the analysis and development of the models. The incorporation of "long-term" simulations has allowed incorporation of information from paleoclimate data to inform projections. Within uncertainties associated with reconstructions of past climate variables from proxy record and forcings, paleoclimate information from the Mid Holocene, Last Glacial Maximum, and Last Millennium have been used to test the ability of models to simulate realistically the magnitude and large scale patterns of past changes. [1.5.2, Figure 1.13, Figure 1.14]

As part of the process of getting model analyses for a range of alternative images of how the future may unfold, four new scenarios for future emissions of important gases and aerosols have been developed for the AR5, referred to as Representative Concentration Pathways (RCPs). [Box 1.1]

¹ In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

² In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

1.1 Chapter Preview

This introductory chapter serves as a lead-in to the science presented in the Working Group I (WGI) contribution to the Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5). Chapter 1 in the IPCC Fourth Assessment Report (AR4) (Le Treut et al., 2007) provided a historical perspective on the understanding of climate science and the evidence regarding human influence on the Earth's climate system. Since the last assessment, the scientific knowledge gained through observations, theoretical analyses, and modelling studies has continued to increase and to further strengthen the evidence linking human activities to the ongoing climate change. In AR5, Chapter 1 focuses on the concepts and definitions applied in the discussions of new findings in the other chapters. It also examines several of the key indicators for a changing climate, and shows how the current knowledge of those indicators compares with the projections made in previous assessments. The new scenarios for projected human-related emissions used in this assessment are also introduced. Finally, the chapter discusses the directions and capabilities of current climate science, while the detailed discussion of new findings is covered in the remainder of the WGI contribution to the AR5.

1.2 Rationale and Key Concepts of the WGI Contribution

1.2.1 *Setting the Stage for the Assessment*

The IPCC was set up in 1988 by the World Meteorological Organization and the United Nations Environment Programme to provide governments with a clear view of the current state of knowledge about the science of climate change, potential impacts, and options for adaptation and mitigation through regular assessments of the most recent information published in the scientific, technical and socio-economic literature worldwide. The WGI contribution to the IPCC AR5 assesses the current state of the physical sciences with respect to climate change. This report presents an assessment of the current state of research results and is not a discussion of all relevant papers as would be included in a review. It thus seeks to make sure that the range of scientific views, as represented in the peer-reviewed literature, is considered and evaluated in the assessment, and that the state of the science is concisely and accurately presented. A transparent review process ensures that disparate views are included (IPCC, 2012a).

As an overview, Table 1.1 shows a selection of key findings from earlier IPCC assessments. This table provides a non-comprehensive selection of key assessment statements from previous assessment reports (IPCC First Assessment Report (FAR, IPCC, 1990), IPCC Second Assessment Report (SAR, IPCC, 1996), IPCC Third Assessment Report (TAR, IPCC, 2001) and IPCC Fourth Assessment Report (AR4, IPCC, 2007) with a focus on policy relevant quantities that have been evaluated in each of the IPCC assessments.

Scientific hypotheses are contingent and always open to revision in the light of new evidence and theory. In this sense the distinguishing features of scientific enquiry are the search for truth and the willingness to subject itself to critical re-examination. Modern research science conducts this critical revision through processes such as the peer review. At conferences and in the procedures that surround publication in peer-reviewed journals, scientific claims about environmental processes are analysed and held up to scrutiny. Even after publication, findings are further analysed and evaluated. That is the self-correcting nature of the scientific process (more details are given in AR4 Chapter 1; Le Treut et al., 2007).

Science strives for objectivity, but inevitably also involves choices and judgments. Scientists make choices regarding data and models, which processes to include and which to leave out. Usually these choices are uncontroversial and play only a minor role in the production of research. Sometimes, however, the choices scientists make are sources of disagreement and uncertainty. These are usually resolved by further scientific enquiry into the sources of disagreement. In some cases, experts cannot agree on a consensus view. Examples in climate science include how best to evaluate climate models relative to observations, how best to evaluate potential sea level rise, and how to evaluate probabilistic projections of climate change. In many cases there may be no definitive solution to these questions. The IPCC process is aimed at assessing the literature as it stands, and attempts to reflect the level of reasonable scientific consensus as well as disagreement.

In order to assess areas of scientific controversy, the peer-reviewed literature is considered and evaluated. Not all papers on a controversial point can be discussed individually in an assessment, but every effort has been made here to ensure that all views represented in the peer-reviewed literature are considered in the assessment process. A list of topical issues is given in Table 1.3.

The Earth sciences study the multitude of processes that shape our environment. Some of these processes can be understood through idealized laboratory experiments, altering a single element and then tracing through the effects of that controlled change. However, in common with other natural and the social sciences, the openness of environmental systems, in terms of our lack of control of the boundaries of the system, their spatially and temporally multi-scale character and the complexity of interactions, often hamper scientists' ability to definitively isolate causal links. This in turn places important limits on the understanding of many of the inferences in the Earth sciences (e.g., Oreskes et al., 1994). There are many cases where scientists are able to make inferences using statistical tools with considerable evidential support and with high degrees of confidence and conceptual and numerical modelling can assist in forming understanding and intuition about the interaction of dynamic processes.

[INSERT TABLE 1.1 HERE]

Table 1.1: Historical overview of major conclusions of previous IPCC assessment reports. The table provides a non-comprehensive selection of key statements from previous assessment reports (IPCC First Assessment Report (FAR; IPCC, 1990), IPCC Second Assessment Report (SAR; IPCC, 1996), IPCC Third Assessment Report (TAR; IPCC, 2001) and IPCC Fourth Assessment Report (AR4; IPCC, 2007)) with a focus on global mean surface air temperature and sea level change as two policy relevant quantities which have been covered in IPCC since the first assessment report.

1.2.2 Key Concepts in Climate Science

Here, some of the key concepts in climate science are briefly described; many of these were summarized more comprehensively in earlier IPCC assessments (Baede et al., 2001). We only focus on several of them to facilitate discussions in this assessment.

First of all, it is important to distinguish the meaning of weather from climate. Weather describes the conditions of the atmosphere at a certain place and time with reference to temperature, pressure, humidity, wind, and other key parameters (meteorological elements), the presence of clouds, precipitation, and the occurrence of special phenomena, such as thunderstorms, dust storms, tornados, etc. Climate in a narrow sense is usually defined as the average weather, or more rigorously, as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years. The relevant quantities are most often surface variables such as temperature, precipitation and wind. The classical period for averaging these variables is 30 years, as defined by the World Meteorological Organization. Climate in a wider sense also includes not just the mean conditions, but also the associated statistics (frequency, magnitude, persistence, trends, etc.), often combining parameters to describe phenomena such as droughts. Climate change refers to a change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer.

The Earth's climate system is powered by solar radiation (Figure 1.1). Approximately half of the energy from the Sun is supplied in the visible part of the electromagnetic spectrum. As the Earth's temperature has been relatively constant over many centuries, the incoming solar energy must be nearly in balance with outgoing radiation. Of the incoming solar shortwave radiation (SWR), about half is absorbed by the Earth's surface. The fraction of SWR reflected back to space by gases and aerosols, clouds and by the Earth's surface (albedo) is approximately 30%, and about 20% is absorbed in the atmosphere. Based on the temperature of the Earth's surface the majority of the outgoing energy flux from the Earth is in the infrared part of the spectrum. The longwave radiation (LWR, also referred to as infrared radiation) emitted from the Earth's surface is largely absorbed by certain atmospheric constituents (water vapour, carbon dioxide; CO₂, methane (CH₄), nitrous oxide (N₂O) and other greenhouse gases (GHG; see Annex III for Glossary)) and clouds, which themselves emit longwave radiation into all directions. The downward directed component of this LWR adds heat to the lower layers of the atmosphere and to the Earth's surface (greenhouse effect). The dominant energy loss of the infrared radiation from the Earth is from higher layers of the troposphere. The

Sun primarily provides its energy to the Earth in the tropics and the subtropics; this energy is then partially redistributed to middle and high latitudes by atmospheric and oceanic transport processes.

Changes in the global energy budget derive from either changes in the net incoming solar radiation or changes in the outgoing longwave radiation (OLR). Changes in the net incoming solar radiation derive from changes in the Sun's output of energy or changes in the Earth's albedo. Reliable measurements of total solar irradiance (TSI) can be made only from space and the precise record extends back only to 1978. The generally accepted mean value of the TSI is about 1361 W m^{-2} (Kopp and Lean, 2011; see Chapter 8 for a detailed discussion on the TSI); this is lower than the previous value of 1365 W m^{-2} used in the earlier assessments. Short-term variations of a few tenths of a percent are common during the approximately 11-year sunspot solar cycle (see Section 5.2 and Section 8.4 for further details). Changes in the outgoing LWR can result from changes in the temperature of the Earth's surface or atmosphere or changes in the emissivity (measure of emission efficiency) of LWR from either the atmosphere or the Earth's surface. For the atmosphere, these changes in emissivity are due predominantly to changes in cloud cover and cloud properties, in greenhouse gases, and in aerosol concentrations. The radiative energy budget of the Earth is almost in balance (Figure 1.1), but ocean heat content and satellite measurements indicate a small positive imbalance (Murphy et al., 2009; Trenberth et al., 2009; Hansen et al., 2011) that is consistent with the rapid changes in the atmospheric composition.

In addition, some aerosols increase atmospheric reflectivity, while others (e.g., particulate black carbon) are strong absorbers and also modify SWR (see Section 7.3 for a detailed assessment). Indirectly, aerosols also affect cloud albedo, because many aerosols serve as cloud condensation nuclei or ice nuclei. This means that changes in aerosol types and distribution can result in small but important changes in cloud albedo and lifetime (Section 7.4). Clouds play a critical role in climate, since they can not only increase albedo, thereby cooling the planet, but they are also important because of their warming effects through infrared radiative transfer. Whether the net radiative effect of a cloud is one of cooling or of warming depends on its physical properties (level of occurrence, vertical extent, water path and effective cloud particle size) as well as on the nature of the cloud condensation nuclei population (Section 7.3). Humans enhance the greenhouse effect directly by emitting greenhouse gases such as CO_2 , CH_4 , N_2O , and chlorofluorocarbons (CFC) (Figure 1.1). In addition, pollutants such as carbon monoxide (CO), volatile organic compounds (VOC), nitrogen oxides (NO_x) and sulfur dioxide (SO_2), which by themselves are negligible GHGs, have an indirect effect on the greenhouse effect by altering, through atmospheric chemical reactions, the abundance of important gases to the amount of outgoing LWR such as CH_4 and ozone (O_3), and/or by acting as precursors of secondary aerosols. Since anthropogenic emission sources simultaneously can emit some chemicals that affect climate and others that affect air pollution, including some that affect both, atmospheric chemistry and climate science are intrinsically linked.

In addition to changing the atmospheric concentrations of gases and aerosols, humans are affecting both the energy and water budget of the planet by changing the land surface including redistributing the balance between latent and sensible heat fluxes (Sections 2.5, 7.2, 7.6 and 8.2). Land use changes, such as the conversion of forests to cultivated land, change the characteristics of vegetation, including its colour, seasonal growth and carbon content (Houghton, 2003; Foley et al., 2005). For example, clearing and burning a forest to prepare agricultural land reduces carbon storage in the vegetation, adds CO_2 to the atmosphere, and changes the reflectivity of the land (surface albedo), rates of evapotranspiration and longwave emissions (Figure 1.1).

Changes in the atmosphere, land, ocean, biosphere and cryosphere—both natural and anthropogenic—can perturb the Earth's radiation budget, producing a radiative forcing (RF) that affects climate. RF is a measure of the net change in the energy balance in response to an external perturbation. The drivers of changes in climate can include, for example, changes in the solar irradiance and changes in atmospheric trace gas and aerosol concentrations (Figure 1.1). The concept of RF cannot capture the interactions of anthropogenic aerosols and clouds, for example, and thus in addition to the RF as used in previous assessments, Sections 7.4 and 8.1 introduce a new concept, effective radiative forcing (ERF), that accounts for rapid response in the climate system. ERF is defined as the change in net downward flux at the top of the atmosphere after allowing for atmospheric temperatures, water vapour, clouds and land albedo to adjust, but with either sea surface temperatures (SST) and sea ice cover unchanged or with global mean surface temperature unchanged.

[INSERT FIGURE 1.1 HERE]

Figure 1.1: Main drivers of climate change. The radiative balance between incoming solar shortwave radiation (SWR) and outgoing longwave radiation (LWR) is influenced by global climate “drivers”. Natural fluctuations in solar output (solar cycles) can cause changes in the energy balance (through fluctuations in the amount of incoming SWR) (Section 2.3). Human activity changes the emissions of gases and aerosols, which are involved in atmospheric chemical reactions, resulting in modified O₃ and aerosol amounts (Section 2.2). O₃ and aerosol particles absorb, scatter and reflect SWR, changing the energy balance. Some aerosols act as cloud condensation nuclei modifying the properties of cloud droplets and possibly affecting precipitation (Section 7.4). Since cloud interactions with SWR and LWR are large, small changes in the properties of clouds have important implications for the radiative budget (Section 7.4). Anthropogenic changes in greenhouse gases (e.g., CO₂, CH₄, N₂O, O₃, CFCs), and large aerosols (>2.5 μm in size) modify the amount of outgoing LWR by absorbing outgoing LWR and re-emitting less energy at a lower temperature (Section 2.2). Surface albedo is changed by changes in vegetation or land surface properties, snow or ice cover and ocean colour (Section 2.3). These changes are driven by natural seasonal and diurnal changes (e.g., snow cover), as well as human influence (e.g., changes in vegetation types) (Forster et al., 2007).

Once a forcing is applied, complex internal feedbacks determine the eventual response of the climate system, and will in general cause this response to differ from a simple linear one (IPCC, 2001, 2007). There are many feedback mechanisms in the climate system that can either amplify (‘positive feedback’) or diminish (‘negative feedback’) the effects of a change in climate forcing (Le Treut et al., 2007) (see Figure 1.2 for a representation of some of the key feedbacks). An example of a positive feedback is the water vapour feedback whereby an increase in surface temperature enhances the amount of water vapour present in the atmosphere. Water vapour is a powerful greenhouse gas: increasing its atmospheric concentration enhances the greenhouse effect and leads to further surface warming. Another example is the ice albedo feedback, where the albedo decreases as highly reflective ice and snow surfaces melt, exposing the darker and more absorbing surfaces below. The dominant negative feedback is the increased emission of energy through longwave radiation as surface temperature increases (sometimes also referred to as blackbody radiation feedback). Some feedbacks operate quickly (hours), while others develop over decades to centuries; in order to understand the full impact of a feedback mechanism, its timescale needs to be considered. Melting of land ice sheets can take days to millennia.

A spectrum of models is used to quantitatively project the climate response to forcings. The simplest energy balance models use one box to represent the Earth system and solve the global energy balance to deduce globally averaged surface air temperature. At the other extreme, full complexity 3-dimensional climate models include the explicit solution of energy, momentum and mass conservation equations at millions of points on the Earth in the atmosphere, land, ocean and cryosphere. More recently, capabilities for the explicit simulation of the biosphere, the carbon cycle and atmospheric chemistry have been added to the full complexity models, and these models are called Earth System Models (ESMs). Earth System Models of Intermediate Complexity include the same processes as ESMs, but at reduced resolution, and thus can be simulated for longer periods (see Annex III for Glossary and Section 9.1).

An equilibrium climate experiment is an experiment in which a climate model is allowed to fully adjust to a specified change in RF. Such experiments provide information on the difference between the initial and final states of the model simulated climate, but not on the time-dependent response. The equilibrium response in global mean surface air temperature to a doubling of atmospheric concentration of CO₂ above pre-industrial levels (e.g., Arrhenius, 1896; see Le Treut et al., 2007 for a comprehensive list) has often been used as the basis for the concept of equilibrium climate sensitivity (e.g., Hansen et al., 1981; see Meehl et al., 2007 for a comprehensive list). For more realistic simulations of climate, changes in RF are applied gradually over time, for example using historical reconstructions of the carbon dioxide, and these simulations are called transient simulations. The temperature response in these transient simulations is different than in an equilibrium simulation. The transient climate response is defined as the change in global surface temperature at the time of atmospheric CO₂ doubling in a global coupled ocean-atmosphere climate model simulation where concentrations of CO₂ were increased by 1% yr⁻¹. The transient climate response is a measure of the strength and rapidity of the surface temperature response to greenhouse gas forcing. It can be more meaningful for some problems as well as easier to derive from observations (see Figure 10.19; Section 10.8; Knutti et al., 2005; Chapter 12; Frame et al., 2006; Forest et al., 2008), but such experiments are not intended to replace the more realistic scenario evaluations.

Climate change commitment is defined as the future change to which the climate system is committed by virtue of past or current forcings. The components of the climate system respond on a large range of timescales, ranging from the essentially rapid responses that characterise some radiative feedbacks, to millennial scale responses such as those associated with the behaviour of the carbon cycle (Section 6.1) and ice sheets (see Figure 1.2 and Box 5.1). Even if anthropogenic emissions were immediately ceased (Matthews and Weaver, 2010) or if climate forcings were fixed at current values (Wigley, 2005) the climate system would continue to change until it came into equilibrium with those forcings (Section 12.5). Because of the slow response time of some components of the climate system, equilibrium conditions will not be reached for many centuries. Slow processes can sometimes only be constrained by data collected over long periods, giving a particular salience to paleoclimate data for understanding equilibrium processes. Climate change commitment is indicative of aspects of inertia in the climate system, since it captures the ongoing nature of some aspects of change.

[INSERT FIGURE 1.2 HERE]

Figure 1.2: Climate feedbacks and timescales. The climate feedbacks related to increasing carbon dioxide and rising temperature include negative feedbacks (–) such as longwave radiation, lapse rate (see Glossary in Annex III), and air-sea carbon exchange and positive feedbacks (+) such as water vapour and snow/ice albedo feedbacks. Some feedbacks may be positive or negative (±): clouds, ocean circulation changes, air-land carbon dioxide exchange, and emissions of non-green house gases and aerosols from natural systems. In the smaller box, the large difference in timescales for the various feedbacks is highlighted.

A summary of perturbations to the forcing of the climate system from changes in solar radiation, greenhouse gases, surface albedo, and aerosols is presented in Box 13.1. The energy fluxes from these perturbations are balanced by increased radiation to space from a warming Earth, reflection of solar radiation, and storage of energy in the Earth system, principally the oceans (Box 3.1, Box 13.1).

The processes affecting climate can exhibit considerable natural variability. Even in the absence of external forcing, periodic and chaotic variations on a vast range of spatial and temporal scales are observed. Much of this variability can be represented by simple (e.g., unimodal or power law) distributions, but many components of the climate system also exhibit multiple states – for instance, the glacial-interglacial cycles and certain modes of internal variability such as El Niño-Southern Oscillation (ENSO) (see Box 2.5 for details on patterns and indices of climate variability). Movement between states can occur as a result of natural variability, or in response to external forcing. The relationship between variability, forcing and response reveals the complexity of the dynamics of the climate system: the relationship between forcing and response for some parts of the system seems reasonably linear; in other cases this relationship is much more complex, characterised by hysteresis (the dependence on past states) and a non-additive combination of feedbacks.

Related to multiple climate states, and hysteresis, is the concept of irreversibility in the climate system. In some cases where multiple states and irreversibility combine, bifurcations or “tipping points” can be reached (see Section 12.5). In these situations, it is difficult if not impossible for the climate system to revert to its previous state, and the change is termed irreversible over some timescale and forcing range. A small number of studies using simplified models find evidence for global-scale “tipping points” (e.g., Lenton et al., 2008); however, there is no evidence for global-scale tipping points in any of the most comprehensive models evaluated to date in studies climate evolution of the of the 21st century. There is evidence for threshold behaviour in certain aspects of the climate system, such as ocean circulation (see Section 12.5) and ice sheets (see Box 5.1), on multi-centennial-to-millennial timescales. There are also arguments for the existence of regional tipping points, most notably in the Arctic (e.g., Lenton et al., 2008; Duarte et al., 2012; Wadhams, 2012), although aspects of this are contested (Armour et al., 2011; Tietsche et al., 2011).

1.2.3 Multiple Lines of Evidence for Climate Change

While the first IPCC assessment depended primarily on observed changes in surface temperature and climate model analyses, more recent assessments include multiple lines of evidence for climate change. The first line of evidence in assessing climate change is based on careful analysis of observational records of the atmosphere, land, ocean and cryosphere systems (Figure 1.3). There is incontrovertible evidence from in situ observations and ice core records that the atmospheric concentrations of greenhouse gases such as CO₂, CH₄, and N₂O have increased substantially over the last 200 years (Section 6.3, Section 8.3). In addition,

instrumental observations show that land and sea surface temperatures have increased over the last 100 years (Chapter 2). Satellites allow a much broader spatial distribution of measurements, especially over the last 30 years. For the upper ocean temperature the observations indicate that the temperature has increased since at least 1950 (Willis et al., 2010; Section 3.2). Observations from satellites and in situ measurements suggest reductions in glaciers, Arctic sea ice and ice sheets (Sections 4.2, 4.3, 4.4). Additionally, analyses based on measurements of the radiative budget and ocean heat content suggest a small imbalance (Section 2.3). These observations, all published in peer-reviewed journals, made by diverse measurement groups in multiple countries using different technologies, investigating various climate-relevant types of data, uncertainties and processes, offer a wide range of evidence on the broad extent of the changing climate throughout our planet.

Conceptual and numerical models of the Earth's climate system offer another line of evidence on climate change (discussions in Chapters 5 and 9 provide relevant analyses of this evidence from paleoclimatic to recent periods). These use our basic understanding of the climate system to provide self-consistent methodologies for calculating impacts of processes and changes. Numerical models include the current knowledge about the laws of physics, chemistry and biology, as well as hypotheses about how complicated processes such as cloud formation can occur. Since these models can only represent the existing state of knowledge and technology, they are not perfect; they are, however, important tools for analysing uncertainties or unknowns, for testing different hypotheses for causation relative to observations, and for making projections of possible future changes.

One of the most powerful methods for assessing changes occurring in climate involves the use of statistical tools to test the analyses from models relative to observations. This methodology is generally called detection and attribution in the climate change community (Section 10.2). For example, climate models indicate that the temperature response to greenhouse gas increases is expected to be different than the effects from aerosols or from solar variability. Radiosonde measurements and satellite retrievals of atmospheric temperature show increases in tropospheric temperature and decreases in stratospheric temperatures, consistent with the increases in greenhouse gas effects found in climate model simulations (e.g., increases in CO₂, changes in O₃), but if the Sun was the main driver of current climate change, stratospheric and tropospheric temperatures would respond with the same sign (Hegerl et al., 2007).

Prior to the instrumental period, historical sources, natural archives, and proxies for key climate variables (e.g., tree rings, marine sediment cores, ice cores) can provide quantitative information on past regional to global climate and atmospheric composition variability and these data provide another line of evidence. Reconstructions of key climate variables based on these datasets have provided important information on the responses of the Earth system to a variety of external forcings and its internal variability over a wide range of timescales (Hansen et al., 2006; Mann et al., 2008). Paleoclimatic reconstructions thus provide a means for placing the current changes in climate in the perspective of natural climate variability (Section 5.1). AR5 includes new information on external RFs caused by variations in volcanic and solar activity (e.g., Steinhilber et al., 2009; see Section 8.4). Extended data sets on past changes in atmospheric concentrations and distributions of atmospheric greenhouse gas concentrations (e.g., Lüthi et al., 2008; Beerling and Royer, 2011) and mineral aerosols (Lambert et al., 2008) have also been used to attribute reconstructed paleoclimate temperatures to past variations in external forcings (Section 5.2).

1.3 Indicators of Climate Change

There are many indicators of climate change. These include physical responses such as changes in surface temperature, changes in atmospheric water vapour, changes in precipitation, changes in severe events, changes in glaciers, changes in ocean and land ice, and changes in sea level. Some key examples of such changes in important climate parameters are discussed in this section and all are assessed in much more detail in other chapters.

As was done to a more limited extent in AR4 (Le Treut et al., 2007), this section provides a test of the planetary-scale hypotheses of climate change against observations. In other words, how well do the projections used in the past assessments compare with observations to date. Seven additional years of observations are now available to evaluate earlier model projections. The projected range that was given in each assessment is compared to observations. The largest possible range of scenarios available for a specific variable for each of the previous assessment reports is shown in the figures.

Based on the assessment of AR4, a number of the key climate and associated environmental parameters are presented in Figure 1.3, which updates the similar figure in the Technical Summary (TS) of IPCC (2001). This section discusses the recent changes in several indicators, while more thorough assessments for each of these indicators are provided in other chapters. Also shown in parentheses in Figure 1.3 are the chapter and section where those indicators of change are assessed in AR5.

Note that projections presented in the IPCC assessments are not predictions (see the Glossary in Annex III); the analyses in the discussion below only examine the short-term plausibility of the projections up to AR4, including the scenarios for future emissions and the models used to simulate these scenarios in the earlier assessments. Model results from the Coupled Model Intercomparison Project Phase 5 (CMIP5) (Taylor et al., 2012) used in AR5 are therefore not included in this section; Chapter 11 and Chapter 12 describe the projections from the new modelling studies. Note that none of the scenarios examined in the IPCC assessments were ever intended to be short-term predictors of change.

[INSERT FIGURE 1.3 HERE]

Figure 1.3: Overview of observed climate change indicators as listed in AR4. Chapter numbers indicate where detailed discussions for these indicators are found in AR5 (temperature: red; hydrological: blue; others: black).

1.3.1 Global and Regional Surface Temperatures

Observed changes in global mean surface air temperature since 1950 (from three major databases, as anomalies relative to 1961–1990) are shown in Figure 1.4. As in the prior assessments, global climate models generally simulate global temperatures that compare well with observations over climate timescales (Section 9.4). Even though the projections from the models were never intended to be predictions over such a short time scale, the observations through 2012 generally fall within the projections made in all past assessments. The 1990–2012 data have been shown to be consistent with the FAR projections (IPCC, 1990), and not consistent with zero trend from 1990, even in the presence of substantial natural variability (Frame and Stone, 2013).

The scenarios were designed to span a broad range of plausible futures, but are not aimed at predicting the most likely outcome. The scenarios considered for the projections from the earlier reports (FAR, SAR) had a much simpler basis than the Special Report on Emission Scenarios (SRES) (IPCC, 2000) scenarios used in the later assessments. For example, the FAR scenarios did not specify future aerosol distributions. In AR4 a multiple-set of projections were presented that were simulated using comprehensive ocean-atmosphere models provided by CMIP3 and these projections are continuations of transient simulations of the 20th century climate. These projections of temperature provide additionally a measure of the natural variability. This could not be obtained from the earlier projections based on models of intermediate complexity (Cubasch et al., 2001).

Note that before TAR the climate models did not include natural forcing (such as volcanic activity and solar variability). Even in AR4 not all models included natural forcing and some also did not include aerosols. Those models that allowed for aerosol effects presented in the AR4 simulated for example the cooling effects of the 1991 Mt. Pinatubo eruption and agree better with the observed temperatures than the previous assessments that did not include those effects.

The bars on the side for FAR, SAR and TAR represent the range of results for the scenarios at the end of the time period and are not error bars. By contrast to the previous reports the AR4 gave an assessment of the individual scenarios with a mean estimate (cross-bar; ensemble mean of the CMIP3 simulations) and a likely range (full bar; –40% to +60% of the mean estimate) (Meehl et al., 2007).

In summary, the trend in globally-averaged surface temperatures falls within the range of the previous IPCC projections. During the last decade the trend in the observations is smaller than the mean of the projections of AR4 (see Section 9.4.1, Box 9.2 for a detailed assessment of the hiatus in global mean surface warming in the last 15 years). As shown by Hawkins and Sutton (2009), trends in the observations during short-time scale periods (decades) can be dominated by natural variability in the Earth's climate system. Similar episodes are also seen in climate model experiments (Easterling and Wehner, 2009). Due to their

experimental design these episodes cannot be duplicated with the same timing as the observed episodes in most of the model simulations; this affects the interpretation of recent trends in the scenario evaluations (Section 11.2). Notwithstanding these points, there is evidence that early forecasts that carried formal estimates of uncertainty have proved highly consistent with subsequent observations (Allen et al., 2013). If the contributions of solar variability, volcanic activity and ENSO are removed from the observations the remaining trend of surface air temperature agree better with observations (Rahmstorf et al., 2012).

[INSERT FIGURE 1.4 HERE]

Figure 1.4: Estimated changes in the observed globally and annually averaged surface temperature anomaly relative to 1961–1990 (in °C) since 1950 compared with the range of projections from the previous IPCC assessments. Values are harmonized to start from the same value in 1990. Observed global annual mean surface air temperature anomaly, relative to 1961–1990, is shown as squares and smoothed time series as solid lines (NASA (dark blue), NOAA (warm mustard), and the UK Hadley Centre (bright green) reanalyses). The coloured shading shows the projected range of global annual mean surface air temperature change from 1990 to 2035 for models used in FAR (Figure 6.11 in Bretherton et al., 1990), SAR (Figure 19 in the TS of IPCC, 1996), TAR (full range of TAR Figure 9.13(b) in Cubasch et al., 2001). TAR results are based on the simple climate model analyses presented and not on the individual full three-dimensional climate model simulations. For the AR4 results are presented as single model runs of the CMIP3 ensemble for the historical period from 1950 to 2000 (light grey lines) and for three scenarios (A2, A1B and B1) from 2001 to 2035. The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. For the three SRES scenarios the bars show the CMIP3 ensemble mean and the likely range given by –40% to +60% of the mean as assessed in Meehl et al. (2007). The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

1.3.2 Greenhouse Gas Concentrations

Key indicators of global climate change also include the changing concentrations of the radiatively important greenhouse gases that are important drivers for this change (e.g., Denman et al., 2007; Forster et al., 2007). Figures 1.5 through 1.7 show the recent globally and annually averaged observed concentrations for the gases of most concern, CO₂, CH₄, and N₂O (see Sections 2.2, 6.3 and 8.3 for more detailed discussion of these and other key gases). As discussed in the later chapters, accurate measurements of these long-lived gases come from a number of monitoring stations throughout the world. The observations in these figures are compared with the projections from the previous IPCC assessments.

The model simulations begin with historical emissions up to 1990. The further evolution of these gases was described by scenario projections. TAR and AR4 model concentrations after 1990 are based on the SRES scenarios but those model results may also account for historical emissions analyses. The range of projections from the FAR (IPCC, 1990) for CO₂ is much larger than those from the scenarios used in more recent assessments. The recent observed trends in CO₂ concentrations tend to be in the middle of the scenarios used for the projections (Figure 1.5).

As discussed in Dlugokencky et al. (2009), trends in CH₄ showed a stabilization from 1999 to 2006, but CH₄ concentrations have been increasing again starting in 2007 (see Sections 6.3 and 2.2 for more discussion on the budget and changing concentration trends for CH₄). Because at the time the scenarios were developed (e.g., the SRES scenarios were developed in 2000), it was thought that past trends would continue, the scenarios used and the resulting model projections assumed in FAR through AR4 all show larger increases than those observed (Figure 1.6).

Concentrations of N₂O have continued to increase at a nearly constant rate (Elkins and Dutton, 2010) since about 1970 as shown in Figure 1.7. The observed trends tend to be in the lower part of the projections for the previous assessments.

[INSERT FIGURE 1.5 HERE]

Figure 1.5: Observed globally and annually averaged CO₂ concentrations in parts per million (ppm) since 1950 compared with projections from the previous IPCC assessments. Observed global annual CO₂ concentrations are shown in dark blue. The shading shows the largest model projected range of global annual CO₂ concentrations from 1950 to 2035 from FAR (Figure A.3 in the Summary for Policymakers (SPM) of IPCC, 1990), SAR (Figure 5b in the TS of IPCC, 1996), TAR (Appendix II of IPCC, 2001), and from the A2, A1B and B1 scenarios presented in the AR4 (Figure 10.26 in Meehl et al., 2007). The bars at the right hand side of the graph show the full range given for 2035 for each

assessment report. The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

[INSERT FIGURE 1.6 HERE]

Figure 1.6: Observed globally and annually averaged CH₄ concentrations in parts per billion (ppb) since 1950 compared with projections from the previous IPCC assessments. Estimated observed global annual CH₄ concentrations are shown in dark blue. The shading shows the largest model projected range of global annual CH₄ concentrations from 1950 to 2035 from FAR (Figure A.3 of the Annex of IPCC, 1990), SAR (Table 2.5a in Schimel et al., 1996), TAR (Appendix II of IPCC, 2001), and from the A2, A1B and B1 scenarios presented in the AR4 (Figure 10.26 in Meehl et al., 2007). The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

[INSERT FIGURE 1.7 HERE]

Figure 1.7: Observed globally and annually averaged N₂O concentrations in parts per billion (ppb) since 1950 compared with projections from the previous IPCC assessments. Observed global annual N₂O concentrations are shown in dark blue. The shading shows the largest model projected range of global annual N₂O concentrations from 1950 to 2035 from FAR (Figure A3 in the Annex of IPCC, 1990), SAR (Table 2.5b in Schimel et al., 1996), TAR (Appendix II of IPCC, 2001), and from the A2, A1B and B1 scenarios presented in the AR4 (Figure 10.26 in Meehl et al., 2007). The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

1.3.3 Extreme Events

Climate change, whether driven by natural or human forcings, can lead to changes in the likelihood of the occurrence or strength of extreme weather and climate events such as extreme precipitation events or warm spells (see Chapter 3 of the IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX); Seneviratne et al., 2012). An extreme weather event is an event that is rare at a particular place and time of year. Definitions of ‘rare’ vary, but an extreme weather event would normally be as rare as or rarer than the 10th or 90th percentile of a probability density function estimated from observations (see also Glossary in Annex III and FAQ 2.2). By definition, the characteristics of what is called extreme weather may vary from place to place in an absolute sense. At present, single extreme events cannot generally be directly attributed to anthropogenic influence, although the change in likelihood for the event to occur has been determined for some events by accounting for observed changes in climate (see Section 10.6). When a pattern of extreme weather persists for some time, such as a season, it may be classified as an extreme climate event, especially if it yields an average or total that is itself extreme (e.g., drought or heavy rainfall over a season). For some climate extremes such as drought, floods and heat waves, several factors such as duration and intensity need to be combined to produce an extreme event (Seneviratne et al., 2012).

The probability of occurrence of values of a climate or weather variable can be described by a probability density function (PDF) that for some variables (e.g., temperature) is shaped similar to a ‘Gaussian’ curve. A PDF is a function that indicates the relative chances of occurrence of different outcomes of a variable. Simple statistical reasoning indicates that substantial changes in the frequency of extreme events (e.g., the maximum possible 24-hour rainfall at a specific location) can result from a relatively small shift in the distribution of a weather or climate variable. Figure 1.8a shows a schematic of such a PDF and illustrates the effect of a small shift in the mean of a variable on the frequency of extremes at either end of the distribution. An increase in the frequency of one extreme (e.g., the number of hot days) can be accompanied by a decline in the opposite extreme (in this case the number of cold days such as frost days). Changes in the variability, skewness or the shape of the distribution can complicate this simple picture (Figure 1.8b, c and d).

While the SAR found that data and analyses of extremes related to climate change were sparse, improved monitoring and data for changes in extremes were available for the TAR, and climate models were being analysed to provide projections of extremes. In AR4, the observational basis of analyses of extremes had increased substantially, so that some extremes were now examined over most land areas (e.g., rainfall extremes). More models with higher resolution, and more regional models have been used in the simulation and projection of extremes, and ensemble integrations now provide information about PDFs and extremes.

Since the TAR, climate change studies have especially focused on changes in the global statistics of extremes, and observed and projected changes in extremes have been compiled in the so-called “Extremes”-Table (Figure 1.9). This table has been further modified to account for the SREX assessment. For some extremes (“higher maximum temperature”, “higher minimum temperature”, “precipitation extremes”, “droughts or dryness”), all of these assessments found an increasing trend in the observations and in the projections. In the observations for the “higher maximum temperature” the confidence level was raised from *likely* in the TAR to *very likely* in SREX. While the diurnal temperature range was assessed in the Extremes-Table of the TAR, it was no longer included in the Extremes-Table of AR4, since it is not considered a climate extreme in a narrow sense. Diurnal temperature range was, however, reported to decrease for 21st century projections in AR4 (Meehl et al., 2007). In projections for precipitation extremes, the spatial relevance has been improved from *very likely* “over many Northern Hemisphere mid-latitudes to high latitudes land areas” from the TAR to *very likely* for all regions in AR4 (these “uncertainty labels” are discussed in Section 1.4). However, confidence in trends in projected precipitation extremes was downscaled to *likely* in the SREX as a result of a perception of biases and a fairly large spread in the precipitation projections in some regions. SREX also had less confidence than TAR and AR4 in the trends for droughts and dryness, “due to lack of direct observations, some geographical inconsistencies in the trends, and some dependencies of inferred trends on the index choice” (IPCC, 2012b).

For some extremes (e.g., “changes in tropical cyclone activity”) the definition changed between the TAR and the AR4. While the TAR only made a statement about the peak wind speed of tropical cyclones, the AR4 also stressed the overall increase in intense tropical cyclone activity. The “low confidence” for any long term trend (>40 years) in the observed changes of the tropical cyclone activities is due to uncertainties in past observational capabilities (IPCC, 2012b). The “increase in extreme sea level” has been added in the AR4. Such an increase is *likely* according to the AR4 and the SREX for observed trends, and *very likely* for the climate projections reported in the SREX.

The assessed likelihood of anthropogenic contributions to trends is lower for variables where the assessment is based on indirect evidence. Especially for extremes that are the result of the combination of factors such as droughts, linking a particular extreme event to specific causal relationships is difficult to determine (e.g., difficult to establish the clear role of climate change in the event) (see Section 10.6 and Peterson et al., 2012). In some cases (e.g., precipitation extremes), however, it may be possible to estimate the human-related contribution to such changes in the probability of occurrence of extremes (Pall et al., 2011; Seneviratne et al., 2012).

[INSERT FIGURE 1.8 HERE]

Figure 1.8: Schematic representations of the probability density function of daily temperature, which tends to be approximately Gaussian, and daily precipitation, which has a skewed distribution. Dashed lines represent a previous distribution and solid lines a changed distribution. The probability of occurrence, or frequency, of extremes is denoted by the shaded areas. In the case of temperature, changes in the frequencies of extremes are affected by changes a) in the mean, b) in the variance or shape, and c) in both the mean and the variance. d) In a skewed distribution such as that of precipitation, a change in the mean of the distribution generally affects its variability or spread, and thus an increase in mean precipitation would also *likely* imply an increase in heavy precipitation extremes, and vice-versa. In addition, the shape of the right hand tail could also change, affecting extremes. Furthermore, climate change may alter the frequency of precipitation and the duration of dry spells between precipitation events. a)-c) modified from Folland et al. (2001) and d) modified from Peterson et al. (2008) as in Zhang and Zwiers (2012).

[INSERT FIGURE 1.9 HERE]

Figure 1.9: Change in the confidence levels for extreme events based on prior IPCC assessments: TAR, AR4, and SREX. Types of extreme events discussed in all three reports are highlighted in green. Confidence levels are defined in Section 1.4. Similar analyses for AR5 are discussed in later chapters. Please note that the nomenclature for confidence level changed from AR4 to SREX and AR5.

1.3.4 Climate Change Indicators

Climate change can lead to other effects on the Earth’s physical system that are also indicators of climate change. Such integrative indicators include changes in sea level (ocean warming + land ice melt), in ocean acidification (ocean uptake of CO₂), and in the amount of ice on ocean and land (temperature and hydrological changes). See Chapters 3, 4 and 13 for detailed assessment.

1.3.4.1 Sea Level

Global mean sea level is an important indicator of climate change (Section 3.7 and Chapter 13). The previous assessments have all shown that observations indicate that the globally-averaged sea level is rising. Direct observations of sea level change have been made for more than 150 years with tide gauges, and for more than 20 years with satellite radar altimeters. Although there is regional variability from non-uniform density change, circulation changes, and deformation of ocean basins, the evidence indicates that the global mean sea level is rising, and that this is *likely* (according to AR4 and SREX) resulting from global climate change (ocean warming plus land ice melt; see Chapter 13 for AR5 findings). The historical tide gauge record shows that the average rate of global mean sea level rise over the 20th century was $1.7 \pm 0.2 \text{ mm yr}^{-1}$ (e.g., Church and White, 2011). This rate increased to $3.2 \pm 0.4 \text{ mm yr}^{-1}$ since 1990, mostly because of increased thermal expansion and land ice contributions (Church and White, 2011; IPCC, 2012b). Although the long-term sea level record shows decadal and multi-decadal oscillations, there is evidence that the rate of global mean sea level rise during the 20th century was greater than during the 19th century.

All of the previous IPCC assessments have projected that global sea level will continue to rise throughout this century for the scenarios examined. Figure 1.10 compares the observed sea level rise since 1950 with the projections from the prior IPCC assessments. Earlier models had greater uncertainties in modelling the contributions, because of limited observational evidence and deficiencies in theoretical understanding of relevant processes. Also, projections for sea level change in the prior assessments are scenarios for the response to anthropogenic forcing only; they do not include unforced or natural interannual variability. Nonetheless, the results show that the actual change is in the middle of projected changes from the prior assessments, and towards the higher end of the studies from TAR and AR4.

1.3.4.2 Ocean Acidification

The observed decrease in ocean pH resulting from increasing concentrations of carbon dioxide is another indicator of global change. As discussed in AR4, the ocean's uptake of carbon dioxide is having a significant impact on the chemistry of sea water. The average pH of ocean surface waters has fallen by about 0.1 units, from about 8.2 to 8.1 (total scale) since 1765 (Section 3.8). Long time series from several ocean sites show ongoing declines in pH, consistent with results from repeated pH measurements on ship transects spanning much of the globe (Section 3.8; Section 6.4; Byrne et al., 2010; Midorikawa et al., 2010). Ocean time-series in the North Atlantic and North Pacific record a decrease in pH ranging between -0.0015 and -0.0024 per year (Section 3.8). Due to the increased storage of carbon by the ocean, ocean acidification will increase in the future (Chapter 6). In addition to other impacts of global climate change, ocean acidification poses potentially serious threats to the health of the world's oceans ecosystems (see AR5 WGII assessment).

[INSERT FIGURE 1.10 HERE]

Figure 1.10: Estimated changes in the observed global annual mean sea level (GMSL) since 1950 relative to 1961–1990. Estimated changes in global annual sea level anomalies are presented based on tide gauge data (Jevrejeva et al., 2008 (warm mustard); Church and White, 2011 (dark blue); Ray and Douglas, 2011 (dark green)) and based on sea surface altimetry (light blue). The altimetry data start in 1993 and are harmonized to start from the mean 1993 value of the tide gauge data. Squares indicate annual mean values, solid lines smoothed values. The shading shows the largest model projected range of global annual sea level rise from 1950 to 2035 for FAR (Figure 9.6 and Figure 9.7 in Warrick and Oerlemans, 1990), SAR (Figure 21 in TS of IPCC, 1996), TAR (Appendix II of IPCC, 2001) and for Church et al. (2011) based on the Coupled Model Intercomparison Project Phase 3 (CMIP3) model results not assessed at the time of AR4 using the SRES B1, A1B, and A2 scenarios. Note that in the AR4 no full range was given for the sea level projections for this period. Therefore, the figure shows results that have been published subsequent to the AR4. The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. For Church et al. (2011) the mean sea level rise is indicated in addition to the full range. See Appendix 1.A for details on the data and calculations used to create this figure.

1.3.4.3 Ice

Rapid sea ice loss is one of the most prominent indicators of Arctic climate change (Section 4.2). There has been a trend of decreasing Northern Hemisphere sea ice extent since 1978, with the summer of 2012 being

the lowest in recorded history (see Section 4.2 for details). The 2012 minimum sea ice extent was 49% below the 1979 to 2000 average and 18% below the previous record from 2007. The amount of multiyear sea ice has been reduced, i.e., the sea ice has been thinning and thus the ice volume is reduced (Haas et al., 2008; Kwok et al., 2009). These changes make the sea ice less resistant to wind forcing. Sea ice extent has been diminishing significantly faster than projected by most of the AR4 climate models (SWIPA, 2011). While AR4 found no consistent trends in Antarctica sea ice, more recent studies indicate a small increase (Section 4.2). Various studies since AR4 suggest that this has resulted in a deepening of the low pressure systems in West Antarctica that in turn caused stronger winds and enhanced ice production in the Ross Sea (Goosse et al., 2009; Turner and Overland, 2009).

AR4 concluded that taken together, the ice sheets in Greenland and Antarctica have *very likely* been contributing to sea level rise. The Greenland Ice Sheet has lost mass since the early 1990s and the rate of loss has increased (see Section 4.4). The interior, high altitude areas are thickening due to increased snow accumulation, but this is more than counterbalanced by the ice loss due to melt and ice discharge (AMAP, 2009; Ettema et al., 2009). Since 1979, the area experiencing surface melting has increased significantly (Tedesco, 2007; Mernild et al., 2009), with 2010 breaking the record for surface melt area, runoff, and mass loss, and the unprecedented areal extent of surface melt of the Greenland Ice Sheet in 2012 (Nghiem et al., 2012). Overall, the Antarctic continent now experiences a net loss of ice (Section 4.4). Significant mass loss has been occurring in the Amundsen Sea sector of West Antarctica and the northern Antarctic Peninsula. The ice sheet on the rest of the continent is relatively stable or thickening slightly (Lemke et al., 2007; Scott et al., 2009; Turner et al., 2009). Since AR4, there have been improvements in techniques of measurement, such as gravity, altimetry and mass balance, and understanding of the change (Section 4.4).

As discussed in the earlier assessments, most glaciers around the globe have been shrinking since the end of the Little Ice Age with increasing rates of ice loss since the early 1980s (Section 4.3). The vertical profiles of temperature measured through the entire thickness of mountain glaciers, or through ice sheets, provide clear evidence of a warming climate over recent decades (e.g., Lüthi and Funk, 2001; Hoelzle et al., 2011). As noted in AR4, the greatest mass losses per unit area in the last four decades have been observed in the Patagonia, Alaska, northwest USA, southwest Canada, the European Alps, and the Arctic. Alaska and the Arctic are especially important regions as contributors to sea level rise (Zemp et al., 2008; Zemp et al., 2009).

1.4 Treatment of Uncertainties

1.4.1 Uncertainty in Environmental Science

Science always involves uncertainties. These arise at each step of the scientific method: in measurements, in the development of models or hypotheses, and in analyses and interpretation of scientific assumptions. Climate science is not different in this regard from other areas of science. The complexity of the climate system and the large range of processes involved bring particular challenges, since for example, gaps in direct measurements of the past can only be filled by reconstructions using proxy-data.

Because the Earth's climate system is characterized by multiple spatial and temporal scales, uncertainties do not usually reduce at a single, predictable rate: for example, new observations may reduce the uncertainties surrounding short timescale processes quite rapidly, while longer timescale processes may require very long observational baselines before much progress can be made. Characterization of the interaction between processes, as quantified by models, can be improved by model development, or can shed light on new areas in which uncertainty is greater than previously thought. The fact that there is only a single realization of the climate, rather than a range of different climates from which to draw, can matter significantly for certain lines of enquiry, most notably for the detection and attribution of causes of climate change and for the evaluation of projections of future states.

1.4.2 Characterizing Uncertainty

“Uncertainty” is a complex and multi-faceted property, sometimes originating in a lack of information, other times from quite fundamental disagreements about what is known or even knowable (Moss and Schneider, 2000). Furthermore, scientists often disagree about the best or most appropriate way to characterize these

uncertainties: some can be quantified easily while others cannot. Moreover, appropriate characterization is dependent upon the intended use of the information and the particular needs of that user community.

Scientific uncertainty can be partitioned in various ways, in which the details of the partitioning usually depend on the context. For instance, the process and classifications used for evaluating observational uncertainty in climate science is not the same as that employed to evaluate projections of future change. Uncertainty in measured quantities can arise from a range of sources, such as statistical variation, variability, inherent randomness, inhomogeneity, approximation, subjective judgement, and linguistic imprecision (Morgan et al., 1990), or from calibration methodologies, instrumental bias or instrumental limitations (JCGM, 2008).

In the modelling studies that underpin projections of future climate change, it is common to partition uncertainty into four main categories: scenario uncertainty, due to uncertainty of future emissions of greenhouse gases and other forcing agents; “model uncertainty” associated with climate models; internal variability and initial condition uncertainty; and forcing and boundary condition uncertainty for the assessment of historical and paleoclimate simulations (e.g., Collins and Allen, 2002; Yip et al., 2011).

Model uncertainty is an important contributor to uncertainty in climate predictions and projections. It includes, but is not restricted to, the uncertainties introduced by errors in the model's representation of dynamical and physical and bio-geochemical aspects of the climate system as well as in the model's response to external forcing. The phrase “model uncertainty” is a common term in the climate change literature, but different studies use the phrase in different senses: some studies use the phrase to represent the range of behaviour observed in ensembles of climate model (model spread), while other studies use it in more comprehensive senses (see Sections 9.2, 11.2 and 12.2). Model spread is often used as a measure of climate response uncertainty, but such a measure is crude as it takes no account of factors such as model quality (Chapter 9) or model independence (e.g., Masson and Knutti, 2011; Pennell and Reichler, 2011), and not all variables of interest are adequately simulated by global climate models.

To maintain a degree of terminological clarity this report distinguishes between “model spread” for this narrower representation of climate model responses and “model uncertainty” which describes uncertainty about the extent to which any particular climate model provides an accurate representation of the real climate system. This uncertainty arises from approximations required in the development of models. Such approximations affect the representation of all aspects of the climate including the response to external forcings.

Model uncertainty is sometimes decomposed further into parametric and structural uncertainty, comprising, respectively, uncertainty in the values of model parameters and uncertainty in the underlying model structure (see Section 12.2). Some scientific research areas, such as detection and attribution and observationally-constrained model projections of future climate, incorporate significant elements of both observational and model-based science, and in these instances both sets of relevant uncertainties need to be incorporated.

Scenario uncertainty refers to the uncertainties that arise due to limitations in our understanding of future emissions, concentration or forcing trajectories. Scenarios help in the assessment of future developments in complex systems that are either inherently unpredictable, or that have high scientific uncertainties (IPCC, 2000). The societal choices defining future climate drivers are surrounded by considerable uncertainty, and these are explored by examining the climate response to a wide range of possible futures. In past reports, emissions scenarios from the SRES (IPCC, 2000) were used as the main way of exploring uncertainty in future anthropogenic climate drivers. Recent research has made use of Representative Concentration Pathways (RCP) (van Vuuren et al., 2011b; van Vuuren et al., 2011a).

Internal or natural variability, the natural fluctuations in climate, occur in the absence of any RF of the Earth's climate (Hawkins and Sutton, 2009). Climate varies naturally on nearly all time and space scales, and quantifying precisely the nature of this variability is challenging, and is characterized by considerable uncertainty. The analysis of internal and forced contributions to recent climate is discussed in Chapter 10. The fractional contribution of internal variability compared with other forms of uncertainty varies in time and in space, but usually diminishes with time as other sources of uncertainty become more significant (Hawkins and Sutton, 2009; see also Chapter 11 and FAQ 1.1).

In the WGI contribution to the AR5, uncertainty is quantified using 90% uncertainty intervals unless otherwise stated. The 90% uncertainty interval, reported in square brackets, is expected to have a 90% likelihood of covering the value that is being estimated. The value that is being estimated has a 5% likelihood of exceeding the upper endpoint of the uncertainty interval, and the value has a 5% likelihood of being less than that the lower endpoint of the uncertainty interval. A best estimate of that value is also given where available. Uncertainty intervals are not necessarily symmetric about the corresponding best estimate.

In a subject as complex and diverse as climate change, the information available as well as the way it is expressed, and often the interpretation of that material, varies considerably with the scientific context. In some cases, two studies examining similar material may take different approaches even to the quantification of uncertainty. The interpretation of similar numerical ranges for similar variables can differ from study to study. Readers are advised to pay close attention to the caveats and conditions that surround the results presented in peer-reviewed studies, as well as those presented in this assessment. To help readers in this complex and subtle task, the IPCC draws on specific, calibrated language scales to express uncertainty (Mastrandrea et al., 2010), as well as specific procedures for the expression of uncertainty (see Table 1.2). The aim of these structures is to provide tools through which Chapter teams might consistently express uncertainty in key results.

1.4.3 Treatment of Uncertainty in IPCC

In the course of the IPCC assessment procedure, Chapter teams review the published research literature, document the findings (including uncertainties), assess the scientific merit of this information, identify the key findings, and attempt to express an appropriate measure of the uncertainty that accompanies these findings using a shared guidance procedure. This process has changed over time. The early Assessment Reports (FAR and SAR) were largely qualitative. As the field has grown and matured, uncertainty is being treated more explicitly, with a greater emphasis on the expression, where possible and appropriate, of quantified measures of uncertainty.

Although IPCC's treatment of uncertainty has become more sophisticated since the early reports, the rapid growth and considerable diversity of climate research literature presents on-going challenges. In the wake of the TAR the IPCC formed a Cross-Working Group team charged with identifying the issues and providing a set of Uncertainty Guidance Notes that could provide a structure for consistent treatment of uncertainty across the IPCC's remit (Manning et al., 2004). These expanded on the procedural elements of Moss and Schneider (2000) and introduced calibrated language scales designed to enable Chapter teams to use the appropriate level of precision to describe findings. These notes were revised between the TAR and AR4 and again between AR4 and AR5 (Mastrandrea et al., 2010).

Recently, increased engagement of social scientists (e.g., Patt and Schrag, 2003; Kandlikar et al., 2005; Risbey and Kandlikar, 2007; Broomell and Budescu, 2009; Budescu et al., 2009; CCSP, 2009) and expert advisory panels (CCSP, 2009; InterAcademy Council, 2010) in the area of uncertainty and climate change has helped clarify issues and procedures to improve presentation of uncertainty. Many of the recommendations of these groups are addressed in the revised Guidance Notes. One key revision relates to clarification of the relationship between the "confidence" and "likelihood" language, and pertains to demarcation between qualitative descriptions of "confidence" and the numerical representations of uncertainty that are expressed by the likelihood scale. Additionally, a finding that includes a probabilistic measure of uncertainty does not require explicit mention of the level of confidence associated with that finding if the level of confidence is "high" or "very high". This is a concession to stylistic clarity and readability: if something is described as having a high likelihood, then in the absence of additional qualifiers it should be inferred that it also has high or very high confidence.

1.4.4 Uncertainty Treatment in This Assessment

All three IPCC Working Groups in the AR5 have agreed to use two metrics for communicating the degree of certainty in key findings (Mastrandrea et al., 2010):

- confidence in the validity of a finding, based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and the degree of agreement. Confidence is expressed qualitatively;
- quantified measures of uncertainty in a finding expressed probabilistically (based on statistical analysis of observations or model results, or expert judgment).

A level of confidence synthesizes the Chapter teams' judgments about the validity of findings as determined through evaluation of the available evidence and the degree of scientific agreement. The evidence and agreement scale underpins the assessment, since it is on the basis of evidence and agreement that statements can be made with scientific confidence (in this sense, the evidence and agreement scale replaces the "level of scientific understanding" scale used in previous WGI assessments). There is flexibility in this relationship; for a given evidence and agreement statement, different confidence levels could be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence. Confidence cannot necessarily be assigned for all combinations of evidence and agreement, but where key variables are highly uncertain, the available evidence and scientific agreement regarding that variable is presented and discussed. Confidence should not be interpreted probabilistically, and it is distinct from "statistical confidence".

The confidence level is based on the evidence (robust, medium, and limited) and the agreement (high, medium, and low). A combination of different methods, e.g., observations and modeling, is important for evaluating the confidence level. Figure 1.11 shows how the combined evidence and agreement results in five levels for the confidence level used in this assessment.

[INSERT FIGURE 1.11]

Figure 1.11: The basis for the confidence level is given as a combination of evidence (limited, medium, robust) and agreement (low, medium, and high) (Mastrandrea et al., 2010).

The qualifier "likelihood" provides calibrated language for describing quantified uncertainty. It can be used to express a probabilistic estimate of the occurrence of a single event or of an outcome, e.g., a climate parameter, observed trend, or projected change lying in a given range. Statements made using the likelihood scale may be based on statistical or modelling analyses, elicitation of expert views, or other quantitative analyses. Where sufficient information is available it is preferable to eschew the likelihood qualifier in favour of the full probability distribution or the appropriate probability range. See Table 1.2 for the list of "likelihood" qualifiers to be used in AR5.

Table 1.2: Likelihood terms associated with outcomes used in the AR5.

Term	Likelihood of the Outcome
<i>Virtually certain</i>	99–100% probability
<i>Very likely</i>	90–100% probability
<i>Likely</i>	66–100% probability
<i>About as likely as not</i>	33–66% probability
<i>Unlikely</i>	0–33% probability
<i>Very unlikely</i>	0–10% probability
<i>Exceptionally unlikely</i>	0–1% probability

Notes:

Additional terms that were used in limited circumstances in the AR4 (extremely likely = 95–100% probability, more likely than not = >50–100% probability, and extremely unlikely = 0–5% probability) may also be used in the AR5 when appropriate.

Many social sciences studies have found that the interpretation of uncertainty is contingent upon the presentation of information, the context within which statements are placed, and the interpreter's own lexical preferences. Readers often adjust their interpretation of probabilistic language according to the magnitude of perceived potential consequences (Patt and Schrag, 2003; Patt and Dessai, 2005). Furthermore, the framing of a probabilistic statement impinges on how it is interpreted (Kahneman and Tversky, 1979): e.g., a 10% chance of dying is interpreted more negatively than a 90% chance of surviving.

In addition, work examining expert judgment and decision making shows that people—including scientific experts—suffer from a range of heuristics and biases that affect their judgment (e.g., Kahneman et al., 1982). For example, in the case of expert judgments there is a tendency towards overconfidence both at the individual level (Morgan et al., 1990) and at the group level as people converge on a view and draw confidence in its reliability from each other. However, in an assessment of the state of scientific knowledge across a field such as climate change—characterized by complexity of process and heterogeneity of data constraints—some degree of expert judgment is inevitable (Mastrandrea et al., 2010).

These issues were brought to the attention of Chapter teams so that contributors to the AR5 might be sensitized to the ways presentation, framing, context and potential biases might affect their own assessments and might contribute to readers' understanding of the information presented in this assessment. There will always be room for debate about how to summarize such a large and growing literature. The uncertainty guidance is aimed at providing a consistent, calibrated set of words through which to communicate the uncertainty, confidence and degree of consensus prevailing in the scientific literature. In this sense the guidance notes and practices adopted by IPCC for the presentation of uncertainties should be regarded as an interdisciplinary work in progress, rather than as a finalized, comprehensive approach. Moreover, one precaution that should be considered is that translation of this assessment from English to other languages may lead to a loss of precision.

1.5 Advances in Measurement and Modelling Capabilities

Since AR4, measurement capabilities have continued to advance. The models have been improved following the progress in the understanding of physical processes within the climate system. This section illustrates some of those developments.

1.5.1 Capabilities of Observations

Improved understanding and systematic monitoring of Earth's climate requires observations of various atmospheric, oceanic and terrestrial parameters and therefore has to rely on various technologies (ranging from ground-based instruments to ships, buoys, ocean profilers, balloons, aircraft, satellite-borne sensors, etc.). The Global Climate Observing System (GCOS, 2009) defined a list of so-called Essential Climate Variables, that are technically and economically feasible to observe, but some of the associated observing systems are not yet operated in a systematic manner. However, during recent years, new observational systems have increased the number of observations by orders of magnitude and observations have been made at places where there have been no data before (see Chapters 2, 3, and 4 for an assessment of changes in observations). Parallel to this, tools to analyse and process the data have been developed and enhanced to cope with the increase of information and to provide a more comprehensive picture of the Earth's climate. At the same time, it should be kept in mind that there has been some limited progress in developing countries in filling gaps in their in situ observing networks, but developed countries have made little progress in ensuring long-term continuity for several important observing systems (GCOS, 2009). Additionally, more proxy (non-instrumental) data have been acquired to provide a more comprehensive picture of climate changes in the past (see Chapter 5). Efforts are also occurring to digitize historic observations, mainly of ground-station data from periods prior to the second half of the 20th century (Brunet and Jones, 2011).

Reanalysis is a systematic approach to produce gridded dynamically consistent data sets for climate monitoring and research by assimilating all available observations with help of a climate model (Box 2.3). Model-based reanalysis products play an important role in obtaining a consistent picture of the climate system. However, their usefulness in detecting long-term climate trends is currently limited by changes over time in observational coverage and biases, linked to the presence of biases in the assimilating model (see also Box 2.3 in Chapter 2). Since AR4 both the quantity and quality of the observations that are assimilated through reanalysis have increased (GCOS, 2009). As an example, there has been some overall increase in mostly-atmospheric observations assimilated in European Centre for Medium-Range Weather Forecasts Interim Reanalysis since 2007 (Dee et al., 2011). The overwhelming majority of the data, and most of the increase over recent years, come from satellites (Figure 1.12) (GCOS, 2011). For example, information from Global Positioning System radio occultation measurements has increased significantly since 2007. The increases in data from fixed stations are often associated with an increased frequency of reporting, rather than an increase in the number of stations. Increases in data quality come from improved instrument design,

or more accurate correction in the ground-station processing that is applied before the data are transmitted to users and data centres. As an example for in-situ data, temperature biases of radiosonde measurements from radiation effects have been reduced over recent years. The new generation of satellite sensors such as the high spectral resolution infrared sounders (such as the Atmospheric Infrared Sounder and the Infrared Atmospheric Sounding Interferometer) are instrumental to achieving a better temporal stability for recalibrating sensors like the High-Resolution Infrared Radiation Sounder. Few instruments (e.g., the Advanced Very High Resolution Radiometer) have now been in orbit for about three decades, but these have originally not been designed for climate applications and therefore require careful re-calibration.

A major achievement in ocean observation is due to the implementation of the Argo global array of profiling floats system (GCOS, 2009). Deployment of Argo floats began in 2000, but it took until 2007 for numbers to reach the design target of 3000 floats. Since 2000 the ice-free upper 2000 m of the ocean have been observed systematically for temperature and salinity for the first time in history, because both the Argo profiling float and surface drifting buoy arrays have reached global coverage at their target numbers (in January 2009, there were 3291 floats operating). Biases in historical ocean data have been identified and reduced, and new analytical approaches have been applied (e.g., Willis et al., 2009). One major consequence has been the reduction of an artificial decadal variation in upper ocean temperature and heat content that was apparent in the observational assessment for AR4 (see Section 3.2). The spatial and temporal coverage of biogeochemical measurements in the ocean has also expanded. Satellite observations for sea level (Sections 3.7 and 13.2), sea surface salinity (Section 3.3), sea ice (Section 4.2), and ocean colour have also been further developed over the past few years.

Progress has also been made with regard to observation of terrestrial Essential Climate Variables. Major advances have been achieved in remote sensing of soil moisture due to the launch of the Soil Moisture and Oceanic Salinity mission in 2009 but also due to new retrieval techniques that have been applied to data from earlier and ongoing missions (see Seneviratne et al., 2010 for a detailed review). However, these measurements have limitations. For example the methods fail under dense vegetation and they are restricted to the surface soil. Updated Advanced Very High Resolution Radiometer-based Normalized Differenced Vegetation Index data provide new information on the change in vegetation. During the International Polar Year 2007–2009 the number of borehole sites was significantly increased and therefore allows a better monitoring of the large-scale permafrost features (see Section 4.7).

[INSERT FIGURE 1.12 HERE]

Figure 1.12: Development of capabilities of observations. Top: Changes in the mix and increasing diversity of observations over time create challenges for a consistent climate record (adapted from Brönnimann et al., 2008). Bottom left: First year of temperature data in global historical climatology network daily database (available at <http://www.ncdc.noaa.gov/oa/climate/ghcn-daily/>; Menne et al., 2012). Bottom right: Number of satellite instruments from which data have been assimilated in the European Centre for Medium-Range Weather Forecasts production streams for each year from 1996 to 2010. This figure is used as an example to demonstrate the fivefold increase in the usage of satellite data over this time period.

1.5.2 Capabilities in Global Climate Modelling

Several developments have especially pushed the capabilities in modelling forward over recent years (see Figure 1.13 and a more detailed discussion in Chapter 6, Chapter 7 and Chapter 9).

There has been a continuing increase in horizontal and vertical resolution. This is especially seen in how the ocean grids have been refined, and sophisticated grids are now used in the ocean and atmosphere models making optimal use of parallel computer architectures. More models with higher resolution are available for more regions. Figure 1.14a and 1.14b show the large effect on surface representation from a horizontal grid spacing of 87.5 km (similar to the current global models) to a grid spacing of 30.0 km (similar to the current regional climate models).

Representations of Earth system processes are much more extensive and improved, particularly for the radiation and the aerosol cloud interactions and for the treatment of the cryosphere. The representation of the carbon cycle was added to a larger number of models and has been improved since AR4. A high resolution stratosphere is now included in many models. Other ongoing process development in climate models includes the enhanced representation of nitrogen effects on the carbon cycle. As new processes or treatments

are added to the models, they are also evaluated and tested relative to available observations (see Chapter 9 for more detailed discussion).

Ensemble techniques (multiple calculations to increase the statistical sample, to account for natural variability, and to account for uncertainty in model formulations) are being used more frequently, with larger samples and with different methods to generate the samples (different models, different physics, different initial conditions). Coordinated projects have been set up to generate and distribute large samples (ENSEMBLES, climateprediction.net, Program for Climate Model Diagnosis and Intercomparison).

The model comparisons with observations have pushed the analysis and development of the models. CMIP5, an important input to the AR5, has produced a multi-model dataset that is designed to advance our understanding of climate variability and climate change. Building on previous CMIP efforts, such as the CMIP3 model analysis reported in AR4, CMIP5 includes “long-term” simulations of 20th century climate and projections for the 21st century and beyond. See Chapters 9, 10, 11 and 12 for more details on the results derived from the CMIP5 archive.

Since AR4, the incorporation of “long-term” paleoclimate simulations in the CMIP5 framework has allowed incorporation of information from paleoclimate data to inform projections. Within uncertainties associated with reconstructions of past climate variables from proxy records and forcings, paleoclimate information from the Mid Holocene, Last Glacial Maximum, and Last Millennium have been used to test the ability of models to simulate realistically the magnitude and large-scale patterns of past changes (Section 5.3, Box 5.1 and 9.4).

The capabilities of Earth System Models continue to be enhanced. For example, there are currently extensive efforts towards developing advanced treatments for the processes affecting ice sheet dynamics. Other enhancements are being aimed at land surface hydrology, and the effects of agriculture and urban environments.

As part of the process of getting model analyses for a range of alternative assumptions about how the future may unfold, scenarios for future emissions of important gases and aerosols have been generated for the IPCC assessments (e.g., see the SRES scenarios used in TAR and AR4). The emissions scenarios represent various development pathways based on well-defined assumptions. The scenarios are used to calculate future changes in climate, and are then archived in the Climate Model Intercomparison Project (e.g., CMIP3 for AR4; CMIP5 for AR5). For CMIP5, four new scenarios, referred to as Representative Concentration Pathways (RCPs) were developed (Section 12.3; Moss et al., 2010). See Box 1.1 for a more thorough discussion of the RCP scenarios. Since results from both CMIP3 and CMIP5 will be presented in the later chapters (e.g., Chapters 8, 9, 11 and 12), it is worthwhile considering the differences and similarities between the SRES and the RCP scenarios. Figure 1.15, acting as a prelude to the discussion in Box 1.1, shows that the RF for several of the SRES and RCP scenarios are similar over time and thus should provide results that can be used to compare climate modelling studies.

[INSERT FIGURE 1.13 HERE]

Figure 1.13: The development of climate models over the last 35 years showing how the different components were coupled into comprehensive climate models over time. In each aspect (e.g. the atmosphere, which comprises a wide range of atmospheric processes) the complexity and range of processes has increased over time (illustrated by growing cylinders). Note that during the same time the horizontal and vertical resolution has increased considerably e.g., for spectral models from T21L9 (roughly 500 km horizontal resolution and 9 vertical levels) in the 1970s to T95L95 (roughly 100 km horizontal resolution and 95 vertical levels) at present, and that now ensembles with at least three independent experiments can be considered as standard.

[INSERT FIGURE 1.14 HERE]

Figure 1.14: Horizontal resolutions considered in today’s higher resolution models and in the very high resolution models now being tested: a) Illustration of the European topography at a resolution of 87.5 x 87.5 km; b) same as a) but for a resolution of 30.0 x 30.0 km.

[INSERT FIGURE 1.15 HERE]

Figure 1.15: Historical and projected total anthropogenic RF ($W m^{-2}$) relative to preindustrial (~1765) between 1950 and 2100. Previous IPCC assessments (SAR IS92a, TAR/AR4 SRES A1B, A2 and B1) are compared with

representative concentration pathway (RCP) scenarios (see Chapter 12 and Box 1.1 for their extensions until 2300 and Annex II for the values shown here). The total RF of the three families of scenarios, IS92, SRES and RCP, differ for example for the year 2000, resulting from the knowledge about the emissions assumed having changed since the TAR and AR4.

[START BOX 1.1 HERE]

Box 1.1: Description of Future Scenarios

Long term climate change projections require assumptions on human activities or natural effects that could alter the climate over decades and centuries. Defined scenarios are useful for a variety of reasons, e.g., assuming specific time series of emissions, land-use, atmospheric concentrations or RF across multiple models allows for coherent climate model intercomparisons and synthesis. Scenarios can be formed in a range of ways, from simple, idealized structures to inform process understanding, through to comprehensive scenarios produced by Integrated Assessment Models as internally consistent sets of assumptions on emissions and socio-economic drivers (e.g., regarding population and socio-economic development).

Idealized Concentration Scenarios

As one example of an idealized concentration scenario, a 1%-yr⁻¹ compound increase of atmospheric CO₂ concentration until a doubling or a quadrupling of its initial value has been widely used in the past (Covey et al., 2003). An exponential increase of CO₂ concentrations induces an essentially linear increase in RF (Myhre et al., 1998) due to a ‘saturation effect’ of the strong absorbing bands. Such a linear ramp function is highly useful for comparative diagnostics of models’ climate feedbacks and inertia. The CMIP5 intercomparison project again includes such a stylized pathway up to a quadrupling of CO₂ concentrations, in addition to an instantaneous quadrupling case.

The Socio-Economic Driven SRES Scenarios

The SRES suite of scenarios were developed using Integrated Assessment Models and resulted from specific socio-economic scenarios from storylines about future demographic and economic development, regionalization, energy production and use, technology, agriculture, forestry, and land-use (IPCC, 2000). The climate change projections undertaken as part of CMIP3 and discussed in AR4 were primarily based on the SRES A2, A1B and B1 scenarios. However, given the diversity in models’ carbon cycle and chemistry schemes, this approach implied differences in models’ long lived greenhouse gas and aerosol concentrations for the same emissions scenario. As a result of this and other shortcomings, revised scenarios were developed for AR5 to allow atmosphere-ocean general circulation model (AOGCM) (using concentrations) simulations to be compared with those Earth system model (ESM) simulations that use emissions to calculate concentrations.

Representative Concentration Pathway Scenarios and their Extensions

Representative Concentration Pathway (RCP) scenarios (see Section 12.3 for a detailed description of the scenarios; Moss et al., 2008; Moss et al., 2010; van Vuuren et al., 2011b) are new scenarios that specify concentrations and corresponding emissions, but are not directly based on socio-economic storylines like the SRES scenarios. The RCP scenarios are based on a different approach and include more consistent short-lived gases and land use changes. They are not necessarily more capable of representing future developments than the SRES scenarios. Four RCP scenarios were selected from the published literature (Fujino et al., 2006; Smith and Wigley, 2006; Riahi et al., 2007; van Vuuren et al., 2007; Hijioka et al., 2008; Wise et al., 2009) and updated for use within CMIP5 (Masui et al., 2011; Riahi et al., 2011; Thomson et al., 2011; van Vuuren et al., 2011a). The four scenarios are identified by the 21st century peak or stabilization value of the RF derived by the reference model (in W m⁻²) (Box 1.1, Figure 1): the lowest RCP, RCP2.6 (also referred to as RCP3-PD) which peaks at 3 W m⁻² and then declines to approximately 2.6 W m⁻² by 2100; the medium-low RCP4.5 and the medium-high RCP6 aiming for stabilization at 4.5 and 6 W m⁻², respectively around 2100; and the highest one, RCP8.5, which implies a RF of 8.5 W m⁻² by 2100, but implies rising RF beyond that date (Moss et al., 2010). In addition there is a supplementary extension SCP6to4.5 with an adjustment of emissions after 2100 to reach RCP 4.5 concentration levels in 2250 and thereafter. The RCPs span the full

range of RF associated with emission scenarios published in the peer-reviewed literature at the time of the development of the RCPs, and the two middle scenarios were chosen to be roughly equally spaced between the two extremes (2.6 and 8.5). These forcing values should be understood as comparative labels representative of the forcing associated with each scenario, which will vary somewhat from model to model. This is because concentrations or emissions (rather than the RF) are prescribed in the CMIP5 climate model runs.

[INSERT BOX 1.1, FIGURE 1 HERE]

Box 1.1, Figure 1: Total RF (anthropogenic plus natural) for RCPs and extended concentration pathways (ECP) – for RCP2.6, RCP4.5, and RCP6, RCP8.5, as well as a supplementary extension SCP6to4.5 with an adjustment of emissions after 2100 to reach RCP 4.5 concentration levels in 2250 and thereafter. Note that the stated RF levels refer to the illustrative default median estimates only. There is substantial uncertainty in current and future RF levels for any given scenario. Short-term variations in RF are due to both volcanic forcings in the past (1800–2000) and cyclical solar forcing assuming a constant 11-year solar cycle (following the CMIP5 recommendation), except at times of stabilization (reproduced from Figure 4 in Meinshausen et al., 2011).

Various steps were necessary to turn the selected ‘raw’ RCPs into emission scenarios from Integrated Assessment Models and to turn these into datasets usable by the climate modelling community, including the extension with historical emissions (Granier et al., 2011; Meinshausen et al., 2011), the harmonization (smoothly connected historical reconstruction) and gridding of land-use datasets (Hurtt et al., 2011), the provision of atmospheric chemistry modelling studies, particularly for tropospheric ozone (Lamarque et al., 2011), analyses of 2000–2005 GHG emission levels, and extension of GHG concentrations with historical GHG concentrations and harmonization with analyses of 2000–2005 GHG concentrations levels (Meinshausen et al., 2011). The final RCP datasets comprise land-use data, harmonized GHG emissions and concentrations, gridded reactive gas and aerosol emissions, as well as ozone and aerosol abundance fields (Box 1.1, Figure 2, Figure 3, and Figure 4).

[INSERT BOX 1.1, FIGURE 2 HERE]

Box 1.1, Figure 2: Concentrations of GHG following the 4 RCPs and their extensions (ECP) to 2300. (Reproduced from Figure 5 in Meinshausen et al., 2011). Also see Annex II Table AII.4.1 for CO₂, Table AII.4.2 for CH₄, Table AII.4.3 for N₂O.

[INSERT BOX 1.1, FIGURE 3 HERE]

Box 1.1, Figure 3: (a) Equivalent CO₂ concentration and (b) CO₂ emissions (except land use emissions) for the four RCPs and their ECPs as well as some SRES scenarios.

[INSERT BOX 1.1, FIGURE 4 HERE]

Box 1.1, Figure 4: (a) Anthropogenic BC emissions (Annex II Table AII.2.22), (b) Anthropogenic NO_x emissions (Annex II Table AII.2.18), and (c) Anthropogenic SO_x emissions (Annex II Table AII.2.20).

To aid model understanding of longer-term climate change implications, these RCPs were extended until 2300 (Meinshausen et al., 2011) under reasonably simple and somewhat arbitrary assumptions regarding post-2100 GHG emissions and concentrations. In order to continue to investigate a broad range of possible climate futures, the two outer RCPs, RCP2.6 and RCP8.5 assume constant emissions after 2100, while the two middle RCPs aim for a smooth stabilization of concentrations by 2150. RCP8.5 stabilizes concentrations only by 2250, with CO₂ concentrations of approximately 2000 ppm, nearly 7 times the pre-industrial levels. As the RCP2.6 implies net negative CO₂ emissions after around 2070 and throughout the extension, CO₂ concentrations are slowly reduced towards 360 ppm by 2300.

Comparison of SRES and RCP Scenarios

The four RCP scenarios used in CMIP5 lead to RF values that span a range larger than that of the three SRES scenarios used in CMIP3 (Figure 12.3.3). RCP4.5 is close to SRES B1, RCP6 is close to SRES A1B (more after 2100 than during the 21st century) and RCP8.5 is somewhat higher than A2 in 2100 and close to the SRES A1FI scenario (Box 1.1, Figure 3). RCP2.6 is lower than any of the SRES scenarios (see also Figure 1.15).

[END BOX 1.1 HERE]

1.6 Overview and Road Map to the Rest of the Report

As this chapter has shown, understanding of the climate system and the changes occurring in it continue to advance. The notable scientific advances and associated peer-reviewed publications since AR4 provide the basis for the assessment of the science as found in Chapters 2 to 14. Below a quick summary of these chapters and their objectives is provided.

Observations and Paleoclimate Information (Chapters 2, 3, 4, and 5): These chapters assess information from all climate system components on climate variability and change as obtained from instrumental records and climate archives. This group of chapters covers all relevant aspects of the atmosphere including the stratosphere, the land surface, the oceans, and the cryosphere. Information on the water cycle, including evaporation, precipitation, runoff, soil moisture, floods, drought, etc. is assessed. Timescales from daily to decades (Chapters 2, 3 and 4) and from centuries to many millennia (Chapter 5) are considered.

Process Understanding (Chapters 6 and 7): These chapters cover all relevant aspects from observations and process understanding, to projections from global to regional scale. Chapter 6 covers the carbon cycle and its interactions with other biogeochemical cycles, in particular the nitrogen cycle, as well as feedbacks on the climate system. Chapter 7 treats in detail clouds and aerosols, their interactions and chemistry, the role of water vapour, as well as their role in feedbacks on the climate system.

From Forcing to Attribution of Climate Change (Chapters 8, 9, 10): In these chapters, all the information on the different drivers (natural and anthropogenic) of climate change is collected, expressed in terms of RF, and assessed (Chapter 8). As part of this, the science of metrics commonly used in the literature to compare radiative effects from a range of agents (Global Warming Potential, Global Temperature Change Potential and others) is covered. In Chapter 9, the hierarchy of climate models used in simulating past and present climate change is assessed. Information regarding detection and attribution of changes on global to regional scales is assessed in Chapter 10.

Future Climate Change and Predictability (Chapters 11 and 12): These chapters assess projections of future climate change derived from climate models on time scales from decades to centuries at both global and regional scales, including mean changes, variability and extremes. Fundamental questions related to the predictability of climate as well as long term climate change, climate change commitments, and inertia in the climate system are addressed.

Integration (Chapters 13 and 14): These chapters integrate all relevant information for two key topics in WGI AR5: sea level change (Chapter 13) and climate phenomena across the regions (Chapter 14). Chapter 13 assesses information on sea level change ranging from observations and process understanding to projections from global to regional scales. Chapter 14 assesses the most important modes of variability in the climate system and extreme events. Furthermore, this chapter deals with interconnections between the climate phenomena, their regional expressions, and their relevance for future regional climate change. Maps produced and assessed in Chapter 14, together with Chapters 11 and 12, form the basis of the Atlas of Global and Regional Climate Projections in Annex I. RFs and estimates of future atmospheric concentrations from Chapters 7, 8, 11, and 12 form the basis of the Climate System Scenario Tables in Annex II.

1.6.1 Topical Issues

A number of topical issues are discussed throughout the assessment. These issues include those of areas where there is contention in the peer-reviewed literature and where questions have been raised that are being addressed through ongoing research. Table 1.3 provides a non-comprehensive list of many of these and the chapters where they are discussed.

Table 1.3: Key topical issues discussed in the assessment.

Topic	Section
Abrupt change and irreversibility	5.7, 12.5, 13.4
Aerosols	6.4, 7.3, 7.4, 7.5, 7.6, 8.3, 11.3, 14.1

Antarctic climate change	5.8, 9.4, 10.3, 13.3
Arctic sea ice change	4.2, 5.5, 9.4, 10.3, 11.3, 12.4
Hydrological cycle changes	2.5, 2.6, 3.3, 3.4, 3.5, 7.6, 10.3, 12.4
Carbon-climate feedbacks	6.4, 12.4
Climate sensitivity	5.3, 9.7, 10.8, 12.5
Climate stabilization	6.3, 6.4, 12.5
Cloud feedbacks	5.3, 7.2, 9.7, 11.3, 12.4
Cosmic ray effects on clouds	7.4
Decadal climate variability	5.3, 9.1, 10.3
Earth's Energy (trends, distribution and budget)	2.3, 3.2, 13.3
El Nino-Southern Oscillation	2.7, 5.4, 9.4, 9.5, 14.4
Geo-engineering	6.4, 7.7
Glacier change	4.3, 5.5, 10.5, 13.3
Ice sheet dynamics and mass balance assessment	4.4, 5.3, 5.6, 10.5, 13.3
Monsoons	2.7, 5.5, 9.5, 14.2
Ocean acidification	3.8, 6.4
Permafrost change	4.7, 6.3, 10.5
Solar effects on climate change	5.2, 8.4
Sea level change, including regional effects	3.7, 5.6, 13.1
Temperature trends since 1998	2.4, 3.2, 10.3
Tropical cyclones	2.6, 10.6, 14.6
Upper troposphere temperature trends	2.4, 9.4

[START FAQ 1.1 HERE]

FAQ 1.1: If Understanding of the Climate System Has Increased, Why Hasn't the Range of Temperature Projections Been Reduced?

The models used to calculate the IPCC's temperature projections agree on the direction of future global change, but the projected size of those changes cannot be precisely predicted. Future greenhouse gas emission rates could take any one of many possible trajectories, and some underlying physical processes are not yet completely understood, making them difficult to model. Those uncertainties, combined with natural year-to-year climate variability, produce an 'uncertainty range' in temperature projections.

The uncertainty range around projected greenhouse gas and aerosol precursor emissions, (which depend on predictions of future social and economic conditions) cannot be materially reduced. Nevertheless, improved understanding and climate models—along with observational constraints—may reduce the uncertainty range around some factors that influence the climate's response to those emission changes. The complexity of the climate system, however, makes this a slow process. (FAQ1.1, Figure 1).

Climate science has made many important advances since the last IPCC assessment report, thanks to improvements in measurements and data analysis in the cryosphere, atmosphere, land, biosphere and ocean systems. Scientists also have better understanding and tools to model the role of clouds, sea ice, aerosols, small-scale ocean mixing, the carbon cycle and other processes. More observations mean that models can now be evaluated more thoroughly, and projections can be better constrained. For example, as models and observational analysis have improved, projections of sea level rise have become more accurate, balancing the current sea level rise budget.

Despite these advances, there is still a range in plausible projections for future global and regional climate—what scientists call an 'uncertainty range'. These uncertainty ranges are specific to the variable being considered (precipitation vs. temperature, for instance) and the spatial and temporal extent (such as regional vs. global averages). Uncertainties in climate projections arise from natural variability and uncertainty around the rate of future emissions and the climate's response to them. They can also occur because

representations of some known processes are as yet unrefined, and because some processes are not included in the models.

There are fundamental limits to just how precisely annual temperatures can be projected, because of the chaotic nature of the climate system. Furthermore, decadal-scale projections are sensitive to prevailing conditions—such as the temperature of the deep ocean—that are less well known. Some natural variability over decades arises from interactions between the ocean, atmosphere, land, biosphere and cryosphere, and is also linked to phenomena such as the El Niño-Southern Oscillation (ENSO) and the North Atlantic Oscillation (see Box 2.5 for details on patterns and indices of climate variability).

Volcanic eruptions and variations in the sun's output also contribute to natural variability, although they are externally-forced and explainable. This natural variability can be viewed as part of the 'noise' in the climate record, which provides the backdrop against which the 'signal' of anthropogenic climate change is detected.

Natural variability has a greater influence on uncertainty at regional and local scales than it does over continental or global scales. It is inherent in the Earth system, and more knowledge will not eliminate the uncertainties it brings. However, some progress is possible—particularly for projections up to a few years ahead—which exploit advances in knowledge of, for instance, the cryosphere or ocean state and processes. This is an area of active research. When climate variables are averaged over decadal time scales or longer, the relative importance of internal variability diminishes, making the long-term signals more evident (FAQ1.1, Figure 1). This long-term perspective is consistent with a common definition of climate as an average over 30 years.

A second source of uncertainty stems from the many possible trajectories that future emission rates of greenhouse gases and aerosol precursors might take, and from future trends in land use. Nevertheless, climate projections rely on input from these variables. So to obtain these estimates, scientists consider a number of alternative scenarios for future human society, in terms of population, economic and technological change, and political choices. They then estimate the likely emissions under each scenario. The IPCC informs policy making, therefore climate projections for different emissions scenarios can be useful as they show the possible climatic consequences of different policy choices. These scenarios are intended to be compatible with the full range of emissions scenarios described in the current scientific literature, with or without climate policy. As such, they are designed to sample uncertainty in future scenarios.

Projections for the next few years and decades are sensitive to emissions of short-lived compounds such as aerosols and methane. More distant projections, however, are more sensitive to alternative scenarios around long-lived greenhouse gas emissions. These scenario-dependent uncertainties will not be reduced by improvements in climate science, and will become the dominant uncertainty in projections over longer time scales (e.g., 2100) (FAQ 1.1, Figure 1).

The final contribution to the uncertainty range comes from our imperfect knowledge of how the climate will respond to future anthropogenic emissions and land use change. Scientists principally use computer-based global climate models to estimate this response. A few dozen global climate models have been developed by different groups of scientists around the world. All models are built on the same physical principles, but some approximations are needed because the climate system is so complex. Different groups choose slightly different approximations to represent specific processes in the atmosphere, such as clouds. These choices produce differences in climate projections from different models. This contribution to the uncertainty range is described as 'response uncertainty' or 'model uncertainty'.

The complexity of the Earth system means that future climate could follow many different scenarios, yet still be consistent with current understanding and models. As observational records lengthen and models improve, researchers will be able to narrow that range in probable temperature for the next few decades (FAQ 1.1, Figure 1). It is also possible to use information about the current state of the oceans and cryosphere to produce better projections up to a few years ahead.

As science improves, new geophysical processes can be added to climate models, and representations of those already included can be improved. These developments can appear to increase model-derived estimates of climate response uncertainty, but such increases merely reflect the quantification of previously

unmeasured sources of uncertainty (FAQ1.1, Figure 1). As more and more important processes are added, the influence of unquantified processes lessens, and there can be more confidence in the projections.

[INSERT FAQ1.1, FIGURE 1 HERE]

FAQ 1.1, Figure 1: Schematic diagram showing the relative importance of different uncertainties, and their evolution in time. **a)** Decadal mean surface temperature change (°C) from the historical record (black line), with climate model estimates of uncertainty for historical period (grey), along with future climate projections and uncertainty. Values are normalised by means from 1961 to 1980. Natural variability (orange) derives from model interannual variability, and is assumed constant with time. Emission uncertainty (green) is estimated as the model mean difference in projections from different scenarios. Climate response uncertainty (blue-solid) is based on climate model spread, along with added uncertainties from the carbon cycle, as well as rough estimates of additional uncertainty from poorly-modelled processes. Based on Hawkins and Sutton (2011) and Huntingford et al. (2009). **b)** Climate response uncertainty can appear to increase when a new process is discovered to be relevant, but such increases reflect a quantification of previously unmeasured uncertainty, or **c)** can decrease with additional model improvements and observational constraints. The given uncertainty range of 90% means that the temperature is estimated to be in that range, with a probability of 90%.

Figure 1.4

Documentation of Data Sources

Observed Temperature

NASA GISS evaluation of the observations: Hansen et al. (2010) updated: The data were downloaded from http://data.giss.nasa.gov/gistemp/taledata_v3/GLB.Ts+dSST.txt. Annual means are used (January to December) and anomalies are calculated relative to 1961–1990.

NOAA NCDC evaluation of the observations: Smith et al. (2008) updated: The data were downloaded from ftp://ftp.ncdc.noaa.gov/pub/data/anomalies/annual.land_ocean.90S.90N.df_1901-2000mean.dat. Annual mean anomalies are calculated relative to 1961–1990.

Hadley Centre evaluation of the observations: Morice et al. (2012): The data were downloaded from http://www.metoffice.gov.uk/hadobs/hadcrut4/data/current/download.html#regional_series. Annual mean anomalies are calculated relative to 1961–1990 based on the ensemble median.

IPCC Range of Projections

Table 1.A.1: FAR: The data have been digitized using a graphics tool from FAR Chapter 6, Figure 6.11 (Bretherton et al., 1990) in 5-year increments as anomalies relative to 1990 (°C).

Year	Lower Bound (Scenario D)	Upper Bound (Business as Usual)
1990	0.00	0.00
1995	0.09	0.14
2000	0.15	0.30
2005	0.23	0.53
2010	0.28	0.72
2015	0.33	0.91
2020	0.39	1.11
2025	0.45	1.34
2030	0.52	1.58
2035	0.58	1.86

Table 1.A.2: SAR: The data have been digitized using a graphics tool from Figure 19 of the TS (IPCC, 1996) in 5-year increments as anomalies relative to 1990. The scenarios include changes in aerosols beyond 1990 (°C).

Year	Lower Bound (IS92c/1.5)	Upper Bound (IS92e/4.5)
1990	0.00	0.00
1995	0.05	0.09
2000	0.11	0.17
2005	0.16	0.28
2010	0.19	0.38
2015	0.23	0.47
2020	0.27	0.57
2025	0.31	0.67
2030	0.36	0.79

2035	0.41	0.92
------	------	------

Table 1.A.3: TAR: The data have been digitized using a graphics tool from Figure 9.13(b) (Cubasch et al., 2001) in 5-year increments based on the GFDL_R15_a and DOE PCM parameter settings (°C).

Year	Lower Bound	Upper Bound
1990	0.00	0.00
1995	0.05	0.09
2000	0.11	0.20
2005	0.14	0.34
2010	0.17	0.52
2015	0.22	0.70
2020	0.28	0.87
2025	0.37	1.08
2030	0.43	1.28
2035	0.52	1.50

AR4: The temperature projections of the AR4 are presented for three SRES scenarios: B1, A1B and A2. Annual mean anomalies relative to 1961–1990 of the individual CMIP3 ensemble simulations (as used in AR4 SPM Figure SPM5) are shown. One outlier has been eliminated based on the advice of the model developers because of the model drift that leads to an unrealistic temperature evolution. As assessed by Meehl et al. (2007), the *likely*-range for the temperature change is given by the ensemble mean temperature change +60% and –40% of the ensemble mean temperature change. Note that in the AR4 the uncertainty range was explicitly estimated for the end of the 21st century results. Here, it is shown for 2035. The time dependence of this range has been assessed in Knutti et al. (2008). The relative uncertainty is approximately constant over time in all estimates from different sources, except for the very early decades when natural variability is being considered (see Figure 3 in Knutti et al., 2008).

Data Processing

Observations

The observations are shown from 1950 to 2012 as annual mean anomaly relative to 1961–1990 (squares). For smoothing, first, the trend of each of the observational datasets was calculated by locally weighted scatter plot smoothing (Cleveland, 1979; $f=1/3$). Then, the 11-year running means of the residuals were determined with reflected ends for the last 5 years. Finally, the trend was added back to the 11-year running means of the residuals.

Projections

For FAR, SAR and TAR, the projections have been harmonized to match the average of the three smoothed observational datasets at 1990.

Figure 1.5

Documentation of Data Sources

Observed CO₂ Concentrations

Global annual mean CO₂ concentrations are presented as annual mean values from Annex II Table AII.1.1a.

IPCC Range of Projections

Table 1.A.4: FAR: The data have been digitized using a graphics tool from Figure A.3 (Annex, IPCC, 1990) as anomalies compared to 1990 in 5-year increments (ppm) and the observed 1990 value (353.6) has been added.

Year	Lower Bound (Scenario D)	Upper Bound (Business as Usual)
1990	353.6	353.6
1995	362.8	363.7
2000	370.6	373.3
2005	376.5	386.5
2010	383.2	401.5
2015	390.2	414.3
2020	396.6	428.8
2025	401.5	442.0
2030	406.0	460.7
2035	410.0	480.3

Table 1.A.5: SAR: The data have been digitized using a graphics tool from Figure 5b in the TS (IPCC, 1996) in 5-year increments (ppm) as anomalies compared to 1990 and the observed 1990 value (353.6) has been added.

Year	Lower Bound (IS92c)	Upper Bound (IS92e)
1990	353.6	353.6
1995	358.4	359.0
2000	366.8	369.2
2005	373.7	380.4
2010	382.3	392.9
2015	391.4	408.0
2020	400.7	423.0
2025	408.0	439.6
2030	416.9	457.7
2035	424.5	477.7

TAR: The data were taken in 10-year increments from table Appendix II (IPCC, 2001) SRES Data Tables Table II.2.1 (ISAM model high and low setting). The scenarios that give the upper bound or lower bound respectively vary over time.

AR4: The data used was obtained from Figure 10.26 in Chapter 10 of AR4 (Meehl et al., 2007, provided by Malte Meinshausen). Annual means are used.

Data Processing

The projections have been harmonized to start from the observed value in 1990.

Figure 1.6

Documentation of Data Sources

Observed CH₄ Concentrations

Global annual mean CH₄ concentrations are presented as annual mean values from Annex II Table AII.1.1a.

IPCC Range of Projections

Table 1.A.6: FAR: The data have been digitized using a graphics tool from FAR SPM Figure 5 (IPCC, 1990) in 5-year increments (ppb) as anomalies compared to 1990 the observed 1990 value (1714.4) has been added.

Year	Lower Bound (Scenario D)	Upper Bound (Business as Usual)
1990	1714.4	1714.4
1995	1775.7	1816.7
2000	1809.7	1938.7
2005	1819.0	2063.8
2010	1823.1	2191.1
2015	1832.3	2314.1
2020	1847.7	2441.3
2025	1857.9	2562.3
2030	1835.3	2691.6
2035	1819.0	2818.8

SAR: The data were taken in 5-year increments from Table 2.5a (Schimel et al., 1996). The scenarios that give the upper bound or lower bound respectively vary over time.

TAR: The data were taken in 10-year increments from Appendix II SRES Data Tables Table II.2.2 (IPCC, 2001). The upper bound is given by the A1p scenario, the lower bound by the B1p scenario.

AR4: The data used was obtained from Figure 10.26 in Chapter 10 of AR4 (Meehl et al., 2007, provided by Malte Meinshausen). Annual means are used.

Data Processing

The observations are shown as annual means. The projections have been harmonized to start from the same value in 1990.

Figure 1.7

Documentation of Data Sources

Observed N₂O Concentrations

Global annual mean N₂O concentrations are presented as annual mean values from Annex II Table AII.1.1a.

IPCC Range of Projections

Table 1.A.7: FAR: The data have been digitized using a graphics tool from FAR A.3 (Annex, IPCC, 1990) in 5-year increments (ppb) as anomalies compared to 1990 and the observed 1990 value (308.7) has been added.

Year	Lower bound (Scenario D)	Upper bound (Business as Usual)
1990	308.7	308.7
1995	311.7	313.2

2000	315.4	317.7
2005	318.8	322.9
2010	322.1	328.0
2015	325.2	333.0
2020	328.2	337.9
2025	331.7	343.0
2030	334.0	348.9
2035	336.1	354.1

SAR: The data were taken in 5-year increments from Table 2.5b (Schimel et al., 1996). The upper bound is given by the IS92e and IS92f scenario, the lower bound by the IS92d scenario.

TAR: The data were taken in 10-year increments from Appendix II SRES Data Tables Table II.2.3 (IPCC, 2001). The upper bound is given by the A1FI scenario, the lower bound by the B2 and A1T scenario.

AR4: The data used was obtained from Figure 10.26 in Chapter 10 of AR4 (Meehl et al., 2007, provided by Malte Meinshausen). Annual means are used.

Data Processing

The observations are shown as annual means. No smoothing is applied. The projections have been harmonized to start from the same value in 1990.

Figure 1.10

Documentation of Data Sources

Observed Global Mean Sea Level Rise

Three datasets based on tide gauge measurements are presented: Church and White (2011), Jevrejeva et al. (2008), and Ray and Douglas (2011). Annual mean anomalies are calculated relative to 1961–1990.

Estimates based on sea surface altimetry are presented as the ensemble mean of five different data sets (Section 3.7, Figure 3.13, Section 13.2, Figure 13.3) from 1993 to 2012. Annual means have been calculated. The data are harmonized to start from the mean of the three tide gauge based estimates (see above) at 1993.

IPCC Range of Projections

Table 1.A.8: FAR: The data have been digitized using a graphics tool from Chapter 9, Figure 9.6 for the upper bound and Figure 9.7 for the lower bound (Warrick and Oerlemans, 1990) in 5-year increments as anomalies relative to 1990 (cm) and the observed anomaly relative to 1961–1990 (2.0 cm) has been added.

Year	Lower Bound (Scenario D)	Upper Bound (Business as Usual)
1990	2.0	2.0
1995	2.7	5.0
2000	3.7	7.9
2005	4.6	11.3
2010	5.5	15.0
2015	6.3	18.7
2020	6.9	22.8

2025	7.7	26.7
2030	8.4	30.9
2035	9.2	35.4

Table 1.A.9: SAR: The data have been digitized using a graphics tool from Figure 21 (TS, IPCC, 1996) in 5-year increments as anomalies relative to 1990 (cm) and the observed anomaly relative to 1961–1990 (2.0 cm) has been added.

Year	Lower Bound (IS92c/1.5)	Upper Bound (IS92e/4.5)
1990	2.0	2.0
1995	2.4	4.3
2000	2.7	6.5
2005	3.1	9.0
2010	3.4	11.7
2015	3.8	14.9
2020	4.4	18.3
2025	5.1	21.8
2030	5.7	25.4
2035	6.4	29.2

TAR: The data are given in Table II.5.1 in 10-year increments. They are harmonized to start from mean of the observed anomaly relative to 1961–1990 at 1990 (2.0 cm).

AR4: The AR4 did not give a time-dependent estimate of sea level rise. These analyses have been conducted post AR4 by Church et al. (2011) based on the CMIP3 model results that were available at the time of AR4. Here, the SRES B1, A1B, and A2 scenarios are shown from Church et al. (2011). The data start in 2001 and are given as anomalies with respect to 1990. They are displayed from 2001 to 2035, but the anomalies are harmonized to start from mean of the observed anomaly relative to 1961–1990 at 1990 (2.0 cm).

Data Processing

The observations are shown from 1950 to 2012 as the annual mean anomaly relative to 1961–1990 (squares) and smoothed (solid lines). For smoothing, first, the trend of each of the observational datasets was calculated by locally weighted scatter plot smoothing (Cleveland, 1979; $f=1/3$). Then, the 11-year running means of the residuals were determined with reflected ends for the last 5 years. Finally, the trend was added back to the 11-year running means of the residuals.

3

Topic	FAR SPM Statement	SAR SPM Statement	TAR SPM Statement	AR4 SPM Statement	
Human and Natural Drivers of Climate Change	<p>There is a natural greenhouse effect which already keeps the Earth warmer than it would otherwise be. Emissions resulting from human activities are substantially increasing the atmospheric concentrations of the greenhouse gases carbon dioxide, methane, chlorofluorocarbons and nitrous oxide. These increases will enhance the greenhouse effect, resulting on average in an additional warming of the Earth's surface.</p> <p>Continued emissions of these gases at present rates would commit us to increased concentrations for centuries ahead.</p>	<p>Greenhouse gas concentrations have continued to increase. These trends can be attributed largely to human activities, mostly fossil fuel use, land use change and agriculture.</p> <p>Anthropogenic aerosols are short-lived and tend to produce negative radiative forcing.</p>	<p>Emissions of greenhouse gases and aerosols due to human activities continue to alter the atmosphere in ways that are expected to affect the climate. The atmospheric concentration of CO₂ has increased by 31% since 1750 and that of methane by 151%.</p> <p>Anthropogenic aerosols are short-lived and mostly produce negative radiative forcing by their direct effect. There is more evidence for their indirect effect, which is negative, although of very uncertain magnitude.</p> <p>Natural factors have made small contributions to radiative forcing over the past century.</p>	<p>Global atmospheric concentrations of carbon dioxide, methane and nitrous oxide have increased markedly as a result of human activities since 1750 and now far exceed pre-industrial values determined from ice cores spanning many thousands of years. The global increases in carbon dioxide concentration are due primarily to fossil fuel use and land use change, while those of methane and nitrous oxide are primarily due to agriculture.</p> <p>Very high confidence that the global average net effect of human activities since 1750 has been one of warming, with a radiative forcing of +1.6 [+0.6 to +2.4] W m⁻².</p>	
Direct Observations of Recent Climate Change	Temperature	<p>Global mean surface air temperature has increased by 0.3°C to 0.6°C over the last 100 years, with the five global-average warmest years being in the 1980s.</p>	<p>Climate has changed over the past century. Global mean surface temperature has increased by between about 0.3 and 0.6°C since the late 19th century. Recent years have been among the warmest since 1860, despite the cooling effect of the 1991 Mt. Pinatubo volcanic eruption.</p>	<p>An increasing body of observations gives a collective picture of a warming world and other changes in the climate system. The global average temperature has increased since 1861. Over the 20th century the increase has been 0.6°C.</p> <p>Some important aspects of climate appear not to have changed.</p>	<p>Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level.</p> <p>Eleven of the last twelve years (1995–2006) rank among the 12 warmest years in the instrumental record of global surface temperature (since 1850). The updated 100-year linear trend (1906 to 2005) of 0.74°C [0.56°C to 0.92°C] is therefore larger than the corresponding trend for 1901 to 2000 given in the TAR of</p>

					0.6°C [0.4°C to 0.8°C]. Some aspects of climate have not been observed to change.
	Sea Level	Over the same period global sea level has increased by 10–20 cm. These increases have not been smooth with time, nor uniform over the globe.	Global sea level has risen by between 10 and 25 cm over the past 100 years and much of the rise may be related to the increase in global mean temperature.	Tide gauge data show that global average sea level rose between 0.1 and 0.2 m during the 20th century.	Global average sea level rose at an average rate of 1.8 [1.3 to 2.3] mm per year over 1961 to 2003. The rate was faster over 1993 to 2003: about 3.1 [2.4 to 3.8] mm per year. The total 20th century rise is estimated to be 0.17 [0.12 to 0.22] m.
A Palaeoclimatic Perspective		Climate varies naturally on all time-scales from hundreds of millions of years down to the year-to-year. Prominent in the Earth's history have been the 100,000 year glacial-interglacial cycles when climate was mostly cooler than at present. Global surface temperatures have typically varied by 5°C–7°C through these cycles, with large changes in ice volume and sea level, and temperature changes as great as 10°C–15°C in some middle and high latitude regions of the Northern Hemisphere. Since the end of the last ice age, about 10,000 years ago, global surface temperatures have probably fluctuated by little more than 1°C. Some fluctuations have lasted several centuries, including the Little Ice Age which ended in the nineteenth century and which appears to have been global in extent.	The limited available evidence from proxy climate indicators suggests that the 20th century global mean temperature is at least as warm as any other century since at least 1400 AD. Data prior to 1400 are too sparse to allow the reliable estimation of global mean temperature.	New analyses of proxy data for the Northern Hemisphere indicate that the increase in temperature in the 20th century is likely to have been the largest of any century during the past 1,000 years. It is also likely that, in the Northern Hemisphere, the 1990s was the warmest decade and 1998 the warmest year. Because less data are available, less is known about annual averages prior to 1,000 years before present and for conditions prevailing in most of the Southern Hemisphere prior to 1861.	Palaeoclimatic information supports the interpretation that the warmth of the last half century is unusual in at least the previous 1,300 years. The last time the polar regions were significantly warmer than present for an extended period (about 125,000 years ago), reductions in polar ice volume led to 4 to 6 m of sea level rise.
Understanding and Attributing Climate Change		The size of this warming is broadly consistent with predictions of climate models, but it is also of the same magnitude as natural climate variability. Thus the observed increase could be largely due to this	The balance of evidence suggests a discernible human influence on global climate. Simulations with coupled atmosphere-ocean models have provided important information about decade to	There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities. There is a longer and more scrutinized temperature record and new model	Most of the observed increase in global average temperatures since the mid-20th century is likely due to the observed increase in anthropogenic greenhouse gas concentrations. Discernible human

		natural variability; alternatively this variability and other human factors could have offset a still larger human-induced greenhouse warming. The unequivocal detection of the enhanced greenhouse effect from observations is not likely for a decade or more.	century time-scale natural internal climate variability.	estimates of variability. Reconstructions of climate data for the past 1,000 years indicate this warming was unusual and is unlikely to be entirely natural in origin.	influences now extend to other aspects of climate, including ocean warming, continental-average temperatures, temperature extremes and wind patterns.
Projections of Future Changes in Climate	Temperature	Under the IPCC Business-as-Usual emissions of greenhouse gases, a rate of increase of global mean temperature during the next century of about 0.3°C per decade (with an uncertainty range of 0.2°C to 0.5°C per decade); this is greater than that seen over the past 10,000 years.	Climate is expected to continue to change in the future. For the mid-range IPCC emission scenario, IS92a, assuming the 'best estimate' value of climate sensitivity and including the effects of future increases in aerosols, models project an increase in global mean surface air temperature relative to 1990 of about 2°C by 2100.	Global average temperature and sea level are projected to rise under all IPCC SRES scenarios. The globally averaged surface temperature is projected to increase by 1.4°C to 5.8°C over the period 1990 to 2100. Confidence in the ability of models to project future climate has increased. Anthropogenic climate change will persist for many centuries.	For the next two decades, a warming of about 0.2°C per decade is projected for a range of SRES emission scenarios. Even if the concentrations of all greenhouse gases and aerosols had been kept constant at year 2000 levels, a further warming of about 0.1°C per decade would be expected. There is now higher confidence in projected patterns of warming and other regional-scale features, including changes in wind patterns, precipitation and some aspects of extremes and of ice. Anthropogenic warming and sea level rise would continue for centuries, even if greenhouse gas concentrations were to be stabilised.
	Sea Level	An average rate of global mean sea level rise of about 6 cm per decade over the next century (with an uncertainty range of 3–10 cm per decade) is projected.	Models project a sea level rise of 50 cm from the present to 2100.	Global mean sea level is projected to rise by 0.09 to 0.88 m between 1990 and 2100.	Global sea level rise for the range of scenarios is projected as 0.18 to 0.59 m by the end of the 21st century.

Chapter 1: Introduction

Figures

Figure 1.1: Main drivers of climate change. The radiative balance between incoming solar shortwave radiation (SWR) and outgoing longwave radiation (LWR) is influenced by global climate “drivers”. Natural fluctuations in solar output (solar cycles) can cause changes in the energy balance (through fluctuations in the amount of incoming SWR) (Section 2.3). Human activity changes the emissions of gases and aerosols, which are involved in atmospheric chemical reactions, resulting in modified O₃ and aerosol amounts (Section 2.2). O₃ and aerosol particles absorb, scatter and reflect SWR, changing the energy balance. Some aerosols act as cloud condensation nuclei modifying the properties of cloud droplets and possibly affecting precipitation (Section 7.4). Since cloud interactions with SWR and LWR are large, small changes in the properties of clouds have important implications for the radiative budget (Section 7.4). Anthropogenic changes in greenhouse gases (e.g., CO₂, CH₄, N₂O, O₃, CFCs), and large aerosols (>2.5 μm in size) modify the amount of outgoing LWR by absorbing outgoing LWR and re-emitting less energy at a lower temperature (Section 2.2). Surface albedo is changed by changes in vegetation or land surface properties, snow or ice cover and ocean colour (Section 2.3). These changes are driven by natural seasonal and diurnal changes (e.g., snow cover), as well as human influence (e.g., changes in vegetation types) (Forster et al., 2007).

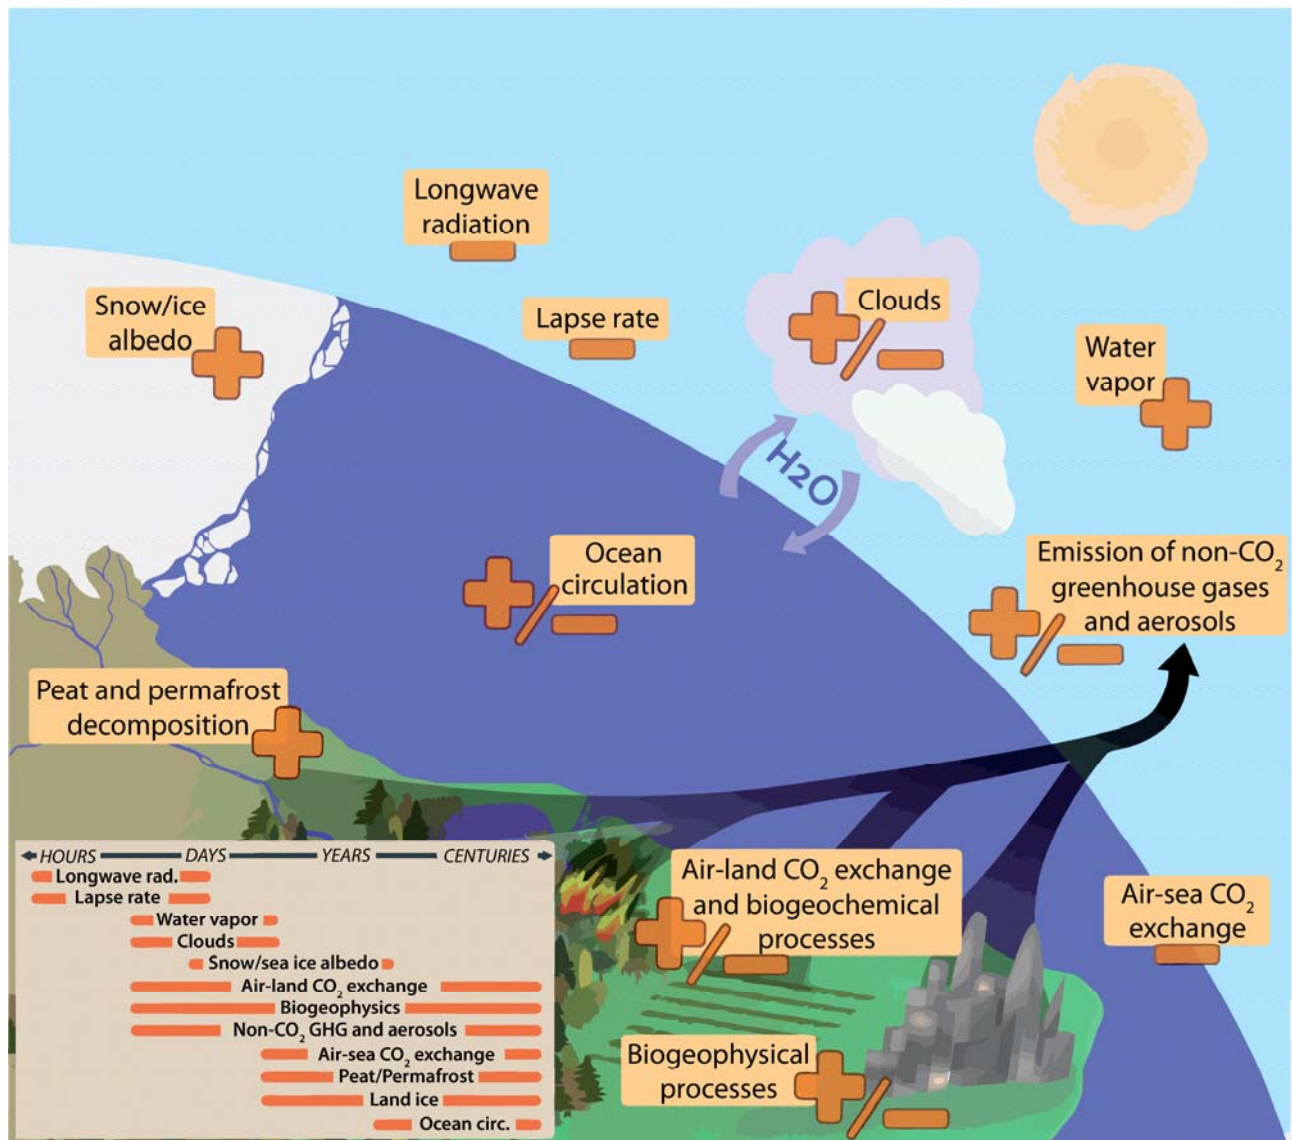

Figure 1.2: Climate feedbacks and timescales. The climate feedbacks related to increasing carbon dioxide and rising temperature include negative feedbacks (-) such as longwave radiation, lapse rate (see Glossary in Annex III), and air-sea carbon exchange and positive feedbacks (+) such as water vapour and snow/ice albedo feedbacks. Some feedbacks may be positive or negative (±): clouds, ocean circulation changes, air-land carbon dioxide exchange, and emissions of non-green house gases and aerosols from natural systems. In the smaller box, the large difference in timescales for the various feedbacks is highlighted.

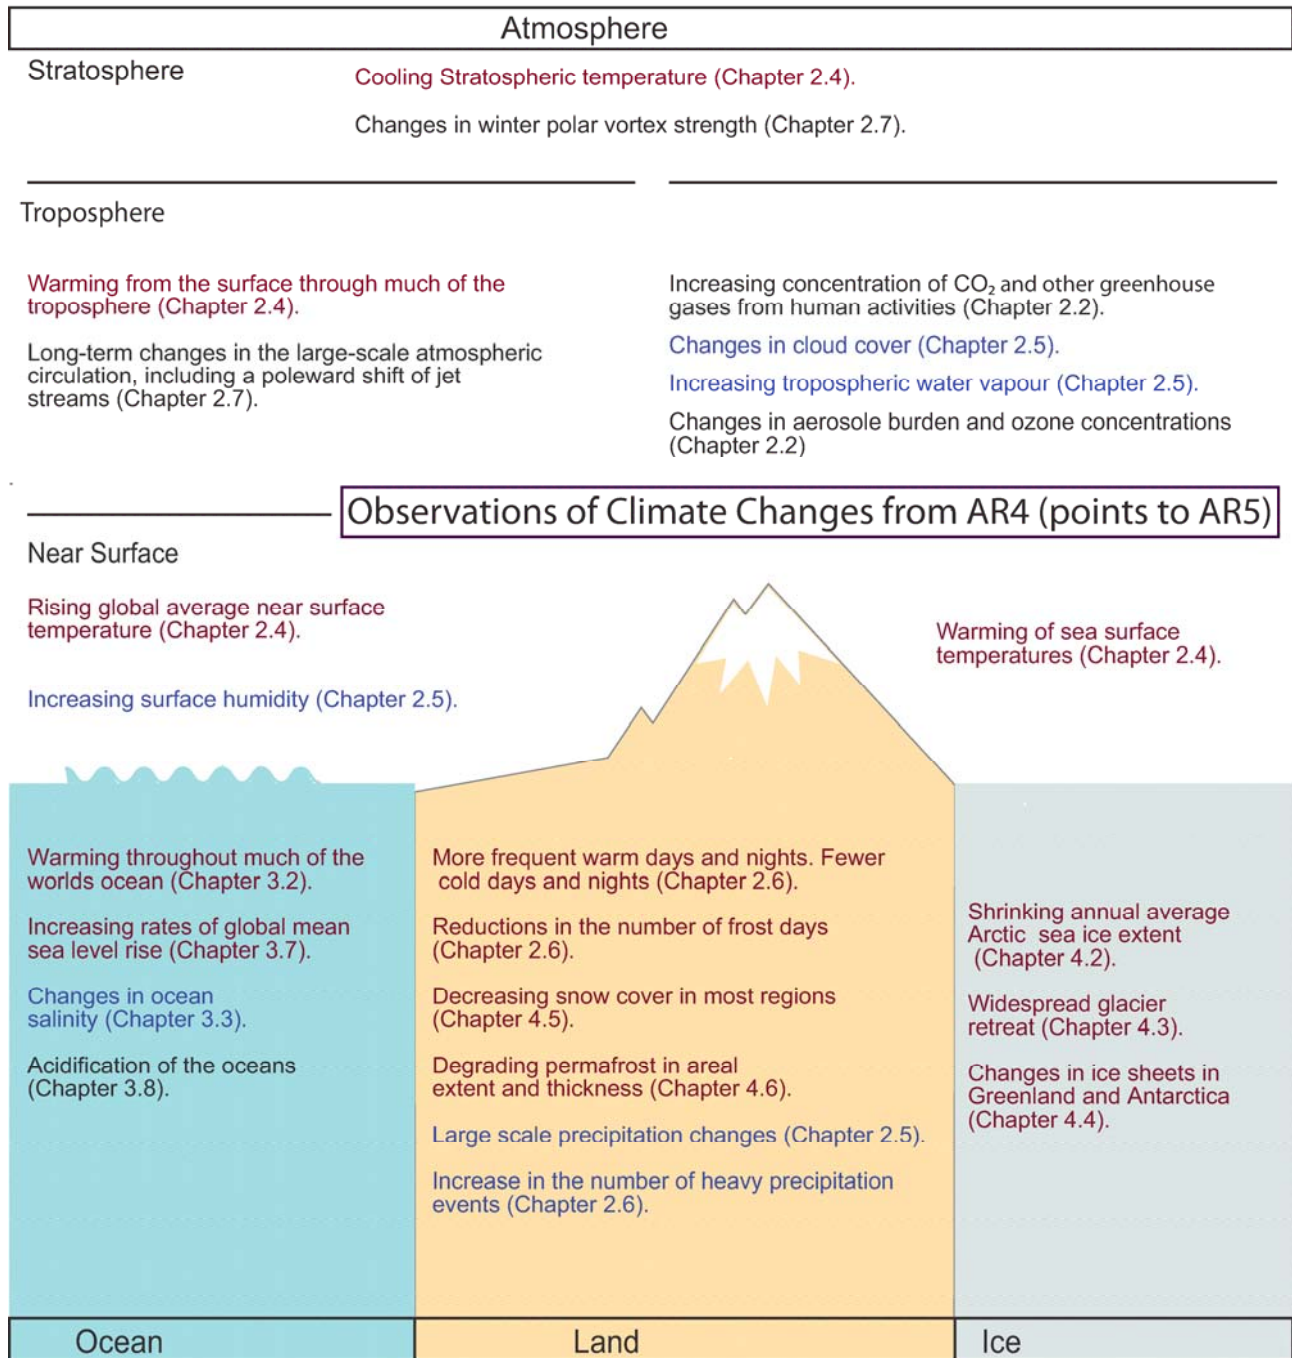

Figure 1.3: Overview of observed climate change indicators as listed in AR4. Chapter numbers indicate where detailed discussions for these indicators are found in AR5 (temperature: red; hydrological: blue; others: black).

Figure 1.4: Estimated changes in the observed globally and annually averaged surface temperature anomaly relative to 1961–1990 (in °C) since 1950 compared with the range of projections from the previous IPCC assessments. Values are harmonized to start from the same value in 1990. Observed global annual mean surface air temperature anomaly, relative to 1961–1990, is shown as squares and smoothed time series as solid lines (NASA (dark blue), NOAA (warm mustard), and the UK Hadley Centre (bright green) reanalyses). The coloured shading shows the projected range of global annual mean surface air temperature change from 1990 to 2035 for models used in FAR (Figure 6.11 in Bretherton et al., 1990), SAR (Figure 19 in the TS of IPCC, 1996), TAR (full range of TAR Figure 9.13(b) in Cubasch et al., 2001). TAR results are based on the simple climate model analyses presented and not on the individual full three-dimensional climate model simulations. For the AR4 results are presented as single model runs of the CMIP3 ensemble for the historical period from 1950 to 2000 (light grey lines) and for three scenarios (A2, A1B and B1) from 2001 to 2035. The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. For the three SRES scenarios the bars show the CMIP3 ensemble mean and the likely range given by -40% to $+60\%$ of the mean as assessed in Meehl et al. (2007). The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

Figure 1.5: Observed globally and annually averaged CO₂ concentrations in parts per million (ppm) since 1950 compared with projections from the previous IPCC assessments. Observed global annual CO₂ concentrations are shown in dark blue. The shading shows the largest model projected range of global annual CO₂ concentrations from 1950 to 2035 from FAR (Figure A.3 in the Summary for Policymakers (SPM) of IPCC, 1990), SAR (Figure 5b in the TS of IPCC, 1996), TAR (Appendix II of IPCC, 2001), and from the A2, A1B and B1 scenarios presented in the AR4 (Figure 10.26 in Meehl et al., 2007). The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

Figure 1.6: Observed globally and annually averaged CH₄ concentrations in parts per billion (ppb) since 1950 compared with projections from the previous IPCC assessments. Estimated observed global annual CH₄ concentrations are shown in dark blue. The shading shows the largest model projected range of global annual CH₄ concentrations from 1950 to 2035 from FAR (Figure A.3 of the Annex of IPCC, 1990), SAR (Table 2.5a in Schimel et al., 1996), TAR (Appendix II of IPCC, 2001), and from the A2, A1B and B1 scenarios presented in the AR4 (Figure 10.26 in Meehl et al., 2007). The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

Figure 1.7: Observed globally and annually averaged N₂O concentrations in parts per billion (ppb) since 1950 compared with projections from the previous IPCC assessments. Observed global annual N₂O concentrations are shown in dark blue. The shading shows the largest model projected range of global annual N₂O concentrations from 1950 to 2035 from FAR (Figure A3 in the Annex of IPCC, 1990), SAR (Table 2.5b in Schimel et al., 1996), TAR (Appendix II of IPCC, 2001), and from the A2, A1B and B1 scenarios presented in the AR4 (Figure 10.26 in Meehl et al., 2007). The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. The publication years of the assessment reports are shown. See Appendix 1.A for details on the data and calculations used to create this figure.

Figure 1.8: Schematic representations of the probability density function of daily temperature, which tends to be approximately Gaussian, and daily precipitation, which has a skewed distribution. Dashed lines represent a previous distribution and solid lines a changed distribution. The probability of occurrence, or frequency, of extremes is denoted by the shaded areas. In the case of temperature, changes in the frequencies of extremes are affected by changes a) in the mean, b) in the variance or shape, and c) in both the mean and the variance. d) In a skewed distribution such as that of precipitation, a change in the mean of the distribution generally affects its variability or spread, and thus an increase in mean precipitation would also *likely* imply an increase in heavy precipitation extremes, and vice-versa. In addition, the shape of the right hand tail could also change, affecting extremes. Furthermore, climate change may alter the frequency of precipitation and the duration of dry spells between precipitation events. a)-c) modified from Folland et al. (2001) and d) modified from Peterson et al. (2008) as in Zhang and Zwiers (2012).

Changes in Phenomenon	Confidence in observed changes (latter half of the 20 th century)			Confidence in projected changes (up to 2100)		
	TAR	AR4	SREX	TAR	AR4	SREX
Higher maximum temperatures and more hot days	Likely over nearly all land areas	Very Likely over most land areas	Very Likely at a global scale	Very Likely over nearly all land areas	Virtually Certain over most land areas	Virtually Certain at a global scale
Higher minimum temperatures, fewer cold days	Very Likely over nearly all land areas	Very Likely over most land areas	Very Likely at a global scale	Very Likely over nearly all land areas	Virtually Certain over most land areas	Virtually Certain at a global scale
Warm spells/heat waves. frequency, length or intensity increases	-	Likely over most land areas	Medium Confidence in many regions	-	Very Likely over most land areas	Very Likely over most land areas
Precipitation extremes	Likely ¹ , over many Northern Hemisphere mid-to high latitude land areas	Likely ² over most areas	Likely ³	Very Likely ¹ over many areas	Very Likely ²	Likely ²⁻⁴ in many land areas of the globe
Droughts or dryness	Likely ⁵ , in a few areas	Likely ⁶ , in many regions since 1970s	Medium Confidence in more intense and longer droughts in some regions, but some opposite trend exists	Likely ⁵ , over most mid-latitude continental interiors (Lack of consistent projections in other areas)	Likely ⁶	Medium Confidence ⁷ that droughts will intensify in some seasons and areas; Overall low confidence elsewhere
Changes in tropical cyclone activity (i.e. intensity, frequency, duration)	Not Observed ⁸ , in the few analyses available	Likely ⁹ , in some regions since 1970	Low confidence ¹⁰	Likely ⁸ , over some areas	Likely ⁹	Likely ¹¹
Increase in extreme sea level (excludes tsunamis)	-	Likely	Likely ¹²	-	Likely	Very Likely ¹³

¹More intense precipitation events

²Heavy precipitation events. Frequency (or proportion of total rainfall from heavy falls) increases

³Statistically significant trends in the number of heavy precipitation events in some regions. It is likely that more of these regions have experienced increases than decreases.

⁴ See SREX Table 3-3 for details on precipitation extremes for the different regions.

⁵Increased summer continental drying and associated risk of drought

⁶Area affected by droughts increases

⁷ Some areas include southern Europe and the Mediterranean region, central Europe, central North America and Mexico, northeast Brazil and southern Africa

⁸Increase in tropical cyclone peak wind intensities

⁹Increase in intense tropical cyclone activity

¹⁰In any observed long-term (i.e., 40 years or more) after accounting for past changes in observing capabilities (see SREX, section 3.4.4)

¹¹Increase in average tropical cyclone maximum wind speed is, although not in all ocean basins; either decrease or no change in the global frequency of tropical cyclones

¹² Increase in extreme coastal high water worldwide related to increases in mean sea level in the late 20th century

¹³ Mean sea level rise will contribute to upward trends in extreme coastal high water levels

Figure 1.9: Change in the confidence levels for extreme events based on prior IPCC assessments: TAR, AR4, and SREX. Types of extreme events discussed in all three reports are highlighted in green. Confidence levels are defined in Section 1.4. Similar analyses for AR5 are discussed in later chapters. Please note that the nomenclature for confidence level changed from AR4 to SREX and AR5.

Figure 1.10: Estimated changes in the observed global annual mean sea level (GMSL) since 1950 relative to 1961–1990. Estimated changes in global annual sea level anomalies are presented based on tide gauge data (Church and White, 2011 (dark blue); Jevrejeva et al., 2008 (warm mustard); Ray and Douglas, 2011 (dark green)) and based on sea surface altimetry (light blue). The altimetry data start in 1993 and are harmonized to start from the mean 1993 value of the tide gauge data. Squares indicate annual mean values, solid lines smoothed values. The shading shows the largest model projected range of global annual sea level rise from 1950 to 2035 for FAR (Figure 9.6 and Figure 9.7 in Warrick and Oerlemans, 1990), SAR (Figure 21 in TS of IPCC, 1996), TAR (Appendix II of IPCC, 2001) and for Church et al. (2011) based on the Coupled Model Intercomparison Project Phase 3 (CMIP3) model results not assessed at the time of AR4 using the SRES B1, A1B, and A2 scenarios. Note that in the AR4 no full range was given for the sea level projections for this period. Therefore, the figure shows results that have been published subsequent to the AR4. The bars at the right hand side of the graph show the full range given for 2035 for each assessment report. For Church et al. (2011) the mean sea level rise is indicated in addition to the full range. See Appendix 1.A for details on the data and calculations used to create this figure.

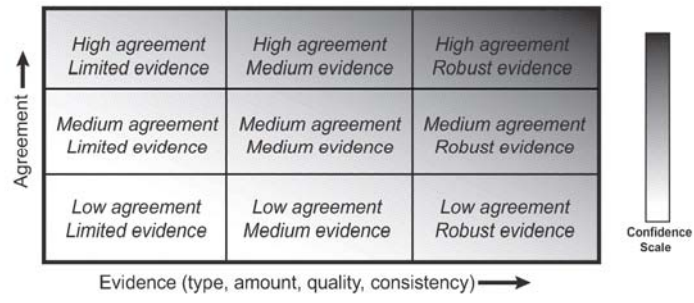

Figure 1.11: The basis for the confidence level is given as a combination of evidence (limited, medium, robust) and agreement (low, medium, and high) (Mastrandrea et al., 2010).

Figure 1.12: Development of capabilities of observations. Top: Changes in the mix and increasing diversity of observations over time create challenges for a consistent climate record (adapted from Brönnimann et al., 2008). Bottom left: First year of temperature data in global historical climatology network daily database (available at <http://www.ncdc.noaa.gov/oa/climate/ghcn-daily/>; Menne et al., 2012). Bottom right: Number of satellite instruments from which data have been assimilated in the European Centre for Medium-Range Weather Forecasts production streams for each year from 1996 to 2010. This figure is used as an example to demonstrate the fivefold increase in the usage of satellite data over this time period.

Figure 1.13: The development of climate models over the last 35 years showing how the different components were coupled into comprehensive climate models over time. In each aspect (e. g. the atmosphere, which comprises a wide range of atmospheric processes) the complexity and range of processes has increased over time (illustrated by growing cylinders). Note that during the same time the horizontal and vertical resolution has increased considerably e.g., for spectral models from T21L9 (roughly 500 km horizontal resolution and 9 vertical levels) in the 1970s to T95L95 (roughly 100 km horizontal resolution and 95 vertical levels) at present, and that now ensembles with at least three independent experiments can be considered as standard.

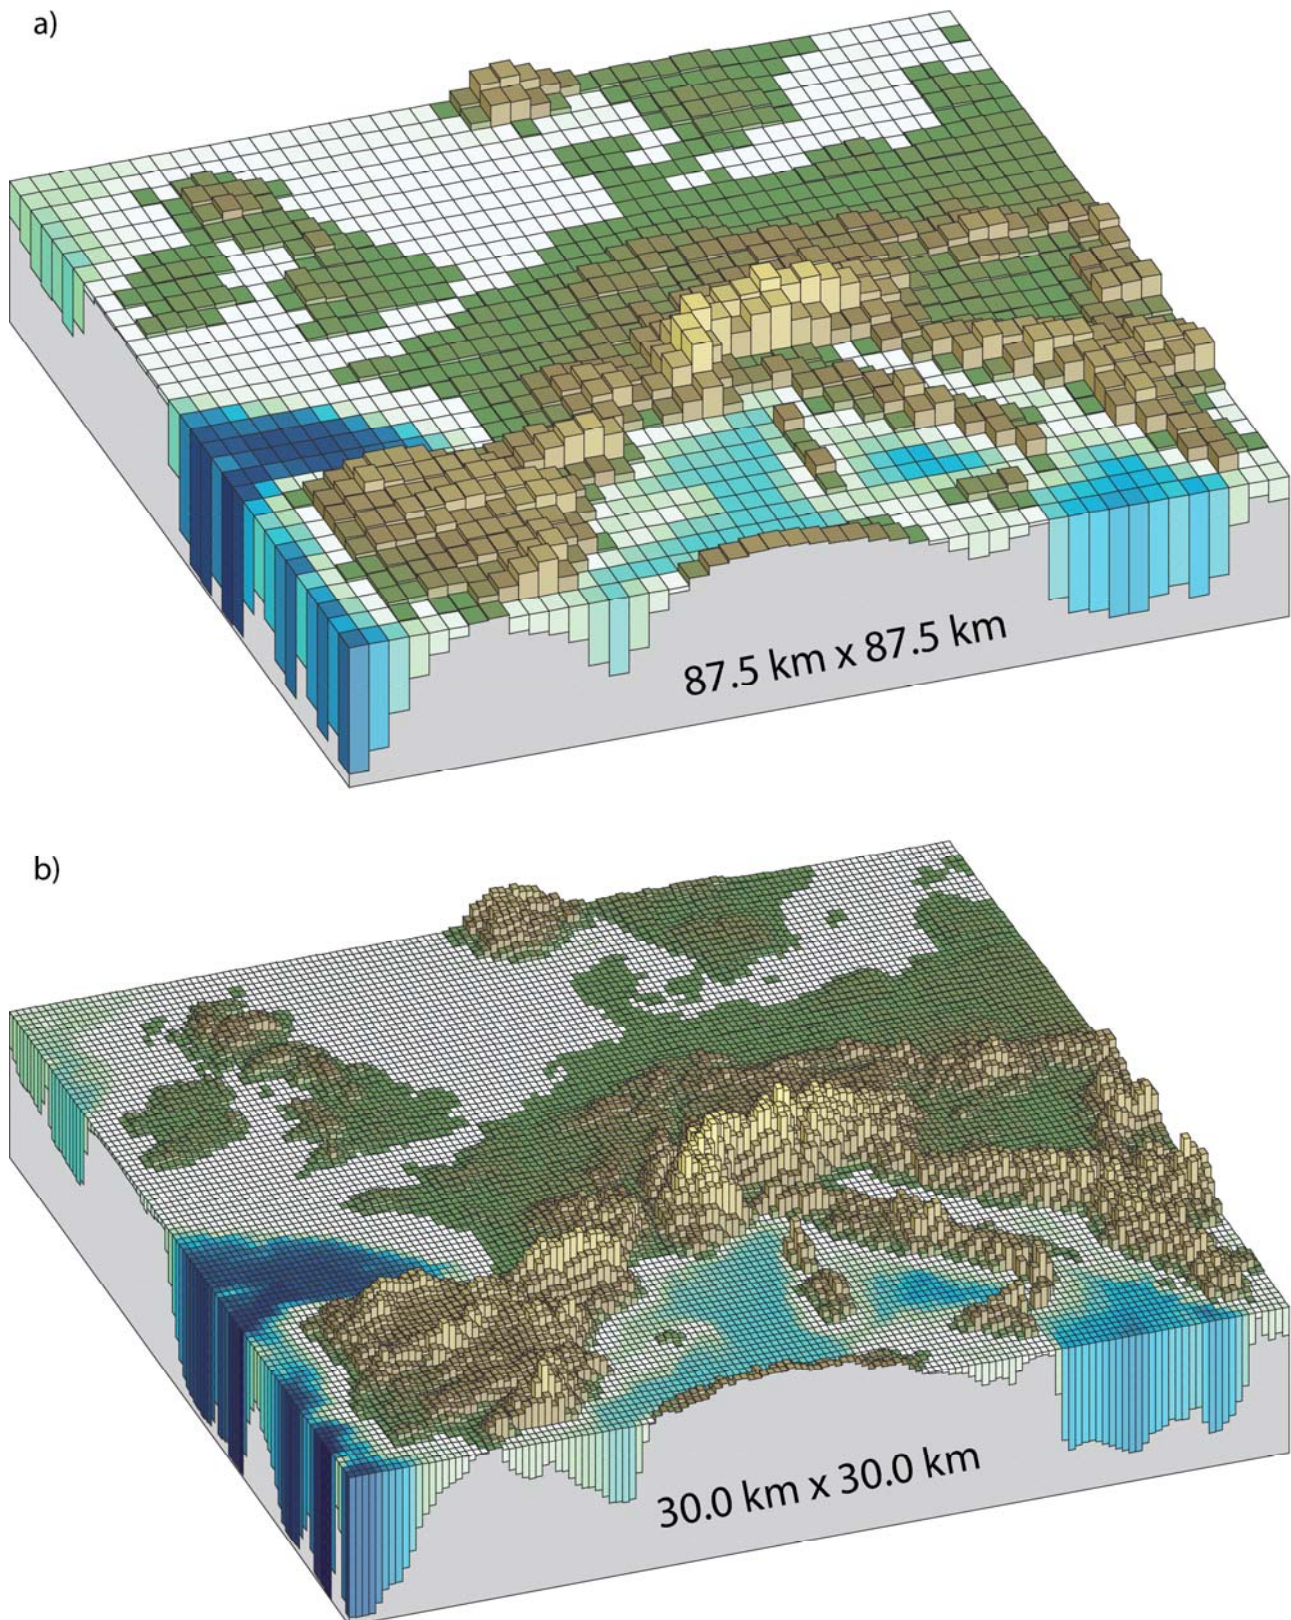

Figure 1.14: Horizontal resolutions considered in today's higher resolution models and in the very high resolution models now being tested: a) Illustration of the European topography at a resolution of 87.5 x 87.5 km; b) same as a) but for a resolution of 30.0 x 30.0 km.

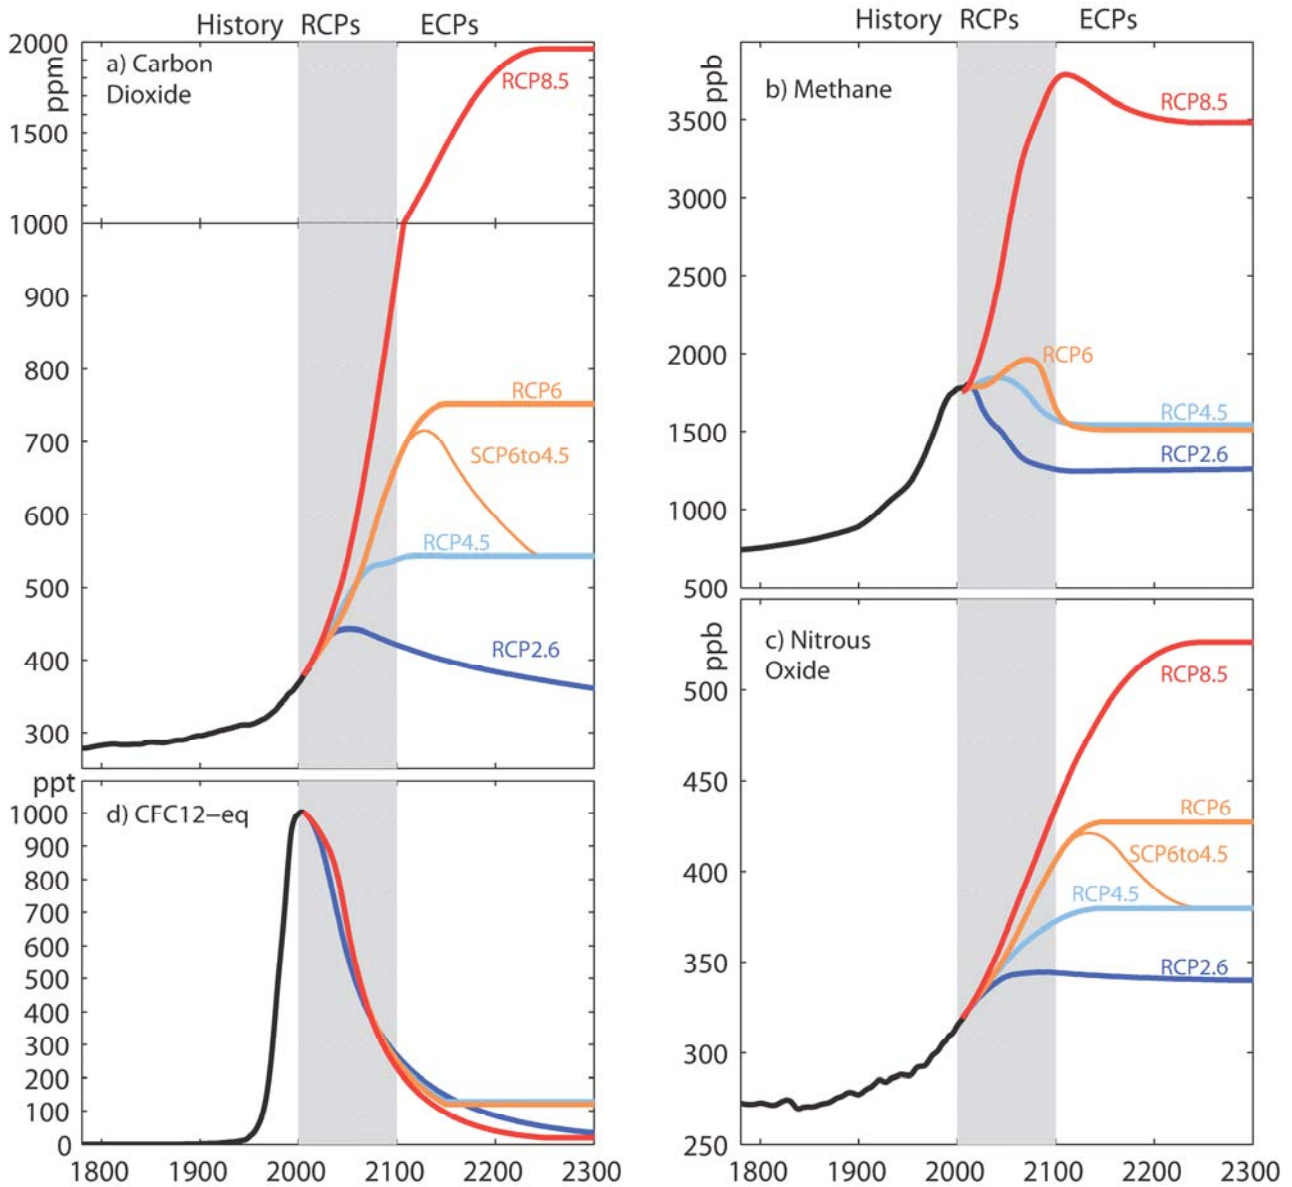

Figure 1.15: Historical and projected total anthropogenic RF (W m^{-2}) relative to preindustrial (~ 1765) between 1950 and 2100. Previous IPCC assessments (SAR IS92a, TAR/AR4 SRES A1B, A2 and B1) are compared with representative concentration pathway (RCP) scenarios (see Chapter 12 and Box 1.1 for their extensions until 2300 and Annex II for the values shown here). The total RF of the three families of scenarios, IS92, SRES and RCP, differ for example for the year 2000, resulting from the knowledge about the emissions assumed having changed since the TAR and AR4.

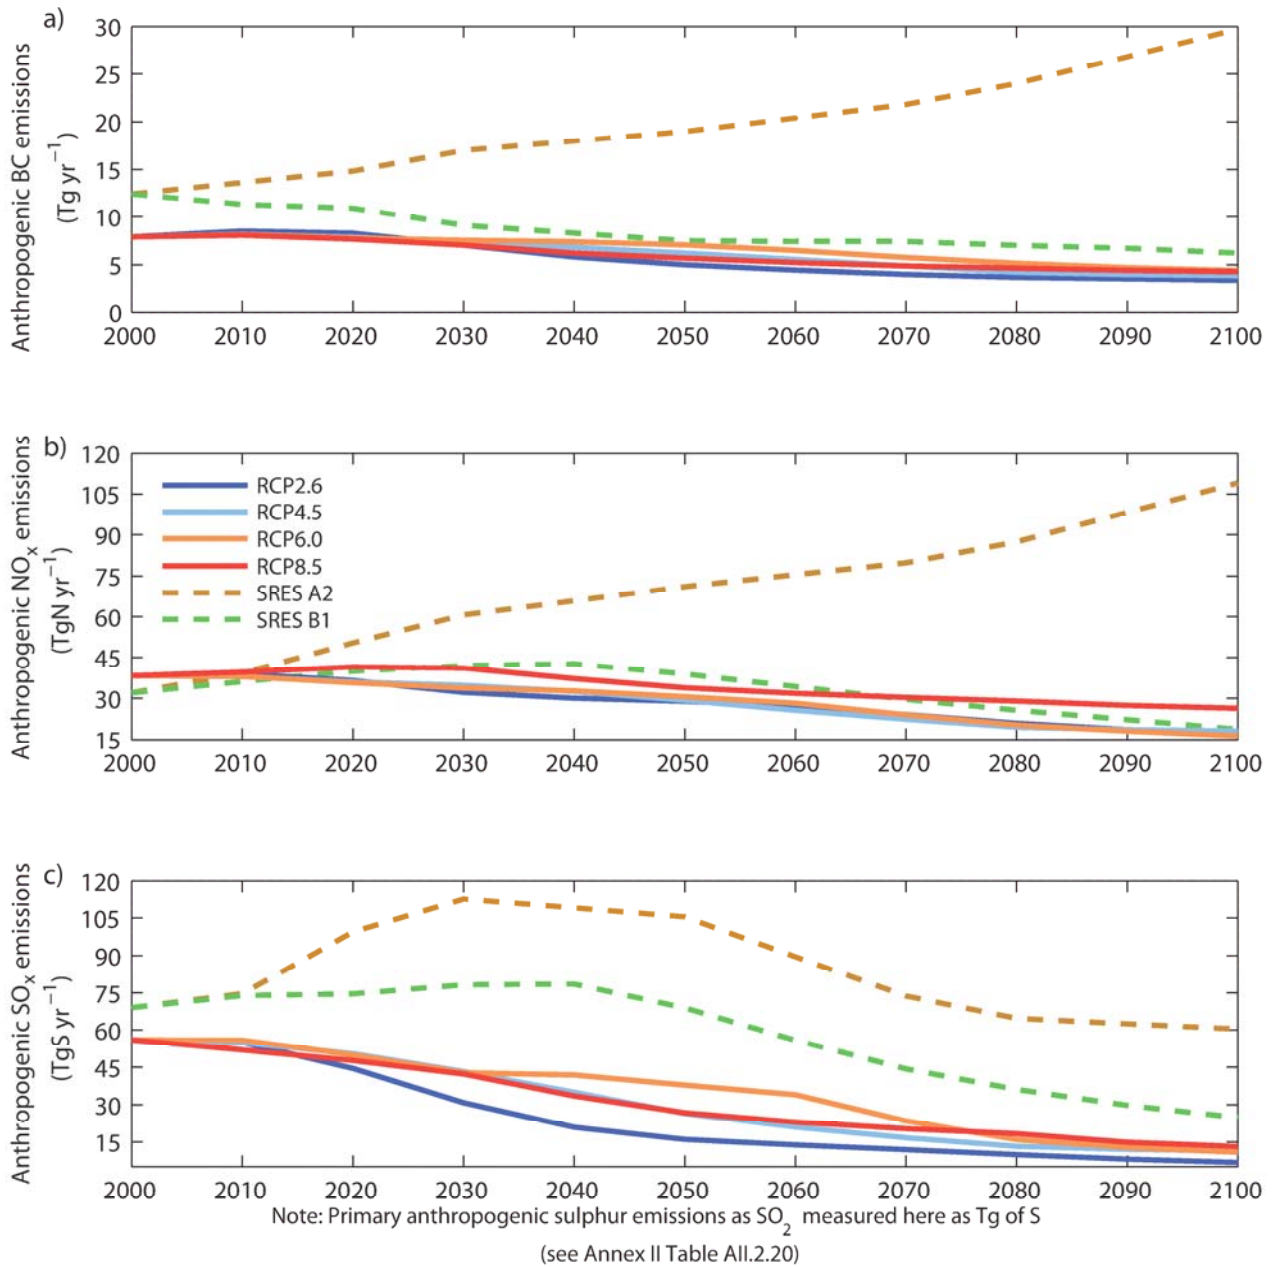

Box 1.1, Figure 1: Total RF (anthropogenic plus natural) for RCPs and extended concentration pathways (ECP) – for RCP2.6, RCP4.5, and RCP6, RCP8.5, as well as a supplementary extension SCP6to4.5 with an adjustment of emissions after 2100 to reach RCP 4.5 concentration levels in 2250 and thereafter. Note that the stated RF levels refer to the illustrative default median estimates only. There is substantial uncertainty in current and future RF levels for any given scenario. Short-term variations in RF are due to both volcanic forcings in the past (1800–2000) and cyclical solar forcing assuming a constant 11-year solar cycle (following the CMIP5 recommendation), except at times of stabilization (reproduced from Figure 4 in Meinshausen et al., 2011).

Box 1.1, Figure 2: Concentrations of GHG following the 4 RCPs and their extensions (ECP) to 2300. (Reproduced from Figure 5 in Meinshausen et al., 2011). Also see Annex II Table AII.4.1 for CO₂, Table AII.4.2 for CH₄, Table AII.4.3 for N₂O.

Box 1.1, Figure 3: (a) Equivalent CO₂ concentration and (b) CO₂ emissions (except land use emissions) for the four RCPs and their ECPs as well as some SRES scenarios.

Box 1.1, Figure 4: (a) Anthropogenic BC emissions (Annex II Table AII.2.22), (b) Anthropogenic NO_x emissions (Annex II Table AII.2.18), and (c) Anthropogenic SO_x emissions (Annex II Table II.2.20).

FAQ 1.1, Figure 1: Schematic diagram showing the relative importance of different uncertainties, and their evolution in time. **a)** Decadal mean surface temperature change (°C) from the historical record (black line), with climate model estimates of uncertainty for historical period (grey), along with future climate projections and uncertainty. Values are normalised by means from 1961 to 1980. Natural variability (orange) derives from model interannual variability, and is assumed constant with time. Emission uncertainty (green) is estimated as the model mean difference in projections from different scenarios. Climate response uncertainty (blue-solid) is based on climate model spread, along with added uncertainties from the carbon cycle, as well as rough estimates of additional uncertainty from poorly-modelled processes. Based on Hawkins and Sutton (2011) and Huntingford et al. (2009). **b)** Climate response uncertainty can appear to increase when a new process is discovered to be relevant, but such increases reflect a quantification of previously unmeasured uncertainty, or **c)** can decrease with additional model improvements and observational constraints. The given uncertainty range of 90% means that the temperature is estimated to be in that range, with a probability of 90%.

Executive Summary

The evidence of climate change from observations of the atmosphere and surface has grown significantly during recent years. At the same time new improved ways of characterizing and quantifying uncertainty have highlighted the challenges that remain for developing long-term, global and regional climate quality data records. Currently, the observations of the atmosphere and surface indicate the following changes:

Atmospheric Composition

It is certain that atmospheric burdens of the well-mixed greenhouse gases targeted by the Kyoto Protocol increased from 2005 to 2011. The atmospheric abundance of CO₂ was 390.5 ppm (390.3–390.7)¹ in 2011; this is 40% greater than in 1750. Atmospheric N₂O was 324.2 ppb (324.0–324.4) in 2011 and has increased by 20% since 1750. Average annual increases in CO₂ and N₂O from 2005 to 2011 are comparable to those observed from 1996 to 2005. Atmospheric CH₄ was 1803.2 ppb (1801.2–1805.2) in 2011; this is 150% greater than before 1750. CH₄ began increasing in 2007 after remaining nearly constant from 1999 to 2006. HFCs, PFCs, and SF₆ all continue to increase relatively rapidly, but their contributions to radiative forcing are less than 1% of the total by well-mixed greenhouse gases. [2.2.1.1]

For ozone depleting substances (Montreal Protocol gases), it is certain that the global mean abundances of major CFCs are decreasing and HCFCs are increasing. Atmospheric burdens of major CFCs and halons have decreased since 2005. HCFCs, which are transitional substitutes for CFCs, continue to increase, but the spatial distribution of their emissions is changing. [2.2.1.2]

Because of large variability and relatively short data records, confidence² in stratospheric H₂O vapour trends is low. Near-global satellite measurements of stratospheric water vapour show substantial variability but small net changes for 1992–2011. [2.2.2.1]

It is certain that global stratospheric ozone has declined from pre-1980 values. Most of the decline occurred prior to the mid 1990s; since then ozone has remained nearly constant at about 3.5% below the 1964–1980 level. [2.2.2.2]

Confidence is medium in large-scale increases of tropospheric ozone across the Northern Hemisphere since the 1970s. Confidence is low in ozone changes across the Southern Hemisphere due to limited measurements. It is *likely*³ that surface ozone trends in eastern North America and western Europe since 2000 have levelled off or decreased and that surface ozone strongly increased in East Asia since the 1990s. Satellite and surface observations of ozone precursor gases NO_x, CO, and non-methane volatile organic carbons indicate strong regional differences in trends. Most notably NO₂ has *likely* decreased by 30–50% in Europe and North America and increased by more than a factor of 2 in Asia since the mid-1990s. [2.2.2.3, 2.2.2.4]

It is very likely that aerosol column amounts have declined over Europe and the eastern USA since the mid 1990s and increased over eastern and southern Asia since 2000. These shifting aerosol regional patterns have been observed by remote sensing of Aerosol Optical Depth (AOD), a measure of total atmospheric aerosol load. Declining aerosol loads over Europe and North America are consistent with

¹ Values in parentheses are 90% confidence intervals. Elsewhere in this chapter usually the half-widths of the 90% confidence intervals are provided for the estimated changes from the trend method.

² In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

³ In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

ground-based in situ monitoring of particulate mass. *Confidence* in satellite based global average AOD trends is *low*. [2.2.3]

Radiation Budgets

Satellite records of Top-of-Atmosphere radiation fluxes have been substantially extended since AR4, and it is *unlikely* that significant trends exist in global and tropical radiation budgets since 2000.

Interannual variability in the Earth's energy imbalance related to El Niño Southern Oscillation is consistent with ocean heat content records within observational uncertainty. [2.3.2]

Surface solar radiation *likely* underwent widespread decadal changes after 1950, with decreases ('dimming') until the 1980s and subsequent increases ('brightening') observed at many land-based sites. There is *medium confidence* for increasing downward thermal and net radiation at land-based observation sites since the early 1990s. [2.3.3]

Temperature

It is certain that Global Mean Surface Temperature has increased since the late 19th century. Each of the past three decades has been significantly warmer than all the previous decades in the instrumental record, and the first decade of the 21st century has been the warmest. The global combined land and ocean surface temperature data show an increase of about 0.89°C (0.69°C–1.08°C) over the period 1901–2012 and about 0.72°C (0.49°C–0.89°C) over the period 1951–2012 when described by a linear trend. Despite the robust multi-decadal timescale warming, there exists substantial multi-annual variability in the rate of warming with several periods exhibiting almost no linear trend including the warming hiatus since 1998. The rate of warming over 1998–2012 (0.05°C [–0.05 to +0.15] per decade) is smaller than the trend since 1951 (0.12°C [0.08 to 0.14] per decade). Several independently analyzed data records of global and regional Land-Surface Air Temperature (LSAT) obtained from station observations are in broad agreement that LSAT has increased. Sea Surface Temperatures (SSTs) have also increased. Intercomparisons of new SST data records obtained by different measurement methods, including satellite data, have resulted in better understanding of uncertainties and biases in the records. [2.4.1, 2.4.2, 2.4.3, Box 9.2]

It is *unlikely* that any uncorrected urban heat-island effects and land use change effects have raised the estimated centennial globally averaged LSAT trends by more than 10% of the reported trend. This is an average value; in some regions with rapid development, urban heat island and land use change impacts on regional trends may be substantially larger. [2.4.1.3]

***Confidence* is *medium* in reported decreases in observed global Diurnal Temperature Range (DTR), noted as a key uncertainty in the AR4.** Several recent analyses of the raw data on which many previous analyses were based point to the potential for biases that differently affect maximum and minimum average temperatures. However, apparent changes in DTR are much smaller than reported changes in average temperatures and therefore it is *virtually certain* that maximum and minimum temperatures have increased since 1950. [2.4.1.2]

Based upon multiple independent analyses of measurements from radiosondes and satellite sensors it is *virtually certain* that globally the troposphere has warmed and the stratosphere has cooled since the mid-20th century. Despite unanimous agreement on the sign of the trends, substantial disagreement exists among available estimates as to the rate of temperature changes, particularly outside the Northern Hemisphere extra-tropical troposphere, which has been well sampled by radiosondes. Hence there is only *medium confidence* in the rate of change and its vertical structure in the Northern Hemisphere extra-tropical troposphere and *low confidence* elsewhere. [2.4.4]

Hydrological Cycle

***Confidence* in precipitation change averaged over global land areas is *low* prior to 1950 and *medium* afterwards because of insufficient data, particularly in the earlier part of the record.** Available globally incomplete records show mixed and nonsignificant long-term trends in reported global mean changes. Further, when virtually all the land area is filled in using a reconstruction method, the resulting time series

shows little change in land-based precipitation since 1900. Northern Hemisphere mid-latitude land areas do show a *likely* overall increase in precipitation (*medium confidence* prior to 1950, but *high confidence* afterwards). [2.5.1.1]

It is very likely that global near surface and tropospheric air specific humidity have increased since the 1970s. However, during recent years the near surface moistening over land has abated (*medium confidence*). As a result, fairly widespread decreases in relative humidity near the surface are observed over the land in recent years. [2.4.4, 2.5.5, 2.5.6]

While trends of cloud cover are consistent between independent datasets in certain regions, substantial ambiguity and therefore low confidence remains in the observations of global-scale cloud variability and trends. [2.5.7]

Extreme Events

It is very likely that the numbers of cold days and nights have decreased and the numbers of warm days and nights have increased globally since about 1950. There is only *medium confidence* that the length and frequency of warm spells, including heat waves, has increased since the middle of the 20th century mostly due to lack of data or studies in Africa and South America. However, it is *likely* that heatwave frequency has increased during this period in large parts of Europe, Asia and Australia. [2.6.1]

It is likely that since about 1950 the number of heavy precipitation events over land has increased in more regions than it has decreased. Regional trends vary but *confidence* is *highest* for central North America with *very likely* trends towards heavier precipitation events. [2.6.2.1]

Confidence is low for a global-scale observed trend in drought or dryness (lack of rainfall) since the middle of the 20th century, due to lack of direct observations, methodological uncertainties and geographical inconsistencies in the trends. Based on updated studies, AR4 conclusions regarding global increasing trends in drought since the 1970s were probably overstated. However, this masks important regional changes: the frequency and intensity of drought has *likely* increased in the Mediterranean and West Africa and *likely* decreased in central North America and north-west Australia since 1950. [2.6.2.2]

Confidence remains low for long-term (centennial) changes in tropical cyclone activity, after accounting for past changes in observing capabilities. However, it is *virtually certain* that the frequency and intensity of the strongest tropical cyclones in the North Atlantic has increased since the 1970s. [2.6.3]

Confidence in large scale trends in storminess or storminess proxies over the last century is low due to inconsistencies between studies or lack of long-term data in some parts of the world (particularly in the Southern Hemisphere). [2.6.4]

Because of insufficient studies and data quality issues *confidence* is also *low* for trends in small-scale severe weather events such as hail or thunderstorms. [2.6.2.2]

Atmospheric Circulation and Indices of Variability

It is likely that circulation features have moved poleward since the 1970s, involving a widening of the tropical belt, a poleward shift of storm tracks and jet streams, and a contraction of the northern polar vortex. Evidence is more robust for the Northern Hemisphere. It is *likely* that the Southern Annular Mode has become more positive since the 1950s. [2.7.5, 2.7.6, 2.7.8, Box 2.5]

Large variability on interannual to decadal time scales hampers robust conclusions on long-term changes in atmospheric circulation in many instances. *Confidence* is *high* that the increase in the northern mid-latitude westerly winds and the NAO index from the 1950s to the 1990s and the weakening of the Pacific Walker circulation from the late 19th century to the 1990s have been largely offset by recent changes. [2.7.5, 2.7.8, Box 2.5]

Confidence in the existence of long-term changes in remaining aspects of the global circulation is low due to observational limitations or limited understanding. These include surface winds over land, the East Asian summer monsoon circulation, the tropical cold-point tropopause temperature and the strength of the Brewer Dobson circulation. [2.7.2, 2.7.4, 2.7.5, 2.7.7]

2.1 Introduction

This chapter assesses the scientific literature on atmospheric and surface observations since AR4 (IPCC, 2007). The most *likely* changes in physical climate variables or climate forcing agents are identified based on current knowledge, following the IPCC AR5 uncertainty guidance (Mastrandrea et al., 2011).

As described in AR4 (Trenberth et al., 2007), the climate comprises a variety of space and time-scales: from the diurnal cycle, to interannual variability such as the El Niño Southern Oscillation (ENSO), to multi-decadal variations. ‘Climate change’ refers to a change in the state of the climate that can be identified by changes in the mean and/or the variability of its properties and that persists for an extended period of time (Annex III: Glossary). In this chapter, climate change is examined for the period with instrumental observations, since about 1850. Change prior to this date is assessed in Chapter 5. The word ‘trend’ is used to designate a long-term movement in a time series that may be regarded, together with the oscillation and random component, as composing the observed values (Annex III: Glossary). Where numerical values are given, they are equivalent linear changes (Box 2.2), though more complex non-linear changes in the variable will often be clear from the description and plots of the time series.

In recent decades, advances in the global climate observing system have contributed to improved monitoring capabilities. In particular satellites provide additional observations of climate change, which have been assessed in this and subsequent chapters together with more traditional ground-based and radiosonde observations. Since AR4, substantial developments have occurred including the production of revised datasets, more digital data records, and new dataset efforts. New dynamical reanalysis datasets of the global atmosphere have been published (Box 2.3). These various innovations have improved understanding of data issues and uncertainties (Box 2.1).

Developing homogeneous long-term records from these different sources remains a challenge. The longest observational series are land surface air temperatures and sea surface temperatures. Like all physical climate system measurements they suffer from non-climatic artefacts that must be taken into account (Box 2.1). The global combined land and sea surface temperature remains an important climate change measure for several reasons. Climate sensitivity is typically assessed in the context of Global Mean Surface Temperature (GMST) responses to a doubling of CO₂ (Chapter 8) and GMST is thus a key metric in the climate change policy framework. Also, because it extends back in time farther than any other instrumental series, GMST is key to understanding both the causes of change and the patterns, role and magnitude of natural variability (Chapter 10). Starting at various points in the 20th century, additional observations, including balloon-borne measurements and satellite measurements, and reanalysis products allow analyses of indicators such as atmospheric composition, radiation budgets, hydrological cycle changes, extreme event characterizations and circulation indices. A full understanding of the climate system characteristics and changes requires analyses of all such variables as well as ocean (Chapter 3) and cryosphere (Chapter 4) indicators. Through such a holistic analysis, a clearer and more robust assessment of the changing climate system emerges (FAQ 2.1).

This chapter starts with an assessment of the observations of the abundances of greenhouse gases (GHGs) and of aerosols, the main drivers of climate change (Section 2.2). Global trends in GHGs are indicative of the imbalance between sources and sinks in GHG budgets, and play an important role in emissions verification on a global scale. The radiative forcing effects of GHGs and aerosols are assessed in Chapter 8. The observed changes in radiation budgets are discussed in Section 2.3. Aerosol-cloud interactions are assessed in Chapter 7. Section 2.4 provides an assessment of observed changes in surface and atmospheric temperature. Observed change in the hydrological cycle, including precipitation and clouds, is assessed in Section 2.5. Changes in variability and extremes (such as cold spells, heat waves, droughts and tropical cyclones) are assessed in Section 2.6. Section 2.7 assesses observed changes in the circulation of the atmosphere and its modes of variability, which help determine seasonal and longer-term anomalies at regional scales (Chapter 14).

Trends have been assessed where possible for multi-decadal periods starting in 1880, 1901 (referred to as long-term trends) and in 1951, 1979 (referred to as short-term trends). The time elapsed since AR4 extends the period for trend calculation from 2005 to 2012 for many variables. The global temperature trend since 1998 has also been considered (see also Box 9.2) as well as the trends for sequential 30-year segments of the time series. For many variables derived from satellite data, information is available for 1979–2012 only. In

general, trend estimates are more reliable for longer time intervals, and trends computed on short intervals have a large uncertainty. Trends for short intervals are very sensitive to the start and end years. An exception to this is trends in greenhouse gases, whose accurate measurement and long lifetimes make them well-mixed and less susceptible to year-to-year variability, so that trends computed on relatively short intervals are very meaningful for these variables. Where possible, the time interval 1961–1990 has been chosen as the climatological reference period (or normal period) for averaging. This choice enables direct comparisons with AR4, but is different from the present-day climate period (1986–2005) used as a reference in the modelling chapters of AR5 and Annex I: Atlas of Global and Regional Climate Projections.

It is important to note that the question of whether the observed changes are outside the possible range of natural internal climate variability and consistent with the climate effects from changes in atmospheric composition is not addressed in this chapter, but rather in Chapter 10. No attempt has been undertaken to further describe and interpret the observed changes in terms of multidecadal oscillatory (or low frequency) variations, (long-term) persistence and/or secular trends (e.g., as in Cohn and Lins, 2005; Koutsoyiannis and Montanari, 2007; Zorita et al., 2008; Lennartz and Bunde, 2009; Mills, 2010; Mann, 2011; Wu et al., 2011; Zhou and Tung, 2012; Tung and Zhou, 2013). In this chapter, the robustness of the observed changes is assessed in relation to various sources of observational uncertainty (Box 2.1). In addition, the reported trend significance and statistical confidence intervals provide an indication of how large the observed trend is compared to the range of observed variability in a given aspect of the climate system (see Box 2.2 for a description of the statistical trend model applied). Unless otherwise stated, 90% confidence intervals are given. The chapter also examines the physical consistency across different observations, which helps to provide additional confidence in the reported changes. Additional information about data sources and methods is described in the Supplementary Material to Chapter 2.

[START BOX 2.1 HERE]

Box 2.1: Uncertainty in Observational Records

The vast majority of historical (and modern) weather observations were not made explicitly for climate monitoring purposes. Measurements have changed in nature as demands on the data, observing practices and technologies have evolved. These changes almost always alter the characteristics of observational records, changing their mean, their variability or both, such that it is necessary to process the raw measurements before they can be considered useful for assessing the true climate evolution. This is true of all observing techniques that measure physical atmospheric quantities. The uncertainty in observational records encompasses instrumental / recording errors, effects of representation (e.g., exposure, observing frequency or timing), as well as effects due to physical changes in the instrumentation (such as station relocations or new satellites). All further processing steps (transmission, storage, gridding, interpolating, averaging) also have their own particular uncertainties. Since there is no unique, unambiguous, way to identify and account for non-climatic artefacts in the vast majority of records, there must be a degree of uncertainty as to how the climate system has changed. The only exceptions are certain atmospheric composition and flux measurements whose measurements and uncertainties are rigorously tied through an unbroken chain to internationally recognized absolute measurement standards (e.g., the CO₂ record at Mauna Loa; Keeling et al., 1976a).

Uncertainty in dataset production can result either from the choice of parameters within a particular analytical framework - parametric uncertainty, or from the choice of overall analytical framework - structural uncertainty. Structural uncertainty is best estimated by having multiple independent groups assess the same data using distinct approaches. More analyses assessed now than in AR4 include published estimates of parametric or structural uncertainty. It is important to note that the literature includes a very broad range of approaches. Great care has been taken in comparing the published uncertainty ranges as they almost always do not constitute a like-for-like comparison. In general, studies that account for multiple potential error sources in a rigorous manner yield larger uncertainty ranges. This yields an apparent paradox in interpretation as one might think that smaller uncertainty ranges should indicate a better product. However, in many cases this would be an incorrect inference as the smaller uncertainty range may instead reflect that the published estimate considered only a subset of the plausible sources of uncertainty. Within the timeseries figures, where this issue would be most acute, such parametric uncertainty estimates are therefore not

generally included. Consistent with AR4 HadCRUT4 uncertainties in GMST are included in Figure 2.19, which in addition includes structural uncertainties in GMST.

To conclude, the vast majority of the raw observations used to monitor the state of the climate contain residual non-climatic influences. Removal of these influences cannot be done definitively and neither can the uncertainties be unambiguously assessed. Therefore, care is required in interpreting both data products and their stated uncertainty estimates. Confidence can be built from: redundancy in efforts to create products; dataset heritage; and cross-comparisons of variables that would be expected to co-vary for physical reasons, such as land surface temperatures and sea surface temperatures around coastlines. Finally, trends are often quoted as a way to synthesize the data into a single number. Uncertainties that arise from such a process and the choice of technique used within this chapter are described in more detail in Box 2.2.

[END BOX 2.1 HERE]

2.2 Changes in Atmospheric Composition

2.2.1 Well-Mixed Greenhouse Gases

AR4 (Forster et al., 2007; IPCC, 2007) concluded that increasing atmospheric burdens of well-mixed greenhouse gases (GHG) resulted in a 9% increase in their radiative forcing from 1998 to 2005. Since 2005, the atmospheric abundances of many well-mixed GHG increased further, but the burdens of some ozone depleting substances (ODS) whose production and use were controlled by the Montreal Protocol on Substances that Deplete the Ozone Layer (1987; hereinafter, 'Montreal Protocol') decreased.

Based on updated in situ observations, this assessment concludes that these trends resulted in a 7.5% increase in radiative forcing from greenhouse gases from 2005 to 2011, with CO₂ contributing 80%. Of note is an increase in the average growth rate of atmospheric CH₄ from ~0.5 ppb yr⁻¹ during 1999–2006 to ~6 ppb yr⁻¹ from 2007 through 2011. Current observation networks are sufficient to quantify global annual mean burdens used to calculate radiative forcing and to constrain global emission rates (with knowledge of loss rates), but they are not sufficient for accurately estimating regional scale emissions and how they are changing with time.

The globally, annually averaged well-mixed GHG mole fractions reported here are used in Chapter 8 to calculate radiative forcing. A direct, inseparable connection exists between observed changes in atmospheric composition and well-mixed GHG emissions and losses (discussed in Chapter 6 for CO₂, CH₄, and N₂O). A global GHG budget consists of the total atmospheric burden, total global rate of production or emission (i.e., sources), and the total global rate of destruction or removal (i.e., sinks). Precise, accurate systematic observations from independent globally distributed measurement networks are used to estimate global annual mean well-mixed GHG mole fractions at Earth's surface, and these allow estimates of global burdens. Emissions are predominantly from surface sources, which are described in Chapter 6 for CO₂, CH₄, and N₂O. Direct use of observations of well-mixed GHG to model their regional budgets can also play an important role in verifying inventory estimates of emissions (Nisbet and Weiss, 2010).

Systematic measurements of well-mixed GHG in ambient air began at various times during the last six decades, with earlier atmospheric histories being reconstructed from measurements of air stored in air archives and trapped in polar ice cores or in firn. In contrast to the physical meteorological parameters discussed elsewhere in this chapter, measurements of well-mixed GHG are reported relative to standards developed from fundamental SI base units (SI = International System of Units) as dry-air mole fractions, a unit that is conserved with changes in temperature and pressure (Box 2.1). This eliminates dilution by H₂O vapour, which can reach 4% of total atmospheric composition. Here, the following abbreviations are used: ppm = $\mu\text{mol mol}^{-1}$; ppb = nmol mol^{-1} ; and ppt = pmol mol^{-1} . Unless noted otherwise, an average of NOAA and AGAGE annually averaged surface global mean mole fractions are described in Section 2.2.1 (see Supplementary Material 2.SM.2 for further species not listed here).

Table 2.1 summarizes globally, annually averaged well-mixed GHG mole fractions from four independent measurement programs. Sampling strategies and techniques for estimating global means and their uncertainties vary among programs. Differences among measurement programs are relatively small and will

not add significantly to uncertainty in radiative forcing. Time series of the well-mixed GHG are plotted in Figures 2.1 (CO₂), 2.2 (CH₄), 2.3 (N₂O), and 2.4 (halogen-containing compounds).

[INSERT TABLE 2.1 HERE]

Table 2.1: Global annual mean surface dry-air mole fractions and their change since 2005 for well-mixed GHG from four measurement networks. Units are ppt except where noted. Uncertainties are 90% confidence intervals. ^aRES (radiative efficiency) and lifetimes (except CH₄ and N₂O, which are from Prather et al. (2012)) are from Chapter 8.

2.2.1.1 Kyoto Protocol Gases (CO₂, CH₄, N₂O, HFCs, PFCs, and SF₆)

2.2.1.1.1 Carbon dioxide (CO₂)

Precise, accurate systematic measurements of atmospheric CO₂ at Mauna Loa, Hawaii and South Pole were started by C. D. Keeling from Scripps Institution of Oceanography in the late 1950s (Keeling et al., 1976a; Keeling et al., 1976b). The 1750 globally averaged abundance of atmospheric CO₂ based on measurements of air extracted from ice cores and from firn is 278 ± 2 ppm (Etheridge et al., 1996). Globally averaged CO₂ mole fractions since the start of the instrumental record are plotted in Figure 2.1. The main features in the contemporary CO₂ record are the long-term increase and the seasonal cycle resulting from photosynthesis and respiration by the terrestrial biosphere, mostly in the NH. The main contributors to increasing atmospheric CO₂ abundance are fossil fuel combustion and land use change (Section 6.3). Multiple lines of observational evidence indicate that during the past few decades, most of the increasing atmospheric burden of CO₂ is from fossil fuel combustion (Tans, 2009). Since the last year for which the AR4 reported (2005), CO₂ has increased by 11.7 ppm to 390.5 ppm in 2011 (Table 2.1). From 1980 to 2011, the average annual increase in globally averaged CO₂ (from 1 January in one year to 1 January in the next year) was 1.7 ppm yr⁻¹ (1 standard deviation = 0.5 ppm yr⁻¹; 1 ppm globally corresponds to 2.1 PgC increase in the atmospheric burden). Since 2001, CO₂ has increased at 2.0 ppm yr⁻¹ (1 standard deviation = 0.3 ppm yr⁻¹). The CO₂ growth rate varies from year to year; since 1980 the range in annual increase is 0.7 ± 0.1 ppm in 1992 to 2.9 ± 0.1 ppm in 1998. Most of this interannual variability in growth rate is driven by small changes in the balance between photosynthesis and respiration on land, each having global fluxes of ~120 PgC yr⁻¹ (Chapter 6).

[INSERT FIGURE 2.1 HERE]

Figure 2.1: a) Globally averaged CO₂ dry-air mole fractions from Scripps Institution of Oceanography (SIO) at monthly time resolution based on measurements from Mauna Loa, Hawaii and South Pole (red) and NOAA/ESRL/GMD at quasi-weekly time resolution (blue). SIO values are deseasonalized. b) Instantaneous growth rates for globally averaged atmospheric CO₂ using the same colour code as in (a). Growth rates are calculated as the time derivative of the deseasonalized global averages (Dlugokencky et al., 1994).

2.2.1.1.2 Methane (CH₄)

Globally averaged CH₄ in 1750 was 722 ± 25 ppb (after correction to the NOAA-2004 CH₄ standard scale) (Etheridge et al., 1998; Dlugokencky et al., 2005), although human influences on the global CH₄ budget may have begun thousands of years earlier than this time that is normally considered “pre-industrial” (Ruddiman, 2003; Ferretti et al., 2005; Ruddiman, 2007). In 2011, the global annual mean was 1803 ± 2 ppb. Direct atmospheric measurements of CH₄ of sufficient spatial coverage to calculate global annual means began in 1978 and are plotted through 2011 in Figure 2.2a. This time period is characterized by a decreasing growth rate (Figure 2.2b) from the early 1980s until 1998, stabilization from 1999 to 2006, and an increasing atmospheric burden from 2007 to 2011 (Rigby et al., 2008; Dlugokencky et al., 2009). Assuming no long-term trend in hydroxyl radical (OH) concentration, the observed decrease in CH₄ growth rate from the early 1980s through 2006 indicates an approach to steady state where total global emissions have been approximately constant at ~550 TgCH₄ yr⁻¹. Superimposed on the long-term pattern is significant interannual variability; studies of this variability are used to improve understanding of the global CH₄ budget (Chapter 6). The most likely drivers of increased atmospheric CH₄ were anomalously high temperatures in the Arctic in 2007 and greater than average precipitation in the tropics during 2007 and 2008 (Dlugokencky et al., 2009; Bousquet, 2011). Observations of the difference in CH₄ between zonal averages for northern and southern polar regions (53°–90°) (Dlugokencky et al., 2009; Dlugokencky et al., 2011) suggest that, so far, it is unlikely that there has been a permanent measureable increase in Arctic CH₄ emissions from wetlands and shallow sub-sea CH₄ clathrates.

[INSERT FIGURE 2.2 HERE]

Figure 2.2: a) Globally averaged CH₄ dry-air mole fractions from UCI (green; 4 values per year, except prior to 1984, when they are of lower and varying frequency), AGAGE (red; monthly), and NOAA/ESRL/GMD (blue; quasi-weekly). b) Instantaneous growth rate for globally averaged atmospheric CH₄ using the same colour code as in (a). Growth rates were calculated as in Figure 2.1.

Reaction with OH is the main loss process for CH₄ (and for HFCs and HCFCs), and it is the largest term in the global CH₄ budget. Therefore, trends and interannual variability in OH concentration significantly impact our understanding of changes in CH₄ emissions. CH₃CCl₃ (Section 2.2.1.2) has been used extensively to estimate globally averaged OH concentrations (e.g., Prinn et al., 2005). AR4 reported no trend in [OH] from 1979 to 2004, and there is no evidence from this assessment to change that conclusion for 2005 to 2011. Montzka et al. (2011a) exploited the exponential decrease and small emissions in CH₃CCl₃ to show that interannual variations in OH concentration from 1998 to 2007 are $2.3 \pm 1.5\%$, which is consistent with estimates based on CH₄, C₂Cl₄, CH₂Cl₂, CH₃Cl, and CH₃Br.

2.2.1.1.3 Nitrous oxide (N₂O)

Globally averaged N₂O in 2011 was 324.2 ppb, an increase of 5.0 ppb over the value reported for 2005 in AR4 (Table 2.1). This is an increase of 20% over the estimate for 1750 from ice cores, 270 ± 7 ppb (Prather et al., 2012). Measurements of N₂O and its isotopic composition in firn air suggest the increase, at least since the early 1950s, is dominated by emissions from soils treated with synthetic and organic (manure) nitrogen fertilizer (Rockmann and Levin, 2005; Ishijima et al., 2007; Davidson, 2009; Syakila and Kroeze, 2011). Since systematic measurements began in the late 1970s, N₂O has increased at an average rate of ~ 0.75 ppb yr⁻¹ (Figure 2.3). Because the atmospheric burden of CFC-12 is decreasing, N₂O has replaced CFC-12 as the third most important well-mixed GHG contributing to radiative forcing (Elkins and Dutton, 2011).

[INSERT FIGURE 2.3 HERE]

Figure 2.3: a) Globally averaged N₂O dry-air mole fractions from AGAGE (red) and NOAA/ESRL/GMD (blue) at monthly resolution. b) Instantaneous growth rates for globally averaged atmospheric N₂O. Growth rates were calculated as in Figure 2.1.

Persistent latitudinal gradients in annually averaged N₂O are observed at background surface sites, with maxima in the northern subtropics, values about 1.7 ppb lower in the Antarctic, and values about 0.4 ppb lower in the Arctic (Huang et al., 2008). These persistent gradients contain information about anthropogenic emissions from fertilizer use at northern tropical to mid-latitudes and natural emissions from soils and ocean upwelling regions of the tropics. N₂O time series also contain seasonal variations with peak-to-peak amplitudes of about 1 ppb in high latitudes of the NH and about 0.4 ppb at high southern and tropical latitudes. In the NH, exchange of air between the stratosphere (where N₂O is destroyed by photochemical processes) and troposphere is the dominant contributor to observed seasonal cycles, not seasonality in emissions (Jiang et al., 2007). Nevison et al. (2011) found correlations between the magnitude of detrended N₂O seasonal minima and lower stratospheric temperature providing evidence for a stratospheric influence on the timing and amplitude of the seasonal cycle at surface monitoring sites. In the Southern Hemisphere (SH), observed seasonal cycles are also affected by stratospheric influx, and by ventilation and thermal out-gassing of N₂O from the oceans.

2.2.1.1.4 HFCs, PFCs, SF₆, and NF₃

The budgets of HFCs, PFCs, and SF₆ were recently reviewed in Chapter 1 of the Scientific Assessment of Ozone Depletion: 2010 (Montzka et al., 2011b), so only a brief description is given here. The current atmospheric abundances of these species are summarized in Table 2.1 and plotted in Figure 2.4.

[INSERT FIGURE 2.4 HERE]

Figure 2.4: Globally averaged dry-air mole fractions at Earth's surface of the major halogen-containing well-mixed GHG. These are derived mainly using monthly mean measurements from the AGAGE and NOAA/ESRL/GMD networks. For clarity, only the most abundant chemicals are shown in different compound classes and results from different networks have been combined when both are available.

Atmospheric HFC abundances are low and their contribution to radiative forcing is small relative to the CFCs and HCFCs they replace (less than 1% of the total by well-mixed greenhouse gases; Chapter 8). As they replace CFCs and HCFCs phased out by the Montreal Protocol, however, their contribution to future

climate forcing is projected to grow considerably in the absence of controls on global production (Velders et al., 2009).

HFC-134a is a replacement for CFC-12 in automobile air conditioners and is also used in foam blowing applications. In 2011, it reached 62.7 ppt, an increase of 28.2 ppt since 2005. Based on analysis of high-frequency measurements, the largest emissions occur in N. America, Europe, and East Asia (Stohl et al., 2009).

HFC-23 is a by-product of HCFC-22 production. Direct measurements of HFC-23 in ambient air at 5 sites began in 2007. The 2005 global annual mean used to calculate the increase since AR4 in Table 2.1, 5.2 ppt, is based on an archive of air collected at Cape Grim, Tasmania (Miller et al., 2010). In 2011, atmospheric HFC-23 was at 24.0 ppt. Its growth rate peaked in 2006 as emissions from developing countries increased, then declined as emissions were reduced through abatement efforts under the Clean Development Mechanism (CDM) of the UNFCCC. Estimates of total global emissions based on atmospheric observations and bottom-up inventories agree within uncertainties (Miller et al., 2010; Montzka et al., 2010). Currently, the largest emissions of HFC-23 are from east Asia (Yokouchi et al., 2006; Kim et al., 2010; Stohl et al., 2010); developed countries emit <20% of the global total. Keller et al. (2011) found that emissions from developed countries may be larger than those reported to the UNFCCC, but their contribution is small. The lifetime of HFC-23 was revised from 270 to 222 years since AR4.

After HFC-134a and HFC-23, the next most abundant HFCs are HFC-143a at 12.04 ppt in 2011, 6.39 ppt greater than in 2005; HFC-125 (O'Doherty et al., 2009) at 9.58 ppt, increasing by 5.89 ppt since 2005; HFC-152a (Greally et al., 2007) at 6.4 ppt with a 3.0 ppt increase since 2005; and HFC-32 at 4.92 ppt in 2011, 3.77 ppt greater than in 2005. Since 2005, all of these were increasing exponentially except for HFC-152a, whose growth rate slowed considerably in ~2007 (Figure 2.4). HFC-152a has a relatively short atmospheric lifetime of 1.5 years, so its growth rate will respond quickly to changes in emissions. Its major uses are as a foam blowing agent and aerosol spray propellant while HFC-143a, HFC-125, and HFC-32 are mainly used in refrigerant blends. The reasons for slower growth in HFC-152a since ~2007 are unclear. Total global emissions of HFC-125 estimated from the observations are within ~20% of emissions reported to the UNFCCC, after accounting for estimates of unreported emissions from east Asia (O'Doherty et al., 2009).

CF₄ and C₂F₆ (PFCs) have lifetimes of 50 kyr and 10 kyr, respectively, and they are emitted as by-products of aluminium production and used in plasma etching of electronics. CF₄ has a natural lithospheric source (Deeds et al., 2008) with a 1750 level determined from Greenland and Antarctic firn air of 34.7 ± 0.2 ppt (Worton et al., 2007; Muhle et al., 2010). In 2011, atmospheric abundances were 79.0 ppt for CF₄, increasing by 4.0 ppt since 2005, and 4.16 ppt for C₂F₆, increasing by 0.50 ppt. The sum of emissions of CF₄ reported by aluminium producers and for non-aluminium production in EDGAR (Emission Database for Global Atmospheric Research) v4.0 only accounts for about half of global emissions inferred from atmospheric observations (Muhle et al., 2010). For C₂F₆, emissions reported to the UNFCCC are also substantially lower than those estimated from atmospheric observations (Muhle et al., 2010).

The main sources of atmospheric SF₆ emissions are electricity distribution systems, magnesium production, and semi-conductor manufacturing. Global annual mean SF₆ in 2011 was 7.29 ppt, increasing by 1.65 ppt since 2005. SF₆ has a lifetime of 3200 years, so its emissions accumulate in the atmosphere and can be estimated directly from its observed rate of increase. Levin et al. (2010) and Rigby et al. (2010) showed that SF₆ emissions decreased after 1995, most likely because of emissions reductions in developed countries, but then increased after 1998. During the past decade, they found that actual SF₆ emissions from developed countries are at least twice the reported values.

NF₃ was added to the list of GHG in the Kyoto Protocol with the Doha Amendment, December, 2012. Weiss et al. (2008) determined 0.45 ppt for its global annual mean mole fraction in 2008, growing from almost zero in 1978. In 2011, NF₃ was 0.60 ppt, increasing by 0.30 ppt since 2005. Initial bottom-up inventories underestimated its emissions; based on the atmospheric observations, NF₃ emissions were 1.18 ± 0.21 Gg in 2008 (Arnold et al., 2013).

In summary, it is certain that atmospheric burdens of well-mixed greenhouse gases targeted by the Kyoto Protocol increased from 2005 to 2011. The atmospheric abundance of CO₂ was 390.5 ± 0.2 ppm in 2011; this

is 40% greater than before 1750. Atmospheric N₂O was 324.2 ± 0.2 ppb in 2011 and has increased by 20% since 1750. Average annual increases in CO₂ and N₂O from 2005 to 2011 are comparable to those observed from 1996 to 2005. Atmospheric CH₄ was 1803.2 ± 2.0 ppb in 2011; this is 150% greater than before 1750. CH₄ began increasing in 2007 after remaining nearly constant from 1999 to 2006. HFCs, PFCs, and SF₆ all continue to increase relatively rapidly, but their contributions to radiative forcing are less than 1% of the total by well-mixed greenhouse gases (Chapter 8).

2.2.1.2 Ozone Depleting Substances (CFCs, Chlorinated solvents, and HCFCs)

CFC atmospheric abundances are decreasing (Figure 2.4) because of the successful reduction in emissions resulting from the Montreal Protocol. By 2010, emissions from ODSs had been reduced by ~ 11 Pg CO₂-eq yr⁻¹, which is 5 to 6 times the reduction target of the first commitment period (2008–2012) of the Kyoto Protocol (2 PgCO₂-eq yr⁻¹) (Velders et al., 2007). These avoided equivalent-CO₂ emissions account for the offsets to radiative forcing by stratospheric O₃ depletion caused by ODSs and the use of HFCs as substitutes for them. Recent observations in Arctic and Antarctic firn air further confirm that emissions of CFCs are entirely anthropogenic (Martinerie et al., 2009; Montzka et al., 2011b). CFC-12 has the largest atmospheric abundance and GWP-weighted emissions (which are based on a 100 yr time horizon) of the CFCs. Its tropospheric abundance peaked during 2000–2004. Since AR4, its global annual mean mole fraction declined by 13.8 ppt to 528.5 ppt in 2011. CFC-11 continued the decrease that started in the mid-1990s, by 12.9 ppt since 2005. In 2011, CFC-11 was 237.7 ppt. CFC-113 decreased by 4.3 ppt since 2005 to 74.3 ppt in 2011. A discrepancy exists between top-down and bottom-up methods for calculating CFC-11 emissions (Montzka et al., 2011b). Emissions calculated using top-down methods come into agreement with bottom-up estimates when a lifetime of 64 years is used for CFC-11 in place of the accepted value of 45 years; this longer lifetime (64 years) is at the upper end of the range estimated by Douglass et al. (2008) with models that more accurately simulate stratospheric circulation. Future emissions of CFCs will largely come from ‘banks’ (i.e., material residing in existing equipment or stores) rather than current production.

The mean decrease in globally, annually averaged CCl₄ based on NOAA and AGAGE measurements since 2005 was 7.4 ppt, with an atmospheric abundance of 85.8 ppt in 2011 (Table 2.1). The observed rate of decrease and inter hemispheric difference of CCl₄ suggest that emissions determined from the observations are on average greater and less variable than bottom-up emission estimates, although large uncertainties in the CCl₄ lifetime result in large uncertainties in the top-down estimates of emissions (Xiao et al., 2010; Montzka et al., 2011b). CH₃CCl₃ has declined exponentially for about a decade, decreasing by 12.0 ppt since 2005 to 6.3 ppt in 2011.

HCFCs are classified as ‘transitional substitutes’ by the Montreal Protocol. Their global production and use will ultimately be phased out, but their global production is not currently capped and, based on changes in observed spatial gradients, there has likely been a shift in emissions within the NH from regions north of about 30°N to regions south of 30°N (Montzka et al., 2009). Global levels of the three most abundant HCFCs in the atmosphere continue to increase. HCFC-22 increased by 44.5 ppt since 2005 to 213.3 ppt in 2011. Developed country emissions of HCFC-22 are decreasing, and the trend in total global emissions is driven by large increases from south and Southeast Asia (Saikawa et al., 2012). HCFC-141b increased by 3.7 ppt since 2005 to 21.4 ppt in 2011, and for HCFC-142b, the increase was 5.73 ppt to 21.1 ppt in 2011. The rates of increase in these three HCFCs increased since 2004, but the change in HCFC-141b growth rate was smaller and less persistent than for the other two, which approximately doubled from 2004 to 2007 (Montzka et al., 2009).

In summary, for ozone depleting substances, whose production and consumption are controlled by the Montreal Protocol, it is certain that the global mean abundances of major CFCs are decreasing and HCFCs are increasing. Atmospheric burdens of CFC-11, CFC-12, CFC-113, CCl₄, CH₃CCl₃, and halons have decreased since 2005. HCFCs, which are transitional substitutes for CFCs, continue to increase, but the spatial distribution of their emissions is changing.

2.2.2 Near Term Climate Forcers

This section covers observed trends in stratospheric water vapour; stratospheric and tropospheric ozone (O₃); the O₃ precursor gases, nitrogen dioxide (NO₂) and carbon monoxide (CO); and column and surface aerosol.

Since trend estimates from the cited literature are used here, issues such as data records of different length, potential lack of comparability among measurement methods, and different trend calculation methods, add to the uncertainty in assessing trends.

2.2.2.1 Stratospheric H₂O Vapour

Stratospheric H₂O vapour has an important role in Earth's radiative balance and in stratospheric chemistry. Increased stratospheric H₂O vapour causes the troposphere to warm and the stratosphere to cool (Manabe and Strickler, 1964; Solomon et al., 2010), and also causes increased rates of stratospheric O₃ loss (Stenke and Grewe, 2005). Water vapour enters the stratosphere through the cold tropical tropopause. As moisture-rich air masses are transported through this region, most water vapour condenses resulting in extremely dry lower stratospheric air. Because tropopause temperature varies seasonally, so does H₂O abundance there. Other contributions include oxidation of methane within the stratosphere, and possibly direct injection of H₂O vapour in overshooting deep convection (Schiller et al., 2009). AR4 reported that stratospheric H₂O vapour showed significant long-term variability and an upward trend over the last half of the 20th century, but no net increase since 1996. This updated assessment finds large interannual variations that have been observed by independent measurement techniques, but no significant net changes since 1996.

The longest continuous time series of stratospheric water vapour abundance is from in situ measurements made with frost point hygrometers starting in 1980 over Boulder, USA (40°N, 105°W) (Scherer et al., 2008), with values ranging from 3.5 to 5.5 ppm, depending on altitude. These observations have been complemented by long-term global satellite observations from SAGE II (1984–2005; Stratospheric Aerosol and Gas Experiment II (Chu et al., 1989)), HALOE (1991–2005; HALogen Occultation Experiment (RUSSELL et al., 1993)), Aura MLS (2004–present; Microwave Limb Sounder (Read et al., 2007)) and Envisat MIPAS (2002–2012; Michelson Interferometer for Passive Atmospheric Sounding (Milz et al., 2005; von Clarmann et al., 2009)). Discrepancies in water vapour mixing ratios from these different instruments can be attributed to differences in the vertical resolution of measurements, along with other factors. For example, offsets of up to 0.5 ppm in lower stratospheric water vapour mixing ratios exist between the most current versions of HALOE (v20) and Aura MLS (v3.3) retrievals during their 16-month period of overlap (2004 to 2005), although such biases can be removed to generate long-term records. Since AR4, new studies characterize the uncertainties in measurements from individual types of in situ H₂O sensors (Vomel et al., 2007b; Vomel et al., 2007a; Weinstock et al., 2009), but discrepancies between different instruments (50 to 100% at H₂O mixing ratios less than 10 ppm), particularly for high-altitude measurements from aircraft, remain largely unexplained.

Observed anomalies in stratospheric H₂O from the near-global combined HALOE+MLS record (1992–2011) (Figure 2.5) include effects linked to the stratospheric quasi-biennial oscillation (QBO) influence on tropopause temperatures, plus a step-like drop after 2001 (noted in AR4), and an increasing trend since 2005. Variability during 2001–2011 was large yet there was only a small net change from 1992 through 2011. These interannual water vapour variations for the satellite record are closely linked to observed changes in tropical tropopause temperatures (Fueglistaler and Haynes, 2005; Randel et al., 2006; Rosenlof and Reid, 2008; Randel, 2010), providing reasonable understanding of observed changes. The longer record of Boulder balloon measurements (since 1980) has been updated and reanalyzed (Scherer et al., 2008; Hurst et al., 2011), showing decadal-scale variability and a long-term stratospheric (16–26 km) increase of 1.0 ± 0.2 ppm for 1980–2010. Agreement between interannual changes inferred from the Boulder and HALOE+MLS data is good for the period since 1998 but was poor during 1992–1996. About 30% of the positive trend during 1980–2010 determined from frost point hygrometer data (Fujiwara et al., 2010; Hurst, 2011) can be explained by increased production of H₂O from CH₄ oxidation (Rohs et al., 2006), but the remainder can not be explained by changes in tropical tropopause temperatures (Fueglistaler and Haynes, 2005) or other known factors.

In summary, near-global satellite measurements of stratospheric H₂O show substantial variability for 1992–2011, with a step-like decrease after 2000 and increases since 2005. Because of this large variability and relatively short time series, *confidence* in long-term stratospheric H₂O trends is *low*. There is good understanding of the relationship between the satellite-derived H₂O variations and tropical tropopause temperature changes. Stratospheric H₂O changes from temporally sparse balloon-borne observations at one location (Boulder, Colorado) are in good agreement with satellite observations from 1998 to present, but

discrepancies exist for changes during 1992–1996. Long-term balloon measurements from Boulder indicate a net increase of 1.0 ± 0.2 ppm over 16–26 km for 1980–2010, but these long-term increases cannot be fully explained by changes in tropical tropopause temperatures, methane oxidation, or other known factors.

[INSERT FIGURE 2.5 HERE]

Figure 2.5: Water vapour anomalies in the lower stratosphere (~16–19 km) from satellite sensors and in situ measurements normalized to 2000–2011. (a) Monthly mean water vapour anomalies at 83 hPa for 60°S–60°N (blue) determined from HALOE and MLS satellite sensors. (b) Approximately monthly balloon-borne measurements of stratospheric water vapour from Boulder, Colorado at 40°N (green dots; green curve is 15-point running mean) averaged over 16–18 km and monthly means as in (a), but averaged over 30°N–50°N (black).

2.2.2.2 Stratospheric Ozone

AR4 did not explicitly discuss measured stratospheric ozone trends. For the current assessment report such trends are relevant because they are the basis for revising the radiative forcing from -0.05 ± 0.10 W m⁻² in 1750 to -0.10 ± 0.15 W m⁻² in 2005 (Section 8.3.3.2). These values strongly depend on the vertical distribution of the stratospheric ozone changes.

Total ozone is a good proxy for stratospheric ozone, since tropospheric ozone accounts for only about 10% of the total ozone column. Long-term total ozone changes over various latitudinal belts, derived from Weber et al. (2012), are illustrated in Figure 2.6 (a-d). Annually averaged total column ozone declined during the 1980s and early 1990s and has remained constant for the past decade, about 3.5 and 2.5% below the 1964–1980 average for the entire globe (not shown) and 60°S–60°N, respectively with changes occurring mostly outside the tropics, particularly the SH where the current extratropical (30°S–60°S) mean values are 6% below the 1964–1980 average, compared to 3.5% for the Northern Hemisphere (NH) extratropics (Douglass et al., 2011). In the NH, the 1993 minimum of about –6% was primarily caused by ozone loss through heterogeneous reactions on volcanic aerosols from Mt. Pinatubo.

Two altitude regions are mainly responsible for long-term changes in total column ozone (Douglass et al., 2011). In the upper stratosphere (35–45 km), there was a strong and statistically significant decline (about 10%) up to the mid-1990s and little change or a slight increase since. The lower stratosphere, between 20 and 25 km over mid-latitudes, also experienced a statistically significant decline (7–8%) between 1979 and the mid-1990s, followed by stabilization or a slight (2–3%) ozone increase.

Springtime averages of total ozone poleward of 60° latitude in the Arctic and Antarctic are shown in Figure 2.6e. By far the strongest ozone loss in the stratosphere occurs in austral spring over Antarctica (ozone hole) and its impact on SH climate is discussed in Chapters 11, 12, and 14. Interannual variability in polar stratospheric ozone abundance and chemistry is driven by variability in temperature and transport due to year-to-year differences in dynamics. This variability is particularly large in the Arctic where the most recent large depletion occurred in 2011, when chemical ozone destruction was, for the first time in the observational record, comparable to that in the Antarctic (Manney et al., 2011).

In summary, it is certain that global stratospheric ozone has declined from pre-1980 values. Most of the decline occurred prior to the mid-1990s; since then there has been little net change and ozone has remained nearly constant at about 3.5% below the 1964–1980 level.

Figure 2.6: Zonally averaged, annual mean total column ozone in Dobson Units (DU; 1 DU = 2.69×10^{16} O₃/cm²) from ground-based measurements combining Brewer, Dobson, and filter spectrometer data WOUDC (red), GOME/SCIAMACHY/GOME-2 GSG (green) and merged satellite BUV/TOMS/SBUV/OMI MOD V8 (blue) for a) Non-Polar Global (60°S–60°N), b) NH (30°N–60°N), c) Tropics (25°S–25°N), d) SH (30°S–60°S) and e) March NH Polar (60°N–90°N) and October SH Polar. Adapted from Weber et al. (2012; see also for abbreviations).

2.2.2.3 Tropospheric Ozone

Tropospheric ozone is a short-lived trace gas that either originates in the stratosphere or is produced in situ by precursor gases and sunlight (e.g., Monks et al., 2009). An important greenhouse gas with an estimated radiative forcing of 0.40 ± 0.20 W m⁻² (Chapter 8), tropospheric ozone also impacts human health and

vegetation at the surface. Its average atmospheric lifetime of a few weeks produces a global distribution highly variable by season, altitude and location. These characteristics and the paucity of long-term measurements make the assessment of long-term global ozone trends challenging. However, new studies since AR4 provide greater understanding of surface and free tropospheric ozone trends from the 1950s through 2010. An extensive compilation of measured ozone trends is presented in the Supplementary Material, Figure 2.SM.1 and Table 2.SM.2.

The earliest (1876–1910) quantitative ozone observations are limited to Montsouris near Paris where ozone averaged 11 ppb (Volz and Kley, 1988). Semi-quantitative ozone measurements from over 40 locations around the world in the late 1800s and early 1900s range from 5–32 ppb with large uncertainty (Pavelin et al., 1999). The low 19th century ozone values cannot be reproduced by most models (Section 8.2.3.1), and this discrepancy is an important factor contributing to uncertainty in radiative forcing calculations (Section 8.3.3.1). Limited quantitative measurements from the 1870s–1950s indicate that surface ozone in Europe increased by more than a factor of 2 compared to observations made at the end of the 20th century (Marenco et al., 1994; Parrish et al., 2012).

Satellite-based tropospheric column ozone retrievals across the tropics and mid-latitudes reveal a greater burden in the NH than in the SH (Ziemke et al., 2011). Tropospheric column ozone trend analyses are few. An analysis by Ziemke et al. (2005) found no trend over the tropical Pacific Ocean but significant positive trends (5–9%/decade) in the mid-latitude Pacific of both hemispheres during 1979–2003. Significant positive trends (2–9%/decade) were found across broad regions of the tropical South Atlantic, India, southern China, southeast Asia, Indonesia and the tropical regions downwind of China (Beig and Singh, 2007).

Long-term ozone trends at the surface and in the free troposphere (of importance for calculating radiative forcing, Chapter 8) can only be assessed from in situ measurements at a limited number of sites, leaving large areas such as the tropics and SH sparsely sampled (Table 2.SM.2, Figure 2.7). Nineteen predominantly rural surface sites or regions around the globe have long-term records that stretch back to the 1970s, and in two cases the 1950s (Lelieveld et al., 2004; Parrish et al., 2012; Oltmans et al., 2013). Thirteen of these sites are in the NH, and 11 sites have statistically significant positive trends of 1–5 ppb/decade, corresponding to > 100% ozone increases since the 1950s and 9–55% ozone increases since the 1970s. In the SH, 3 of 6 sites have significant trends of approximately 2 ppb/decade and 3 have insignificant trends. Free tropospheric monitoring since the 1970s is more limited. Significant positive trends since 1971 have been observed using ozone sondes above western Europe, Japan and coastal Antarctica (rates of increase range from 1–3 ppb/decade), but not at all levels (Oltmans et al., 2013). In addition aircraft have measured significant upper tropospheric trends in one or more seasons above the north eastern USA, the North Atlantic Ocean, Europe, the Middle East, northern India, southern China and Japan (Schnadt Poberaj et al., 2009). Insignificant free tropospheric trends were found above the Mid-Atlantic USA (1971–2010) (Oltmans et al., 2013) and in the upper troposphere above the western USA (1975–2001) (Schnadt Poberaj et al., 2009). No site or region showed a significant negative trend.

In recent decades ozone precursor emissions have decreased in Europe and North America and increased in Asia (Granier et al., 2011), impacting ozone production on regional and hemispheric scales (Skeie et al., 2011). Accordingly, 1990–2010 surface ozone trends vary regionally. In Europe ozone generally increased through much of the 1990s but since 2000 ozone has either levelled off or decreased at rural and mountaintop sites, as well as for baseline ozone coming ashore at Mace Head, Ireland (Tarasova et al., 2009; Logan et al., 2012; Parrish et al., 2012; Oltmans et al., 2013). In North America surface ozone has increased in eastern and Arctic Canada, but is unchanged in central and western Canada (Oltmans et al., 2013). Surface ozone has increased in baseline air masses coming ashore along the west coast of the USA (Parrish et al., 2012) and at half of the rural sites in the western USA during spring (Cooper et al., 2012). In the eastern USA surface ozone has decreased strongly in summer, is largely unchanged in spring and has increased in winter (Lefohn et al., 2010; Cooper et al., 2012). East Asian surface ozone is generally increasing (Table 2.SM.2) and at downwind sites ozone is increasing at Mauna Loa, Hawaii but decreasing at Minami Tori Shima in the subtropical western North Pacific (Oltmans et al., 2013). In the SH ozone has increased at the eight available sites, although trends are insignificant at four sites (Helmig et al., 2007; Oltmans et al., 2013).

[INSERT FIGURE 2.7 HERE]

Figure 2.7: Annual average surface ozone concentrations from regionally representative ozone monitoring sites around the world. a) Europe. b) Asia and North America. c) Remote sites in the Northern and Southern Hemispheres. The station name in the legend is followed by its latitude and height. Time series include data from all times of day and trend lines are linear regressions following the method of Parrish et al. (2012). Trend lines are fit through the full time series at each location, except for Jungfraujoch, Zugspitze, Arosa and Hohenpeissenberg where the linear trends end in 2000 (indicated by the dashed vertical line in a)). Twelve of these 19 sites have significant positive ozone trends (i.e., a trend of zero lies outside the 90% confidence interval); the 7 sites with non-significant trends are: Japanese MBL (marine boundary layer), Summit (Greenland), Barrow (Alaska), Storfjörður (Iceland), Samoa (tropical South Pacific Ocean), Cape Point (South Africa) and South Pole (Antarctica).

Due to methodological changes free tropospheric ozone observations are most reliable since the mid-1990s. Ozone has decreased above Europe since 1998 (Logan et al., 2012) and is largely unchanged above Japan (Oltmans et al., 2013). Otherwise the remaining regions with measurements (N. America, North Pacific Ocean, SH) show a range of positive trends (both significant and insignificant) depending on altitude, with no site having a negative trend at any altitude (Table 2.SM.2).

In summary, there is *medium confidence* from limited measurements in the late 19th through mid-20th century that European surface ozone more than doubled by the end of the 20th century. There is *medium confidence* from more widespread measurements beginning in the 1970s that surface ozone has increased at most (non-urban) sites in the NH (1-5 ppb/decade), while there is *low confidence* for ozone increases (2 ppb/decade) in the SH. Since 1990 surface ozone has *likely* increased in East Asia, while surface ozone in the eastern USA and western Europe has levelled off or is decreasing. Ozone monitoring in the free troposphere since the 1970s is very limited and indicates a weaker rate of increase than at the surface. Satellite instruments can now quantify the present-day tropospheric ozone burden on a near-global basis; significant tropospheric ozone column increases were observed over extended tropical regions of southern Asia, as well as mid-latitude regions of the South and North Pacific Ocean since 1979.

2.2.2.4 Carbon Monoxide (CO), Non Methane Volatile Organic Compounds (NMVOC) and Nitrogen Dioxide (NO₂)

Emissions of CO, NMVOC and NO_x (NO + NO₂) do not have a direct effect on radiative forcing, but affect climate indirectly as precursors to tropospheric O₃ and aerosol formation, and their impacts on OH concentrations and CH₄ lifetime. NMVOC include aliphatic, aromatic oxygenated hydrocarbons (e.g., aldehydes, alcohols, and organic acids), and have atmospheric lifetimes ranging from hours to months. Global coverage of NMVOC measurements is poor, except for a few compounds. Reports on trends generally indicate declines in a range of NMVOC in urban and rural regions of North America and Europe on the order of a few percent to more than 10%/yr. Global ethane levels reported by Simpson et al. (2012) declined by about 21% from 1986 to 2010. Measurements of air extracted from firn suggest that NMVOC concentrations were growing until 1980 and declined afterwards (Aydin et al., 2011; Worton et al., 2012). Satellite retrievals of formaldehyde column abundances from 1997 to 2007 show significant positive trends over northeastern China (4%/yr) and India (1.6%/yr), possibly related to strong increases in anthropogenic NMVOC emissions, whereas negative trends of about -3%/yr are observed over Tokyo, Japan and the northeast U.S. urban corridor as a result of pollution regulation (De Smedt et al., 2010).

The major sources of atmospheric CO are in situ production by oxidation of hydrocarbons (mostly CH₄ and isoprene) and direct emission resulting from incomplete combustion of biomass and fossil fuels. An analysis of MOPITT (Measurements of Pollutants in the Troposphere) and AIRS (Atmospheric Infrared Sounder) satellite data suggest a clear and consistent decline of CO columns for 2002–2010 over a number of polluted regions in Europe, North America and Asia with a global trend of about -1%/yr (Yurganov et al., 2010; Fortems-Cheiney et al., 2011; Worden et al., 2013). Analysis of satellite data using two more instruments for recent overlapping years shows qualitatively similar decreasing trends (Worden et al., 2013), but the magnitude of trends remains uncertain due to the presence of instrument biases. Small CO decreases observed in the NOAA and AGAGE networks are consistent with slight declines in global anthropogenic CO emissions over the same time (Supplementary Material 2.SM.2).

Due to its short atmospheric lifetime (~hours), NO_x concentrations are highly variable in time and space. AR4 described the potential of satellite observations of NO₂ to verify and improve NO_x emission inventories

and their trends; and reported strong NO₂ increases by 50% over the industrial areas of China from 1996 to 2004. An extension of this analysis reveals increases between a factor of 1.7 and 3.2 over parts of China, while over Europe and the USA NO₂ has decreased by 30 to 50% between 1996 and 2010 (Hilboll et al., 2013).

Figure 2.8 shows the changes relative to 1996 in satellite derived tropospheric NO₂ columns, with a strong upward trend over central eastern China and an overall downward trend in Japan, Europe and the USA. NO₂ reductions in the USA are very pronounced after 2004, related to differences in effectiveness of NO_x emission abatements in the USA and also to changes in atmospheric chemistry of NO_x (Russell et al., 2010). Increasingly, satellite data are used to derive trends in anthropogenic NO_x emissions, with Castellanos and Boersma (2012) reporting overall increases in global emissions, driven by Asian emission increases of up to 29%/yr (1996–2006), while moderate decreases up to 7%/yr (1996–2006) are reported for North America and Europe.

[INSERT FIGURE 2.8 HERE]

Figure 2.8: Relative changes in tropospheric NO₂ column amounts (logarithmic scale) in 7 selected world regions dominated by high NO_x emissions. Values are normalized for 1996 and derived from the GOME (Global Ozone Monitoring Experiment) instrument from 1996 to 2002 and SCIAMACHY (Scanning Imaging Spectrometer for Atmospheric Cartography) from 2003 to 2010 (Hilboll et al., 2013). The regions are indicated in the map inset.

In summary, satellite and surface observations of ozone precursor gases NO_x, CO, and non-methane volatile organic carbons indicate strong regional differences in trends. Most notably NO₂ has likely decreased by 30-50% in Europe and North America and increased by more than a factor of 2 in Asia since the mid-1990s.

2.2.3 Aerosols

This section assesses trends in aerosol resulting from both anthropogenic and natural sources. The significance of aerosol changes for global dimming and brightening is discussed in Section 2.3. Chapter 7 provides additional discussion of aerosol properties, while Chapter 8 discusses future radiative forcing and the ice-core records that contain information on aerosol changes prior to the 1980s. Chapter 11 assesses air quality-climate change interactions. Due to the short lifetime (days to weeks) of tropospheric aerosol, trends have a strong regional signature. Aerosol from anthropogenic sources (i.e., fossil and biofuel burning) are mainly confined to populated regions in the NH, whereas aerosol from natural sources, such as desert dust, sea salt, volcanoes and the biosphere, are important in both hemispheres and likely dependent on climate and land-use change (Carslaw et al., 2010). Owing to interannual variability, long-term trends in aerosols from natural sources are more difficult to identify (Mahowald et al., 2010).

2.2.3.1 Aerosol Optical Depth (AOD) from Remote Sensing

AOD is a measure of the integrated columnar aerosol load and is an important parameter for evaluating aerosol-radiation interactions. AR4 described early attempts to retrieve AOD from satellites but did not provide estimates of temporal changes in tropospheric aerosol. Little high accuracy information on AOD changes exists prior to 1995. Better satellite sensors and ground-based sun-photometer networks, along with improved retrieval methods and methodological intercomparisons allow assessment of regional AOD trends since about 1995.

AOD sun photometer measurements starting in 1986 at two stations in northern Germany corroborate the long-term decline of AOD in Europe (Ruckstuhl et al., 2008). Ground-based, cloud-screened solar broadband radiometer measurements provide longer time-records than spectrally selective sun-photometer data, but are less specific for aerosol retrieval. Multi-decadal records over Japan (Kudo et al., 2011) indicate an AOD increase until the mid-1980s, followed by an AOD decrease until the late 1990s and almost constant AOD in the 2000s. Similar broad-band solar radiative flux multi-decadal trends have been observed for urban-industrial regions of Europe and North America (Wild et al., 2005), and were linked to successful measures to reduce sulphate emissions since the mid-1980s (Section 2.3). An indirect method to estimate AOD is offered by ground-based visibility observations. These data are more ambiguous to interpret, but records go further back in time than broadband, sun photometer and satellite data. A multi-regional analysis

for 1973–2007 (Wang et al., 2009a) shows that prior to the 1990s visibility-derived AOD was relatively constant in most regions analysed (except for positive trends in southern Asia), but after 1990 positive AOD trends were observed over Asia, and parts of South America, Australia and Africa, and mostly negative AOD trends were found over Europe. In North America, a small step-wise decrease of visibility after 1993 was likely related to methodological changes (Wang et al., 2012f).

AOD can be most accurately determined with sun photometers that measure direct solar intensity in the absence of cloud interferences with an absolute uncertainty of single measurements of $\pm 0.01\%$ (Holben et al., 1998). AERONET (AERosol RObotic NETwork) is a global sun photometer network (Holben et al., 1998), with densest coverage over Europe and North America. AERONET AOD temporal trends were examined in independent studies (de Meij et al., 2012; Hsu et al., 2012; Yoon et al., 2012), using different data selection and statistical methods. Hsu et al. (2012) investigated AOD trends at 12 AERONET sites with data coverage of at least ten years between 1997 and 2010. Yoon et al. (2012) investigated AOD and size trends at 14 AERONET sites with data coverage varying between four and twelve years between 1997 and 2009. DeMeij et al. (2012) investigated AOD trends between 2000 and 2009 (550 nm; monthly data) at 62 AERONET sites mostly located in USA and Europe. Each of these studies noted an increase in AOD over East Asia and reductions in North American and Europe. The only dense sun photometer network over southern Asia, ARFINET (Aerosol Radiative Forcing over India NETwork), shows an increase in AOD of about 2%/yr during the last 1–2 decades (Krishna Moorthy et al., 2013), with an absolute uncertainty of ± 0.02 at 500 nm (Krishna Moorthy et al., 2007). In contrast, negative AOD trends are identified at more than 80% of examined European and North American AERONET sites (de Meij et al., 2012). Decreasing AOD is also observed near the west coast of northern Africa, where aerosol loads are dominated by Saharan dust outflow. Positive AOD trends are found over the Arabian Peninsula, where aerosol is dominated by dust. Inconsistent AOD trends reported for stations in central Africa result from the use of relatively short time series with respect to the large interannual variability caused by wildfires and dust emissions.

Aerosol products from dedicated satellite sensors complement surface-based AOD with better spatial coverage. The quality of the satellite-derived AOD strongly depends on the retrieval's ability to remove scenes contaminated by clouds and to accurately account for reflectivity at Earth's surface. Due to relatively weak reflectance of incoming sunlight by the sea-surface, the typical accuracy of retrieved AOD over oceans (uncertainty of $0.03 + 0.05 \cdot \text{AOD}$; Kahn et al. (2007)) is usually better than over continents (uncertainty of $0.05 + 0.15 \cdot \text{AOD}$, Levy et al. (2010)).

Satellite based AOD trends at 550 nm over oceans from conservatively cloud-screened MODIS data (Zhang and Reid, 2010) for 2000–2009 are presented in Figure 2.9. Strongly positive AOD trends were observed over the oceans adjacent to southern and eastern Asia. Positive AOD trends are also observed over most tropical oceans. The negative MODIS AOD trends observed over coastal regions of Europe and near the east coast of the USA are in agreement with sun photometer observations and in situ measurements (Section 2.2.3.2) of aerosol mass in these regions. These regional changes over oceans are consistent with analyses of AVHRR (Advanced Very High Resolution Radiometer) trends for 1981–2005 (Mishchenko et al., 2007; Cermak et al., 2010; Zhao et al., 2011), except over the Southern Ocean (45°S – 60°S), where negative AOD trends of AVHRR retrievals are neither confirmed by MODIS after 2001 (Zhang and Reid, 2010) nor by ATSR-2 (Along Track Scanning Radiometer) for 1995–2001 (Thomas et al., 2010).

[INSERT FIGURE 2.9 HERE]

Figure 2.9: a) Annual average Aerosol Optical Depth (AOD) trends at $0.55 \mu\text{m}$ for 2000–2009, based on de-seasonalized, conservatively cloud-screened MODIS aerosol data over oceans (Zhang and Reid, 2010). Negative AOD trends off Mexico are due to enhanced volcanic activity at the beginning of the record. Most non-zero trends are significant (i.e., a trend of zero lies outside the 95% confidence interval). b) Seasonal average AOD trends at $0.55 \mu\text{m}$ for 1998 to 2010 using SeaWiFS data (Hsu et al., 2012). Grey areas indicate incomplete or missing data. Black dots indicate significant trends (i.e., a trend of zero lies outside the 95% confidence interval).

Satellite based AOD changes for both land and oceans (Figure 2.9b) were examined with re-processed SeaWiFS (Sea-viewing Wide Field-of-view Sensor) AOD data for 1998–2010 (Hsu et al., 2012). A small positive global average AOD trend is reported, which is likely influenced by interannual natural aerosol emissions variability (e.g., related to ENSO or NAO; Box 2.5), and compensating larger positive and negative regional AOD trends. In addition, temporal changes in aerosol composition are ignored in the retrieval algorithms, giving more uncertain trends than suggested by statistical analysis alone (Mishchenko et

al., 2012). Thus, *confidence* is *low* for global satellite derived AOD trends over these relatively short time periods.

The sign and magnitude of SeaWiFS regional AOD trends over continents are in agreement with most AOD trends by ground-based sun photometer data (see above) and with MODIS trends (Figure 2.9). The strong positive AOD trend over the Arabian Peninsula occurs mainly during spring (MAM) and summer (JJA), during times of dust transport, and is also visible in MODIS data (Figure 2.9). The positive AOD trend over southern and eastern Asia is strongest during the dry seasons (DJF, MAM), when reduced wet deposition allows anthropogenic aerosol to accumulate in the troposphere. AOD over the Saharan outflow region off western Africa displays the strongest seasonal AOD trend differences, with AOD increases only in spring, but strong AOD decreases during the other seasons. SeaWiFS AOD decreases over Europe and the USA and increases over southern and eastern Asia (especially during the dry season) are in agreement with reported temporal trends in anthropogenic emissions, and surface observations (Section 2.2.3.2).

In summary, based on satellite and surface-based remote sensing it is *very likely* that AOD has decreased over Europe and the eastern USA since the mid 1990s and increased over eastern and southern Asia since 2000. In the 2000s dust-related AOD has been increasing over the Arabian Peninsula and decreasing over the North Atlantic Ocean. Aerosol trends over other regions are less strong or not significant during this period due to relative strong interannual variability. Overall, *confidence* in satellite based global average AOD trends is *low*.

2.2.3.2 *In Situ Surface Aerosol Measurements*

AR4 did not report trends in long-term surface-based in situ measurements of particulate matter, its components or its properties. This section summarizes reported trends of PM₁₀, PM_{2.5} (Particulate Matter with aerodynamic diameters < 10 and 2.5 µm, respectively), sulphate, and equivalent black carbon/elemental carbon, from regionally representative measurement networks. An overview of current networks and definitions pertinent to aerosol measurements is given in Supplementary Material 2.SM.2.3. Studies reporting trends representative for regional changes are presented in Table 2.2. Long-term data are almost entirely from North America and Europe, whereas a few individual studies on aerosol trends in India and China are reported in Supplementary Material 2.SM.2.3. Figure 2.10 gives an overview of observed PM₁₀, PM_{2.5}, and sulphate trends in North America and Europe for 1990–2009 and 2000–2009.

[INSERT FIGURE 2.10 HERE]

Figure 2.10: Trends in particulate matter (PM₁₀ and PM_{2.5} with aerodynamic diameters < 10 and 2.5 µm, respectively) and sulphate in Europe and USA for two overlapping periods 2000-2009 (a, b, c) and 1990-2009 (d, e). The trends are based on measurements from the EMEP (Torseth et al., 2012) and IMPROVE (Hand et al., 2011) networks in Europe and USA, respectively. Sites with significant trends (i.e., a trend of zero lies outside the 95% confidence interval) are shown in colour; black dots indicate sites with non-significant trends.

In Europe, strong downward trends are observed for PM₁₀, PM_{2.5} and sulphate from the rural stations in the EMEP (European Monitoring and Evaluation Programme) network. For 2000-2009, PM_{2.5} shows an average reduction of 3.9%/yr for the 6 stations with significant trends, while trends are not significant at 7 other stations. Over 2000-2009, PM₁₀ at 12 (out of 24) sites shows significant downward trend of on average 2.6%/yr. Similarly sulphate strongly decreased at 3.1%/yr from 1990 to 2009 with 26 of 30 sites having significant reductions. The largest decrease occurred before 2000, while for 2000–2009, the trends were weaker and less robust. This is consistent with reported emission reductions of 65% from 1990 to 2000 and 28% from 2001 to 2009 (Yttri et al., 2011; Torseth et al., 2012). Model analysis (Pozzoli et al., 2011) attributed the trends in large part to emission changes.

In the USA, the largest reductions in PM and sulphate are observed in the 2000s, rather than the 1990s as in Europe. IMPROVE (U.S. Interagency Monitoring of Protected Visual Environments Network) PM_{2.5} measurements (Hand et al., 2011) show significant downward trends averaging 4.0%/yr for 2000–2009 at sites with significant trends, and 2.1%/yr at all sites, and PM₁₀ decreases of 3.1%/yr for 2000–2009. Declines of PM_{2.5} and SO₄²⁻ in Canada are very similar (Hidy and Pennell, 2010) with annual mean PM_{2.5} at urban measurement decreasing by 3.6%/yr during 1985-2006 (Canada, 2012).

In the eastern and southwestern USA, IMPROVE data show strong sulphate declines, which range from 2 to 6%/yr, with average of 2.3%/yr for the sites with significant negative trends for 1990–2009. However, four IMPROVE sites show strong SO_4^{2-} increases from 2000 to 2009, amounting to 11.9%/yr, at Hawaii (1225 m above sea level), and 4–7%/yr at 3 sites in southwest Alaska.

A recent study on long-term trends in aerosol optical properties from 24 globally distributed background sites (Collaud Coen et al., 2013) reported statistically significant trends at 16 locations, but the sign and magnitude of the trends varied largely with the aerosol property considered and geographical region (Table 2.3). Among the sites, this study reported strong increases in absorption and scattering coefficients in the free troposphere at Mauna Loa, Hawaii (3400 m above sea level), which is a regional feature also evident in the satellite-based AOD trends (illustrated in Figure 2.9). Possible explanations for these changes include the influence of increasing Asian emissions and changes in clouds and removal processes. More and longer Asian time series, coupled with transport analyses, are needed to corroborate these findings. Aerosol number concentrations (Asmi et al., 2013) are declining significantly at most sites in Europe, North America, the Pacific and the Caribbean, but increasing at South Pole based on a study of 17 globally distributed remote sites.

Table 2.2: Trend estimates for various aerosol variables reported in the literature, using datasets with at least 10 years of measurements. Unless otherwise noted, trends of individual stations were reported in %/yr, and 95% confidence intervals. The standard deviation (in parentheses) is determined from the individual trends of a set of regional stations. Trend numbers indicated by # refer to the subset of stations with significant changes over time - generally in regions strongly influenced by anthropogenic emissions (Figure 2.10).

Aerosol variable	Trend, %/yr (1 σ , standard deviation)	Period	Reference	Comments
Europe				
PM _{2.5}	-2.9 (1.31) -3.9 (0.87) [#]	2000-2009	Adapted from (Torseth et al., 2012) Regional background sites	13 sites available, 6 sites show statistically significant results. Average change was -0.37 and -0.52 [#] $\mu\text{g}/\text{m}^3/\text{yr}$.
PM ₁₀	-1.9 (1.43) -2.6 (1.19) [#]	2000-2009		24 sites available, 12 sites show statistically significant results. Average change was -0.29 and -0.40 [#] $\mu\text{g}/\text{m}^3/\text{yr}$.
SO ₄ ²⁻	-3.0 (0.82) -3.1 (0.72) [#]	1990-2009		30 sites available, 26 sites show statistically significant results. Average change was -0.04 and -0.04 [#] $\mu\text{g}/\text{m}^3/\text{yr}$.
SO ₄ ²⁻	-1.5 (1.41) -2.0 (1.8) [#]	2000-2009		30 sites available, 10 sites show statistically significant results. Average change was -0.01 and -0.01 [#] $\mu\text{g}/\text{m}^3/\text{yr}$.
PM ₁₀	-1.9	1991-2008	(Barnpadimos et al., 2012) Rural and urban sites	10 sites in Switzerland. The trend is adjusted for change in meteorology- unadjusted data did not differ strongly. The average change was -0.51 $\mu\text{g}/\text{m}^3/\text{yr}$.
USA				
PM _{2.5}	-2.1 (2.08) -4.0 (1.01) [#]	2000-2009	Adapted from (Hand et al., 2011)	153 sites available, 52 sites show statistically significant negative results. Only 1 site show statistically positive trend
PM _{2.5}	-1.5 (1.25) -2.1 (0.97) [#]	1990-2009	Regional background sites	153 sites available, 39 sites show statistically significant results.

Table 2.3: Summary table of aerosol optical property trends reported in the literature, using datasets with at least 10 years of measurements. Otherwise as in Table 2.2.

Region	Trend, %/yr (1σ, standard deviation)	Period	Reference	Comments
Scattering coefficient				
Europe (4/1)	+0.6 (1.9) +2.7 [#]	2001-2010	Adapted from (Collaud Coen et al., 2013)	Trend study including 24 regional background sites with more than 10 years of observations. Regional averages for last 10 years are included here. Values in parenthesis show total number of sites / number of sites with significant trend.
USA (14/10)	-2.0 (2.5) -2.9 (2.4) [#]		Regional background sites	
Mauna Loa (1/1)	+2.7			
Arctic (1/0)	+2.4			
Antarctica (1/0)	+2.5			
Absorption coefficient				
Europe (3/0)	+0.3 (0.4)	2001-2010	Adapted from (Collaud Coen et al., 2013)	Trend study of aerosol optical properties including 24 regional background sites with more than 10 years of observations. Regional averages for last 10 years are included here. Values in parenthesis show total number of sites and number of sites with significant trend.
USA (1/1)	-2.0		Regional background sites	
Mauna Loa (1/1)	+9.0			
Arctic (1/1)	-6.5			
Antarctica (1/1)	-0.1			
Particle number concentration				
Europe (4/2)	-0.9 (1.8) -2.3 (1.0) [#]	2001-2010	Adapted from (Asmi et al., 2013)	Trend study of particle number concentration (N) and size distribution including 17 regional background sites. Regional averages of particle number concentration for last 10 years are included here. Values in parenthesis show total number of sites and number of sites with significant trend.
North America and Caribbean (3/3)	-5.3 (2.8) -6.6 (1.1) [#]		Regional background sites	
Mauna Loa (1/1)	-3.5			
Arctic (1/0)	-1.3			
Antarctica (2/2)	+2.7 (1.4)			

Total carbon (= light absorbing carbon + organic carbon) measurements indicate highly significant downward trends between 2.5 and 7.5%/yr along the east and west coasts of the USA, and smaller and less significant trends in other regions of the USA from 1989 to 2008 (Hand et al., 2011; Murphy et al., 2011).

In Europe, Torseth et al. (2012) suggest a slight reduction in elemental carbon concentrations at two stations from 2001 to 2009, subject to large interannual variability. Collaud Coen et al. (2013) reported consistent negative trends in the aerosol absorption coefficient at stations in the continental USA, Arctic and Antarctica, but mostly insignificant trends in Europe over the last decade.

In the Arctic, changes in aerosol impact the atmosphere's radiative balance as well as snow and ice albedo. Similar to Europe and the USA, Hirdman et al. (2010) reported downward trends in equivalent black carbon and SO₄²⁻ for two out of total three Arctic stations and attributed them to emission changes.

In summary, declining AOD in Europe and North America is corroborated by *very likely* downward trends in ground-based in situ particulate matter measurements since the mid-1980s. Robust evidence from around 200 regional background sites with in situ ground based aerosol measurements indicate downward trends in the last 2 decades of PM_{2.5} in parts of Europe (2–6%/yr) and the USA (1–2.5%/yr), and also for SO₄²⁻ (2–5%/yr). The strongest decreases were in the 1990s in Europe and in the

2000s in the USA. There is robust evidence for downward trends of light absorbing aerosol in the USA and the Arctic, while elsewhere in the world in situ time series are lacking or not long enough to reach statistical significance.

Box 2.2: Quantifying Changes in the Mean: Trend Models and Estimation

Many statistical methods exist for estimating trends in environmental time series (see Chandler and Scott, 2011 for a review). The assessment of long-term changes in historical climate data requires trend models that are transparent and reproducible, and that can provide credible uncertainty estimates.

Linear Trends

Historical climate trends are frequently described and quantified by estimating the linear component of the change over time (e.g., AR4). Such linear trend modelling has broad acceptance and understanding based on its frequent and widespread use in the published research assessed in this report, and its strengths and weaknesses are well known (von Storch and Zwiers, 1999; Wilks, 2006). Challenges exist in assessing the uncertainty in the trend and its dependence on the assumptions about the sampling distribution (Gaussian or otherwise), uncertainty in the data used, dependency models for the residuals about the trend line, and treating their serial correlation (Von Storch, 1999; Santer et al., 2008).

The quantification and visualisation of temporal changes are assessed in this chapter using a linear trend model that allows for first order autocorrelation in the residuals (Santer et al., 2008; Supplementary Material 2.SM.3). Trend slopes in such a model are the same as ordinary least squares trends; uncertainties are computed using an approximate method. The 90% confidence interval quoted is solely that arising from sampling uncertainty in estimating the trend. Structural uncertainties, to the extent sampled, are apparent from the range of estimates from different datasets. Parametric and other remaining uncertainties (Box 2.1), for which estimates are provided with some datasets, are not included in the trend estimates shown here, so that the same method can be applied to all datasets considered.

Non-linear Trends

There is no *a priori* physical reason why the long-term trend in climate should be linear in time. Climatic time series often have trends for which a straight line is not a good approximation (e.g., Seidel and Lanzante, 2004). The residuals from a linear fit in time often do not follow a simple autoregressive or moving average process, and linear trend estimates can easily change when estimates are recalculated using data covering shorter or longer time periods or when new data are added. When linear trends for two parts of a longer time series are calculated separately, the trends calculated for two shorter periods may be very different (even in sign) from the trend in the full period, if the time series exhibits significant nonlinear behavior in time (Box 2.2, Table 1).

Many methods have been applied to estimate the long-term change in a time series without assuming the change is linear in time (e.g., Wu et al., 2007; Craigmile and Guttorp, 2011). Box 2.2, Figure 1 shows the linear least squares and a non-linear trend fit to the GMST values from the HadCRUT4 dataset (Section 2.4.3). The non-linear trend is obtained by fitting a smoothing spline trend (Wood, 2006; Scinocca et al., 2010) while allowing for first order autocorrelation in the residuals (Supplementary Material 2.SM.3). This method indicates that there are significant departures from linearity in the trend estimated this way.

Box 2.2, Table 1 shows estimates of the change in the GMST from the two methods. The methods give similar estimates with 90% confidence intervals that overlap one another. Smoothing methods that do not assume the trend is linear can provide useful information on the structure of change that is not as well treated with linear fits. The linear trend fit is used in this chapter because it can be applied consistently to all the datasets, is relatively simple, transparent and easily comprehended, and is frequently used in the published research assessed here.

[INSERT BOX 2.2, FIGURE 1 HERE]

Box 2.2, Figure 1: a) Global Mean Surface Temperature (GMST) anomalies relative to a 1961–1990 climatology based on HadCRUT4 annual data. The straight black lines are Least Squares trends for 1901–2012, 1901–1950 and 1951–2012. b) Same data as in a), with Smoothing Spline (solid curve) and the 90% confidence interval on the smooth curve (dashed lines). Note that the (strongly overlapping) 90% confidence intervals for the least square lines in (a) are omitted for clarity. See Figure 2.20 for the other two GMST data products.

Box 2.2, Table 1: Estimates of the mean change in Global Mean Surface Temperature (GMST) between 1901 and 2012, 1901 and 1950, and 1951 and 2012, obtained from the linear (Least Squares) and non-linear (Smoothing Spline) trend models. Half-widths of the 90% confidence intervals are also provided for the estimated changes from the two trend methods.

Method	Trends in °C/decade		
	1901–2012	1901–1950	1951–2012
Least Squares	0.075 ± 0.013	0.107 ± 0.026	0.106 ± 0.027
Smoothing Spline	0.081 ± 0.010	0.070 ± 0.016	0.090 ± 0.018

[END BOX 2.2 HERE]

2.3 Changes in Radiation Budgets

The radiation budget of Earth is a central element of the climate system. On average, radiative processes warm the surface and cool the atmosphere, which is balanced by the hydrological cycle and sensible heating. Spatial and temporal energy imbalances due to radiation and latent heating produce the general circulation of the atmosphere and oceans. Anthropogenic influence on climate occurs primarily through perturbations of the components of the Earth radiation budget.

The radiation budget at the Top Of Atmosphere (TOA) includes the absorption of solar radiation by Earth, determined as the difference between the incident and reflected solar radiation at the TOA, as well as the thermal outgoing radiation emitted to space. The surface radiation budget takes into account the solar fluxes absorbed at Earth's surface, as well as the upward and downward thermal radiative fluxes emitted by the surface and atmosphere, respectively. In view of new observational evidence since AR4, the mean state as well as multi-decadal changes of the surface and TOA radiation budgets are assessed in the following.

2.3.1 Global Mean Radiation Budget

Since AR4, knowledge on the magnitude of the radiative energy fluxes in the climate system has improved, requiring an update of the global annual mean energy balance diagram (Figure 2.11). Energy exchanges between Sun, Earth and Space are observed from space-borne platforms such as the Clouds and the Earth's Radiant Energy System (CERES, Wielicki et al., 1996) and the Solar Radiation and Climate Experiment (SORCE, Kopp and Lawrence, 2005) which began data collection in 2000 and 2003, respectively. The total solar irradiance (TSI) incident at the TOA is now much better known, with the SORCE Total Irradiance Monitor (TIM) instrument reporting uncertainties as low as 0.035%, compared to 0.1% for other TSI instruments (Kopp et al., 2005). During the 2008 solar minimum, SORCE/TIM observed a solar irradiance of $1360.8 \pm 0.5 \text{ W/m}^2$ compared to $1365.5 \pm 1.3 \text{ W/m}^2$ for instruments launched prior to SORCE and still operating in 2008 (Section 8.2.1). Kopp and Lean (2011) conclude that the SORCE/TIM value of TSI is the most credible value because it is validated by a National Institute of Standards and Technology calibrated cryogenic radiometer. This revised TSI estimate corresponds to a solar irradiance close to 340 W/m^2 globally averaged over Earth's sphere (Figure 2.11).

[INSERT FIGURE 2.11 HERE]

Figure 2.11: Global mean energy budget under present day climate conditions. Numbers state magnitudes of the individual energy fluxes in W/m^2 , adjusted within their uncertainty ranges to close the energy budgets. Numbers in parentheses attached to the energy fluxes cover the range of values in line with observational constraints. Figure adapted from Wild et al. (2013).

The estimate for the reflected solar radiation at the TOA in Figure 2.11, 100 W/m^2 , is a rounded value based on the CERES Energy Balanced and Filled (EBAF) satellite data product (Loeb et al., 2009; Loeb et al.,

2012b) for the period 2001–2010. This dataset adjusts the solar and thermal TOA fluxes within their range of uncertainty to be consistent with independent estimates of the global heating rate based upon in situ ocean observations (Loeb et al., 2012b). This leaves 240 W/m^2 of solar radiation absorbed by Earth, which is nearly balanced by thermal emission to space of about 239 W/m^2 (based on CERES EBAF), considering a global heat storage of 0.6 W/m^2 (imbalance term in Figure 2.11) based on Argo data from 2005 to 2010 (Hansen et al., 2011; Loeb et al., 2012b; Box 3.1). The stated uncertainty in the solar reflected TOA fluxes from CERES due to uncertainty in absolute calibration alone is $\sim 2\%$ (2-sigma), or equivalently 2 W/m^2 (Loeb et al., 2009). The uncertainty of the outgoing thermal flux at the TOA as measured by CERES due to calibration is $\sim 3.7 \text{ W/m}^2$ (2σ). In addition to this, there is uncertainty in removing the influence of instrument spectral response on measured radiance, in radiance-to-flux conversion, and in time-space averaging, which adds up to another 1 W/m^2 (Loeb et al., 2009).

The components of the radiation budget at the surface are generally more uncertain than their counterparts at the TOA because they cannot be directly measured by passive satellite sensors and surface measurements are not always regionally or globally representative. Since AR4, new estimates for the downward thermal infrared radiation at the surface have been established that incorporate critical information on cloud base heights from space-borne radar and lidar instruments (L'Ecuyer et al., 2008; Stephens et al., 2012a; Kato et al., in press). In line with studies based on direct surface radiation measurements (Wild et al., 1998; Wild et al., 2013) these studies propose higher values of global mean downward thermal radiation than presented in previous IPCC assessments and typically found in climate models, exceeding 340 W/m^2 (Figure 2.11). This aligns with the downward thermal radiation in the ERA-Interim and ERA-40 reanalyses (Box 2.3), of 341 and 344 W/m^2 , respectively (Berrisford et al., 2011). Estimates of global mean downward thermal radiation computed as a residual of the other terms of the surface energy budget (Kiehl and Trenberth, 1997; Trenberth et al., 2009) are lower (324 – 333 W/m^2), highlighting remaining uncertainties in estimates of both radiative and non-radiative components of the surface energy budget.

Estimates of absorbed solar radiation at Earth's surface include considerable uncertainty. Published global mean values inferred from satellite retrievals, reanalyses and climate models range from below 160 W/m^2 to above 170 W/m^2 . Recent studies taking into account surface observations as well as updated spectroscopic parameters and continuum absorption for water vapor favour values towards the lower bound of this range, near 160 W/m^2 , and an atmospheric solar absorption around 80 W/m^2 (Figure 2.11) (Kim and Ramanathan, 2008; Trenberth et al., 2009; Kim and Ramanathan, 2012; Trenberth and Fasullo, 2012b; Wild et al., 2013). The ERA-Interim and ERA-40 reanalyses further support an atmospheric solar absorption of this magnitude (Berrisford et al., 2011). Latest satellite-derived estimates constrained by CERES now also come close to these values (Kato et al., in press). Recent independently derived surface radiation estimates favour therefore a global mean surface absorbed solar flux near 160 W/m^2 and a downward thermal flux slightly above 340 W/m^2 , respectively (Figure 2.11).

The global mean latent heat flux is required to exceed 80 W/m^2 to close the surface energy balance in Figure 2.11, and comes close to the 85 W/m^2 considered as upper limit by Trenberth and Fasullo (2012b) in view of current uncertainties in precipitation retrieval in the Global Precipitation Climatology Project (GPCP, Adler et al., 2012) (the latent heat flux corresponds to the energy equivalent of evaporation, which globally equals precipitation; thus its magnitude may be constrained by global precipitation estimates). This upper limit has recently been challenged by Stephens et al. (2012b). The emerging debate reflects potential remaining deficiencies in the quantification of the radiative and non-radiative energy balance components and associated uncertainty ranges, as well as in the consistent representation of the global mean energy and water budgets (Stephens et al., 2012b; Trenberth and Fasullo, 2012b; Wild et al., 2013). Relative uncertainty in the globally averaged sensible heat flux estimate remains high due to the very limited direct observational constraints (Trenberth et al., 2009; Stephens et al., 2012b).

In summary, newly available observations from both space-borne and surface-based platforms allow a better quantification of the Global Energy Budget, even though notable uncertainties remain, particularly in the estimation of the non-radiative surface energy balance components.

2.3.2 Changes in Top of Atmosphere Radiation Budget

While the previous section emphasized the temporally-averaged state of the radiation budget, the focus in the following is on the temporal (multi-decadal) changes of its components. Variations in TSI are discussed in Section 8.4.1. AR4 reported large changes in tropical TOA radiation between the 1980s and 1990s based upon observations from the Earth Radiation Budget Satellite (ERBS) (Wielicki et al., 2002; Wong et al., 2006). While the robust nature of the large decadal changes in tropical radiation remains to be established, several studies have suggested links to changes in atmospheric circulation (Allan and Slingo, 2002; Chen et al., 2002; Clement and Soden, 2005; Merrifield, 2011) (Section 2.7).

Since AR4, CERES enabled the extension of satellite records of TOA fluxes into the 2000s (Loeb et al., 2012b). The extended records from CERES suggest no noticeable trends in either the tropical or global radiation budget during the first decade of the 21st century (e.g., Andronova et al., 2009; Harries and Belotti, 2010; Loeb et al., 2012a; Loeb et al., 2012b). Comparisons between ERBS/CERES thermal radiation and that derived from the NOAA High Resolution Infrared Radiation Sounder (HIRS) (Lee et al., 2007) show good agreement until approximately 1998, corroborating the rise of 0.7 W/m^2 between the 1980s and 1990s reported in AR4. Thereafter the HIRS thermal fluxes show much higher values, likely due to changes in the channels used for HIRS/3 instruments launched after October 1998 compared to earlier HIRS instruments (Lee et al., 2007).

On a global scale, interannual variations in net TOA radiation and ocean heating rate (OHR) should correspond, since oceans have a much larger effective heat capacity than land and atmosphere, and therefore serve as the main reservoir for heat added to the Earth-atmosphere system (Box 3.1). Wong et al. (2006) showed that interannual variations in these two data sources are in good agreement for 1992–2003. In the ensuing 5 years, however, Trenberth and Fasullo (2010) note that the two diverge with ocean in situ measurements (Levitus et al., 2009) indicating a decline in OHR in contrast to expectations from the observed net TOA radiation. The divergence after 2004 is referred to as “missing energy” by Trenberth and Fasullo (2012b), who further argue that the main sink of the missing energy likely occurs at ocean depths below 275 meters. Loeb et al. (2012b) compared interannual variations in CERES net radiation with OHRs derived from three independent ocean heat content anomaly analyses and included an error analysis of both CERES and the OHRs. They conclude that the apparent decline in OHR is not statistically robust and that differences between interannual variations in OHR and satellite net TOA flux are within the uncertainty of the measurements (Figure 2.12). They further note that between January 2001 and December 2012, Earth has been steadily accumulating energy at a rate of $0.50 \pm 0.43 \text{ W/m}^2$ (90% CI). Hansen et al. (2011) obtained a similar value for 2005–2010 using an independent analysis of the ocean heat content anomaly data (von Schuckmann and Le Traon, 2011). The variability in Earth’s energy imbalance is strongly influenced by ocean circulation changes relating to the ENSO (Box 2.5); during cooler La Niña years (e.g., 2009) less thermal radiation is emitted and the climate system gains heat while the reverse is true for warmer El Niño years (e.g., 2010) (Figure 2.12).

In summary, satellite records of TOA radiation fluxes have been substantially extended since AR4. It is unlikely that significant trends exist in global and tropical radiation budgets since 2000. Interannual variability in the Earth’s energy imbalance related to ENSO is consistent with ocean heat content records within observational uncertainty.

[INSERT FIGURE 2.12 HERE]

Figure 2.12: Comparison of net Top Of Atmosphere (TOA) flux and upper Ocean Heating Rates (OHR). Global annual average (July to June) net TOA flux from CERES observations (based upon the EBAF-TOA_Ed2.6r product)(black line) and 0-700 (blue) and 0-1,800 m (red) OHR from the Pacific Marine Environmental Laboratory/Jet Propulsion Laboratory/Joint Institute for Marine and Atmospheric Research (PMEL/JPL/JIMAR), 0-700 m OHR from the National Oceanic Data Center (NODC) (Levitus et al., 2009)(green), and 0-700 m OHR from the Hadley Center (Palmer et al., 2007)(brown). The length of the coloured bars corresponds to the magnitude of OHR. Thin vertical lines are error bars, corresponding to the magnitude of uncertainties. Uncertainties for all annual OHR are given at one standard error derived from ocean heat content anomaly uncertainties (Lyman et al., 2010). CERES net TOA flux uncertainties are given at the 90% confidence level determined following Loeb et al. (2012b). Adapted from Loeb et al.(2012b).

2.3.3 Changes in Surface Radiation Budget

2.3.3.1 Surface Solar Radiation

Changes in radiative fluxes at the surface can be traced further back in time than the satellite-based TOA fluxes, although only at selected terrestrial locations where long-term records exist. Monitoring of radiative fluxes from land-based stations began on a widespread basis in the mid-20th century, predominantly measuring the downward solar component, also known as global radiation or surface solar radiation (SSR).

AR4 reported on the first indications for substantial decadal changes in observational records of SSR. Specifically, a decline of SSR from the beginning of widespread measurements in the 1950s until the mid-1980s has been observed at many land-based sites (popularly known as 'global dimming', Stanhill and Cohen, 2001; Liepert, 2002), as well as a partial recovery from the 1980s onward ('brightening', Wild et al., 2005) (see the longest available SSR series of Stockholm, Sweden, in Figure 2.13 as an illustrative example).

Since AR4, numerous studies have substantiated the findings of significant decadal SSR changes observed both at worldwide distributed terrestrial sites (Dutton et al., 2006; Wild et al., 2008; Gilgen et al., 2009; Ohmura, 2009; Wild, 2009 and references therein) as well as in specific regions. In Europe, Norris and Wild (2007) noted a dimming between 1971 and 1986 of 2.0–3.1 W/m² per decade and subsequent brightening of 1.1–1.4 W/m² per decade from 1987 to 2002 in a pan-European time series comprising 75 sites. Similar tendencies were found at sites in northern Europe (Stjern et al., 2009), Estonia (Russak, 2009) and Moscow (Abakumova et al., 2008). Chiacchio and Wild (2010) pointed out that dimming and subsequent brightening in Europe is mainly seen in spring and summer. Brightening in Europe from the 1980s onward was further documented at sites in Switzerland, Germany, France, the Benelux, Greece and the Iberian Peninsula (Ruckstuhl et al., 2008; Wild et al., 2009; Zerefos et al., 2009; Sanchez-Lorenzo et al., 2013). Concurrent brightening of 2–8 W/m² per decade was also noted at continental sites in the USA (Long et al., 2009; Riihimaki et al., 2009; Augustine and Dutton, 2013). The general pattern of dimming and consecutive brightening was further found at numerous sites in Japan (Norris and Wild, 2009; Ohmura, 2009; Kudo et al., 2011) and in the SH in New Zealand (Liley, 2009). Analyses of observations from sites in China confirmed strong declines in SSR from the 1960s to 1980s on the order of 2–8 W/m² per decade, which also did not persist in the 1990s (Che et al., 2005; Liang and Xia, 2005; Qian et al., 2006; Shi et al., 2008; Norris and Wild, 2009; Xia, 2010a). On the other hand, persistent dimming since the mid-20th century with no evidence for a trend reversal was noted at sites in India (Wild et al., 2005; Kumari et al., 2007; Kumari and Goswami, 2010; Soni et al., 2012), and in the Canadian Prairie (Cutforth and Judiesch, 2007). Updates on latest SSR changes observed since 2000 provide a less coherent picture (Wild, 2012). They suggest a continuation of brightening at sites in Europe, U.S., and parts of Asia, a levelling off at sites in Japan and Antarctica, and indications for a renewed dimming in parts of China (Wild et al., 2009; Xia, 2010a).

The longest observational SSR records, extending back to the 1920s and 1930s at a few sites in Europe, further indicate some brightening during the first half of the 20th century, known as 'early brightening' (cf. Figure 2.13) (Ohmura, 2009; Wild, 2009). This suggests that the decline in SSR, at least in Europe, was confined to a period between the 1950s and 1980s.

A number of issues remain, such as the quality and representativeness of some of the SSR data as well as the large scale significance of the phenomenon (Wild, 2012). The historic radiation records are of variable quality and rigorous quality control is necessary to avoid spurious trends (Dutton et al., 2006; Shi et al., 2008; Gilgen et al., 2009; Tang et al., 2011; Wang et al., 2012e; Sanchez-Lorenzo et al., 2013). Since the mid-1990s, high-quality data are becoming increasingly available from new sites of the Baseline Surface Radiation Network (BSRN) and Atmospheric Radiation Measurement (ARM) Program, which allow the determination of SSR variations with unprecedented accuracy (Ohmura et al., 1998). Alpert et al. (2005) and Alpert and Kishcha (2008) argued that the observed SSR decline between 1960 and 1990 was larger in densely populated than in rural areas. The magnitude of this 'urbanization effect' in the radiation data is not yet well quantified. Dimming and brightening is, however, also notable at remote and rural sites (Dutton et al., 2006; Karnieli et al., 2009; Liley, 2009; Russak, 2009; Wild, 2009; Wang et al., 2012d).

Globally complete satellite estimates are available since the early 1980s (Hatzianastassiou et al., 2005; Pinker et al., 2005; Hinkelman et al., 2009). Since satellites do not directly measure the surface fluxes, they have to be inferred from measurable top-of-atmosphere signals using empirical or physical models to remove atmospheric perturbations. Available satellite-derived products qualitatively agree on a brightening from the mid-1980s to 2000 averaged globally as well as over oceans, on the order of 2–3 W m⁻² per decade (Hatzianastassiou et al., 2005; Pinker et al., 2005; Hinkelman et al., 2009). Averaged over land, however,

trends are positive or negative depending on the respective satellite product (Wild, 2009). Knowledge of the decadal variation of aerosol burdens and optical properties, required in satellite retrievals of SSR and considered relevant for dimming/brightening particularly over land, is very limited (Section 2.2.3). Extensions of satellite-derived SSR beyond 2000 indicate tendencies towards a renewed dimming at the beginning of the new millennium (Hinkelman et al., 2009; Hatzianastassiou et al., 2012).

Reconstructions of SSR changes from more widely measured meteorological variables can help to increase their spatial and temporal coverage. Multi-decadal SSR changes have been related to observed changes in sunshine duration, atmospheric visibility, diurnal temperature range (DTR; Section 2.4.1.2) and pan evaporation (Section 2.5.4). Overall, these proxies provide independent evidence for the existence of large-scale multi-decadal variations in SSR. Specifically, widespread observations of declines in pan evaporation from the 1950s to the 1980s were related to SSR dimming amongst other factors (Roderick and Farquhar, 2002). The observed decline in DTR over global land surfaces from the 1950s to the 1980s (Section 2.4.1.2), and its stabilisation thereafter fits to a large-scale dimming and subsequent brightening, respectively (Wild et al., 2007). Widespread brightening after 1980 is further supported by reconstructions from sunshine duration records (Wang et al., 2012e). Over Europe, SSR dimming and subsequent brightening is consistent with concurrent declines and increases in sunshine duration (Sanchez-Lorenzo et al., 2008), evaporation in energy limited environments (Teuling et al., 2009), visibility records (Vautard et al., 2009; Wang et al., 2009b) and DTR (Makowski et al., 2009). The early brightening in the 1930s and 1940s seen in a few European SSR records is in line with corresponding changes in sunshine duration and DTR (Sanchez-Lorenzo et al., 2008; Wild, 2009; Sanchez-Lorenzo and Wild, 2012). In China, the levelling off in SSR in the 1990s after decades of decline coincides with similar tendencies in the pan evaporation records, sunshine duration and DTR (Liu et al., 2004a; Liu et al., 2004b; Qian et al., 2006; Ding et al., 2007; Wang et al., 2012d). Dimming up to the 1980s and subsequent brightening is also indicated in a set of 237 sunshine duration records in South America (Raichijk, 2011).

[INSERT FIGURE 2.13 HERE]

Figure 2.13: Annual mean Surface Solar Radiation (SSR) as observed at Stockholm, Sweden, from 1923 to 2010. Stockholm has the longest SSR record available worldwide. Updated from Wild (2009) and Ohmura (2009).

2.3.3.2 Surface Thermal and Net Radiation

Thermal radiation, also known as longwave, terrestrial or far-infrared radiation is sensitive to changes in atmospheric greenhouse gases, temperature and humidity. Long-term measurements of the thermal surface components as well as surface net radiation are available at far fewer sites than SSR. Downward thermal radiation observations started to become available during the early 1990s at a limited number of globally distributed terrestrial sites. From these records, Wild et al. (2008) determined an overall increase of 2.6 W m^{-2} per decade over the 1990s, in line with model projections and the expectations of an increasing greenhouse effect. Wang and Liang (2009) inferred an increase in downward thermal radiation of 2.2 W m^{-2} per decade over the period 1973–2008 from globally available terrestrial observations of temperature, humidity and cloud fraction. Prata (2008) estimated a slightly lower increase of 1.7 W m^{-2} per decade for clear sky conditions over the earlier period 1964–1990, based on observed temperature and humidity profiles from globally distributed land-based radiosonde stations and radiative transfer calculations. Philipona et al. (2004; Philipona et al., 2005) and Wacker et al. (2011) noted increasing downward thermal fluxes recorded in the Swiss Alpine Surface Radiation Budget (ASRB) network since the mid-1990s, corroborating an increasing greenhouse effect. For mainland Europe, Philipona et al. (2009) estimated an increase of downward thermal radiation of $2.4\text{--}2.7 \text{ W m}^{-2}$ per decade for the period 1981–2005.

There is limited observational information on changes in surface net radiation, in large part because measurements of upward fluxes at the surface are made at only a few sites and are not spatially representative. Wild et al. (2004; 2008) inferred a decline in land surface net radiation on the order of 2 W/m^2 per decade from the 1960s to the 1980s, and an increase at a similar rate from the 1980s to 2000, based on estimated changes of the individual radiative components that constitute the surface net radiation. Philipona et al. (2009) estimated an increase in surface net radiation of $1.3\text{--}2 \text{ W m}^{-2}$ per decade for central Europe and the Alps between 1981 and 2005.

2.3.3.3 Implications from Observed Changes in Related Climate Elements

The observed multi-decadal SSR variations cannot be explained by changes in TSI, which are an order of magnitude smaller (Willson and Mordvinov, 2003). They therefore have to originate from alterations in the transparency of the atmosphere, which depends on the presence of clouds, aerosols and radiatively active gases (Kvalevag and Myhre, 2007; Kim and Ramanathan, 2008). Cloud cover changes (Section 2.5.7) effectively modulate SSR on an interannual basis, but their contribution to the longer-term SSR trends is ambiguous. While cloud cover changes were found to explain the trends in some areas (e.g., Liley, 2009), this is not always the case, particularly in relatively polluted regions (Qian et al., 2006; Norris and Wild, 2007, 2009; Wild, 2009; Kudo et al., 2012). SSR dimming and brightening has also been observed under cloudless atmospheres at various locations, pointing to a prominent role of atmospheric aerosols (Wild et al., 2005; Qian et al., 2007; Ruckstuhl et al., 2008; Sanchez-Lorenzo et al., 2009; Wang et al., 2009b; Zerefos et al., 2009).

Aerosols can directly attenuate SSR by scattering and absorbing solar radiation, or indirectly, through their ability to act as cloud condensation nuclei, thereby changing cloud reflectivity and lifetime (Chapter 7). SSR dimming and brightening is often reconcilable with trends in anthropogenic emission histories and atmospheric aerosol loadings (Stern, 2006; Streets et al., 2006; Mishchenko et al., 2007; Ruckstuhl et al., 2008; Ohvri et al., 2009; Russak, 2009; Streets et al., 2009; Cermak et al., 2010; Wild, 2012). Recent trends in aerosol optical depth derived from satellites indicate a decline in Europe since 2000 (Section 2.2.3), in line with evidence from SSR observations. However, direct aerosol effects alone may not be able to account for the full extent of the observed SSR changes in remote regions with low pollution levels (Dutton and Bodhaine, 2001; Schwartz, 2005). Aerosol indirect effects have not yet been well quantified, but have the potential to amplify aerosol-induced SSR trends, particularly in relatively pristine environments, such as over oceans (Wild, 2012).

SSR trends are also qualitatively in line with observed multi-decadal surface warming trends (Chapter 10), with generally smaller warming rates during phases of declining SSR, and larger warming rates in phases of increasing SSR (Wild et al., 2007). This is seen more pronounced for the relatively polluted NH than the more pristine SH (Wild, 2012). For Europe, Vautard et al. (2009) found that a decline in the frequency of low-visibility conditions such as fog, mist and haze over the past 30 years and associated SSR increase may be responsible for 10–20% of Europe's recent daytime warming, and 50% of eastern European warming. Philipona (2012) noted that both warming and brightening are weaker in the European Alps compared to the surrounding lowlands with stronger aerosol declines since 1981.

Reanalyses and observationally-based methods have been used to show that increased atmospheric moisture with warming (Willett et al., 2008, Section 2.5) enhances thermal radiative emission of the atmosphere to the surface leading to reduced net thermal cooling of the surface (Prata, 2008; Allan, 2009; Philipona et al., 2009; Wang and Liang, 2009).

In summary, the evidence for widespread multi-decadal variations in solar radiation incident on land surfaces has been substantiated since AR4, with many of the observational records showing a decline from the 1950s to the 1980s ('dimming'), and a partial recovery thereafter ('brightening'). *Confidence* in these changes is *high* in regions with high station densities such as over Europe and parts of Asia. These *likely* changes are generally supported by observed changes in related, but more widely measured variables, such as sunshine duration, DTR and hydrological quantities, and are often in line with aerosol emission patterns. Over some remote land areas and over the oceans, *confidence is low* due to the lack of direct observations, which hamper a truly global assessment. Satellite-derived SSR fluxes support the existence of brightening also over oceans, but are less consistent over land surface where direct aerosol effects become more important. There are also indications for increasing downward thermal and net radiation at terrestrial stations since the early 1990s with *medium confidence*.

[START BOX 2.3 HERE]

Box 2.3: Global Atmospheric Reanalyses

Dynamical reanalyses are increasingly used for assessing weather and climate phenomena. Given their more frequent use in this assessment compared to AR4, their characteristics are described in more detail here.

Reanalyses are distinct from, but complement, more ‘traditional’ statistical approaches to assessing the raw observations. They aim to produce continuous reconstructions of past atmospheric states that are consistent with all observations as well as with atmospheric physics as represented in a numerical weather prediction model, a process termed data assimilation. Unlike real-world observations, reanalyses are uniform in space and time and provide non-observable variables (e.g., potential vorticity).

Several groups are actively pursuing reanalysis development at the global scale and many of these have produced several generations of reanalyses products (Box 2.3, Table 1). Since the first generation of reanalyses produced in the 1990s, substantial development has taken place. The MERRA and ERA-Interim reanalyses show improved tropical precipitation and hence better represent the global hydrological cycle (Dee et al., 2011b). The NCEP/CFSR reanalysis uses a coupled ocean-atmosphere-land-sea-ice model (Saha et al., 2010). The 20th century Reanalyses (20CR, Compo et al., 2011) is a 56 member ensemble and covers 140 years by assimilating only surface and Sea Level Pressure (SLP) information. This variety of groups and approaches provides some indication of the robustness of reanalyses when compared. In addition to the global reanalyses, several regional reanalyses exist or are currently being produced.

Box 2.3, Table 1: Overview of global dynamical reanalysis datasets (ranked by start year; the period extends to present if no end year is provided). A further description of reanalyses and their technical derivation is given in pp. S33-35 of Blunden et al. (2011). Approximate resolution is calculated as $1000 \text{ km} * 20/N$ (with N denoting the spectral truncation, Laprise, 1992).

Institution	Reanalysis	Period	Approximate Resolution at Equator	Reference
Cooperative Institute for Research in Environmental Sciences (CIRES), National Oceanic and Atmospheric Administration (NOAA), USA	20th century Reanalysis, Vers. 2 (20CR)	1871–2010	320 km	Compo et al. (2011)
National Centers for Environmental Prediction (NCEP) and National Center for Atmospheric Research (NCAR), USA	NCEP/NCAR R1 (NNR)	1948–	320 km	Kistler et al. (2001)
European Centre for Medium-Range Weather Forecasts (ECMWF)	ERA-40	1957–2002	125 km	Uppala et al. (2005)
Japan Meteorological Agency (JMA)	JRA-55	1958–	60 km	Ebita et al. (2011)
National Centers for Environmental Prediction (NCEP), US Department of Energy, USA	NCEP/DOE R2	1979–	320 km	Kanamitsu et al. (2002)
Japan Meteorological Agency (JMA)	JRA-25	1979–	190 km	Onogi et al. (2007)
National Aeronautics and Space Administration (NASA), USA	MERRA	1979–	75 km	Rienecker et al. (2011)
European Centre for Medium-Range Weather Forecasts (ECMWF)	ERA-Interim	1979–	80 km	Dee et al. (2011b)
National Centers for Environmental Prediction (NCEP), USA	CFSR	1979–	50 km	Saha et al. (2010)

Reanalyses products provide invaluable information on time scales ranging from daily to interannual variability. However, they may often be unable to characterize long-term trends (Trenberth et al., 2011). Although reanalyses projects by definition use a ‘frozen’ assimilation system, there are many other sources of potential errors. In addition to model biases, changes in the observational systems (e.g., coverage, introduction of satellite data) and time-dependent errors in the underlying observations or in the boundary conditions lead to step changes in time, even in latest generation reanalyses (Bosilovich et al., 2011). Errors of this sort were ubiquitous in early generation reanalyses and rendered them of limited value for trend characterization (Thorne and Vose, 2010). Subsequent products have improved and uncertainties are better understood (Dee et al., 2011a), but artefacts are still present. As a consequence, trend adequacy depends upon the variable under consideration, the time period and the region of interest. For example,

surface air temperature and humidity trends over land in the ERA-Interim reanalysis compare well with observations (Simmons et al., 2010), but polar tropospheric temperature trends in ERA-40 disagree with trends derived from radiosonde and satellite observations (Bitz and Fu, 2008; Grant et al., 2008; Graversen et al., 2008; Thorne, 2008; Screen and Simmonds, 2011) due to problems that were resolved in ERA-Interim (Dee et al., 2011a).

Studies based on reanalyses are used cautiously in AR5 and known inadequacies are pointed out and referenced. Later generation reanalyses are preferred where possible, however, literature based on these new products is still sparse.

[END BOX 2.3 HERE]

2.4 Changes in Temperature

2.4.1 Land-Surface Air Temperature

2.4.1.1 Large-Scale Records and their Uncertainties

AR4 concluded global Land-Surface Air Temperature (LSAT) had increased over the instrumental period of record with the warming rate approximately double that reported over the oceans since 1979. Since AR4, substantial developments have occurred including the production of revised datasets, more digital data records, and new dataset efforts. These innovations have improved understanding of data issues and uncertainties, allowing better quantification of regional changes. This reinforces confidence in the reported globally averaged LSAT time series behaviour.

Global Historical Climatology Network Version 3 (GHCNv3) incorporates many improvements (Lawrimore et al., 2011) but was found to be virtually indistinguishable at the global mean from version 2 (used in AR4). Goddard Institute of Space Studies (GISS) continues to provide an estimate based upon primarily GHCN, accounting for urban impacts through nightlights adjustments (Hansen et al., 2010). CRUTEM4 (Jones et al., 2012) incorporates additional station series and also newly homogenized versions of many individual station records. A new data product from a group based predominantly at Berkeley (Rohde et al., 2013) uses a method that is substantially distinct from earlier efforts (further details on all the datasets and data availability are given in Supplementary Material 2.SM.4). Despite the range of approaches, the long-term variations and trends broadly agree among these various LSAT estimates, particularly after 1900. Global LSAT has increased (Figure 2.14, Table 2.4).

Since AR4, various theoretical challenges have been raised over the verity of global LSAT records (Pielke et al., 2007). Globally, sampling and methodological independence has been assessed through sub-sampling (Parker et al., 2009; Jones et al., 2012), creation of an entirely new and structurally distinct product (Rohde et al., 2013) and a complete reprocessing of GHCN (Lawrimore et al., 2011). None of these yielded more than minor perturbations to the global LSAT records since 1900. Willett et al. (2008) and Peterson et al.

(2011) explicitly showed that changes in specific and relative humidity (Section 2.5.5) were physically consistent with reported temperature trends, a result replicated in the ERA reanalyses (Simmons et al., 2010). Various investigators (Onogi et al., 2007; Simmons et al., 2010; Parker, 2011; Vose et al., 2012a) showed that LSAT estimates from modern reanalyses were in quantitative agreement with observed products.

Particular controversy since AR4 has surrounded the LSAT record over the United States, focussed upon siting quality of stations in the US Historical Climatology Network (USHCN) and implications for long-term trends. Most sites exhibit poor current siting as assessed against official WMO siting guidance, and may be expected to suffer potentially large siting-induced absolute biases (Fall et al., 2011). However, overall biases for the network since the 1980s are *likely* dominated by instrument type (since replacement of Stevenson screens with maximum minimum temperature systems (MMTS) in the 1980s at the majority of sites), rather than siting biases (Menne et al., 2010; Williams et al., 2012). A new automated homogeneity assessment approach (also used in GHCNv3, Menne and Williams, 2009) was developed that has been shown to perform as well or better than other contemporary approaches (Venema et al., 2012). This homogenization procedure *likely* removes much of the bias related to the network-wide changes in the 1980s (Menne et al., 2010; Fall et al., 2011; Williams et al., 2012). Williams et al. (2012) produced an ensemble of dataset realisations using perturbed settings of this procedure and concluded through assessment against plausible test cases that there existed a propensity to under-estimate adjustments. This propensity is critically dependent upon the (unknown) nature of the inhomogeneities in the raw data records. Their homogenization increases both minimum temperature and maximum temperature centennial-timescale United States average LSAT trends. Since 1979 these adjusted data agree with a range of reanalysis products whereas the raw records do not (Fall et al., 2010; Vose et al., 2012a).

Regional analyses of LSAT have not been limited to the United States. Various national and regional studies have undertaken assessments for Europe (Winkler, 2009; Bohm et al., 2010; Tietavainen et al., 2010; van der Schrier et al., 2011), China (Li et al., 2009; Zhen and Zhong-Wei, 2009; Li et al., 2010a; Tang et al., 2010), India (Jain and Kumar, 2012), Australia (Trewin, 2012), Canada (Vincent et al., 2012), South America, (Falvey and Garreaud, 2009) and East Africa (Christy et al., 2009). These analyses have used a range of methodologies and, in many cases, more data and metadata than available to the global analyses. Despite the range of analysis techniques they are generally in broad agreement with the global products in characterizing the long-term changes in mean temperatures. This includes some regions, such as the Pacific coast of S. America, that have exhibited recent cooling (Falvey and Garreaud, 2009). Of specific importance for the early global records, large ($> 1^{\circ}\text{C}$) summer time warm bias adjustments for many European 19th century and early 20th century records were revisited and broadly confirmed by a range of approaches (Bohm et al., 2010; Brunet et al., 2011).

Since AR4 efforts have also been made to interpolate Antarctic records from the sparse, predominantly coastal ground-based network (Chapman and Walsh, 2007; Monaghan et al., 2008; Steig et al., 2009; O'Donnell et al., 2011). Although these agree that Antarctica as a whole has warmed since the late 1950s, substantial multi-annual to multi-decadal variability and uncertainties in reconstructed magnitude and spatial trend structure yield only *low confidence* in the details of pan-Antarctic regional LSAT changes.

In summary, it is certain that globally averaged LSAT has risen since the late 19th century and that this warming has been particularly marked since the 1970s. Several independently analyzed global and regional LSAT data products support this conclusion. There is *low confidence* in changes prior to 1880 owing to the reduced number of estimates, non-standardized measurement techniques, the greater spread among the estimates, and particularly the greatly reduced observational sampling. *Confidence* is also *low* in the spatial detail and magnitude of LSAT trends in sparsely sampled regions such as Antarctica. Since AR4 significant efforts have been undertaken to identify and adjust for data issues and new estimates have been produced. These innovations have further strengthened overall understanding of the global LSAT records.

2.4.1.2 Diurnal Temperature Range

In AR4 Diurnal Temperature Range (DTR) was found, globally, to have narrowed since 1950 with minimum daily temperatures increasing faster than maximum daily temperatures. However, significant multi-decadal variability was highlighted including a recent period from 1997 to 2004 of no change, as both maximum and minimum temperatures rose at similar rates. The Technical Summary of AR4 highlighted changes in DTR

and their causes as a key uncertainty. Since AR4 uncertainties in DTR and its physical interpretation have become even more apparent.

No dedicated global analysis of DTR has been undertaken subsequent to Vose et al. (2005a) although global behaviour has been discussed in two broader ranging analyses. Rohde et al. (2012) note an apparent reversal since the mid-1980s; with DTR subsequently increasing. This decline and subsequent increase in DTR over global land surfaces is qualitatively consistent with the dimming and subsequent brightening noted in Section 2.3.3.1. Donat et al. (2013c) using HadEX2 (Section 2.6) find significant decreasing DTR trends in over half of the land areas assessed but less than 10% of land with significant increases since 1951. Available trend estimates ($-0.04 \pm 0.01^\circ\text{C}$ per decade over 1950–2011 (Rohde et al., 2012), -0.066°C per decade over 1950–2004 (Vose et al., 2005a), are much smaller than global mean LSAT average temperature trends over 1950–2012 (Table 2.4). It therefore logically follows that globally averaged maximum and minimum temperatures over land have both increased by in excess of 0.1°C per decade since 1950.

Regionally, Makowski et al. (2008) found that DTR behaviour in Europe over 1950 to 2005 changed from a decrease to an increase in the 1970s in Western Europe and in the 1980s in Eastern Europe. Sen Roy and Balling (2005) found significant increases in both maximum and minimum temperatures for India, but little change in DTR over 1931–2002. Christy et al. (2009) reported that for East Africa there has been no pause in the narrowing of DTR in recent decades. Zhou and Ren (2011) reported a significant decrease in DTR over mainland China of -0.15°C per decade during 1961–2008.

Various investigators (e.g., Christy et al. (2009), Pielke and Matsui (2005), Zhou and Ren (2011)) have raised doubts about the physical interpretation of minimum temperature trends, hypothesizing that microclimate and local atmospheric composition impacts are more apparent because the dynamical mixing at night is much reduced. Parker (2006) investigated this issue arguing that if data were affected in this way, then a trend difference would be expected between calm and windy nights. However, he found no such minimum temperature differences on a global average basis. Using more complex boundary layer modelling techniques Steeneveld et al. (2011) and McNider et al. (2012) showed much lower sensitivity to windspeed variations than posited by Pielke and Matsui but both concluded that boundary layer understanding was key to understanding the minimum temperature changes. Data analysis and long-term side-by-side instrumentation field studies show that real non-climatic data artefacts certainly affect maximum and minimum differently in the raw records for both recent (Fall et al., 2011; Williams et al., 2012) and older (Bohm et al., 2010; Brunet et al., 2011) records. Hence there could be issues over interpretation of apparent DTR trends and variability in many regions (Christy et al., 2006; Christy et al., 2009; Fall et al., 2011; Zhou and Ren, 2011; Williams et al., 2012), particularly when accompanied by regional-scale Land Use / Land Cover (LULC) changes (Christy et al., 2006).

In summary, *confidence* is *medium* in reported decreases in observed global Diurnal Temperature Range (DTR), noted as a key uncertainty in AR4. Several recent analyses of the raw data on which many previous analyses were based point to the potential for biases that differently affect maximum and minimum average temperatures. However, apparent changes in DTR are much smaller than reported changes in average temperatures and therefore it is *virtually certain* that maximum and minimum temperatures have increased since 1950.

2.4.1.3 Land-Use Change and Urban Heat Island Effects

In AR4 Urban Heat Island (UHI) effects were concluded to be real local phenomena with negligible impact on large-scale trends. UHI and land-use land-cover change (LULC) effects arise mainly because the modified surface affects the storage and transfer of heat, water and airflow. For single discrete locations these impacts may dominate all other factors.

Regionally, most attention has focused upon China. A variety of investigations have used methods as diverse as sea surface temperature comparisons (e.g., Jones et al., 2008), urban minus rural (e.g., Ren et al., 2008; Yang et al., 2011), satellite observations (Ren and Ren, 2011) and observations minus reanalysis (e.g., Hu et al., 2010; Yang et al., 2011). Interpretation is complicated because often studies have used distinct versions of station series. For example the effect in Beijing is estimated at 80% (Ren et al., 2007) or 40% (Yan et al., 2010) of the observed trend depending upon data corrections applied. A representative sample of these

studies suggest the effect of UHI and LULC is approximately 20% of the trend in Eastern China as a whole and of the order 0.1°C per decade nationally (Table 1 in Yang et al., 2011) over the last 30 years, but with very substantial uncertainties. These effects have *likely* been partially or completely accounted for in many homogenized series (e.g., Li et al., 2010b; Yan et al., 2010). Fujibe (2009) ascribes about 25% of Japanese warming trends in 1979–2006 to UHI effects. Das et al. (2011) confirmed that many Japanese sites have experienced UHI warming but that rural stations show unaffected behaviour when compared to nearby SSTs.

There is an important distinction to be made between UHI trend effects in regions underseeing rapid development and those which have been developed for a long time. Jones and Lister (2009) and Wilby et al. (2011) using data from London (UK) concluded that some sites which have always been urban and where the UHI has not grown in magnitude will exhibit regionally indicative trends that agree with nearby rural locations and that in such cases the time series may exhibit multi-decadal trends driven primarily by synoptic variations. A lack of obvious time-varying UHI influences was also noted for Sydney, Melbourne and Hobart in Australia by Trewin (2012). The impacts of urbanization also will be dependent upon the natural LULC characteristics that they replace. Zhang et al. (2010) found no evidence for urban influences in the desert North West region of China despite rapid urbanization.

Global adjusted datasets *likely* account for much of the UHI effect present in the raw data. For the US network, Hausfather et al. (2013) showed that the adjustments method used in GHCNv3 removed much of an apparent systematic difference between urban and rural locations, concluding that this arose from adjustment of biased urban location data. Globally, Hansen et al. (2010) used satellite-based nightlight radiances to estimate the worldwide influence on LSAT of local urban development. Adjustments only reduced the global 1900–2009 temperature change (averaged over land and ocean) from 0.71°C to 0.70°C. Wickham et al. (2013) also used satellite data and found that urban locations in the Berkeley dataset exhibited even less warming than rural stations, although not statistically significantly so, over 1950 to 2010.

Studies of the broader effects of LULC since AR4 have tended to focus upon the effects of irrigation on temperatures, with a large number of studies in the Californian central belt (Christy et al., 2006; Kueppers et al., 2007; Bonfils et al., 2008; Lo and Famiglietti, 2013). They find cooler average temperatures and a marked reduction in DTR in areas of active irrigation and ascribe this to increased humidity; effectively a repartitioning of moist and dry energy terms. Reanalyses have also been used to estimate the LULC signature in LSAT trends. Fall et al. (2010) found that the North American Regional Reanalysis generated overall surface air temperature trends for 1979–2003 similar to observed records. Observations-minus-reanalysis trends were most positive for barren and urban areas, in accord with Lim et al. (2008)'s results using the NCEP/NCAR and ERA-40 reanalyses, and negative in agricultural areas.

McKittrick and Michaels (2004) and de Laat and Maurellis (2006) assessed regression of trends with national socioeconomic and geographical indicators, concluding that UHI and related LULC have caused much of the observed LSAT warming. AR4 concluded that this correlation ceases to be statistically significant if one takes into account the fact that the locations of greatest socioeconomic development are also those that have been most warmed by atmospheric circulation changes but provided no explicit evidence for this overall assessment result. Subsequently McKittrick and Michaels (2007) concluded that about half the reported warming trend in global-average land surface air temperature in 1980–2002 resulted from local land-surface changes and faults in the observations. Schmidt (2009) undertook a quantitative analysis that supported AR4 conclusions that much of the reported correlation largely arose due to naturally occurring climate variability and model over-fitting and was not robust. Taking these factors into account, modified analyses by McKittrick (2010) and McKittrick and Nierenberg (2010) still yielded significant evidence for such contamination of the record.

In marked contrast to regression based studies, several studies have shown the methodologically diverse set of modern reanalysis products and the various LSAT records at global and regional levels to be similar since at least the mid-20th century (Simmons et al., 2010; Parker, 2011; Ferguson and Villarini, 2012; Jones et al., 2012; Vose et al., 2012a). These reanalyses do not directly assimilate the LSAT measurements but rather infer LSAT estimates from an observational constraint provided by much of the rest of the global observing system, thus representing an independent estimate. These reanalysis products on average imply slightly more, rather than significantly less, warming than the observational datasets. A hypothesized residual significant warming artefact argued for by regression-based analyses is therefore physically inconsistent with

many other components of the global observing system according to a broad range of state-of-the-art data assimilation models (Box 2.3). Further, Efthymiadis and Jones (2010) estimated an absolute upper limit on urban influence globally of 0.02°C per decade, or $\sim 15\%$ of the total LSAT trends, in 1951–2009 from trends of coastal land and sea surface temperature.

In summary, it is indisputable that UHI and LULC are real influences on raw temperature measurements. At question is the extent to which they remain in the global products (as residual biases in broader regionally representative change estimates). Based primarily upon the range of urban minus rural adjusted dataset comparisons and the degree of agreement of these products with a broad range of reanalysis products, it is *unlikely* that any uncorrected urban heat-island effects and LULC change effects have raised the estimated centennial globally averaged LSAT trends by more than 10% of the reported trend (*high confidence*, based on robust evidence and high agreement). This is an average value; in some regions with rapid development, UHI and LULC change impacts on regional trends may be substantially larger.

2.4.2 Sea Surface Temperature and Marine Air Temperature

AR4 concluded that ‘recent’ warming (since the 1950s) is strongly evident at all latitudes in SST over each ocean. Prominent spatio-temporal structures including the ENSO and Pacific Decadal variability patterns in the Pacific Ocean (Box 2.5) and a hemispheric asymmetry in the Atlantic Ocean were highlighted as contributors to the regional differences in surface warming rates, which in turn affect atmospheric circulation. Since AR4 the availability of metadata has increased, data completeness has improved and a number of new SST products have been produced. Inter-comparisons of data obtained by different measurement methods, including satellite data, have resulted in better understanding of errors and biases in the record.

2.4.2.1 Advances in Assembling Datasets and in Understanding Data Errors

2.4.2.1.1 In situ data records

Historically, most SST observations were obtained from moving ships. Buoy measurements comprise a significant and increasing fraction of in situ SST measurements from the 1980s onward (Figure 2.15). Improvements in the understanding of uncertainty have been expedited by the use of metadata (Kent et al., 2007) and the recovery of observer instructions and other related documents. Early data were systematically cold biased because they were made using canvas or wooden buckets that, on average, lost heat to the air before the measurements were taken. This effect has long been recognized (Brooks, 1926), and prior to AR4 represented the only artefact adjusted in gridded SST products, like HadSST2 (Rayner et al., 2006) and ERSST (Smith et al., 2005; 2008), which were based on “bucket correction” methods by Folland and Parker (1995) and Smith and Reynolds (2002), respectively. The adjustments, made using ship observations of Night Marine Air Temperature data (NMAT) and other sources, had a striking effect on the SST global mean estimates: note the difference in 1850–1941 between HadSST2 and International Comprehensive Ocean-Atmosphere Dataset (ICOADS) curves in Figure 2.16 (a brief description of SST and NMAT datasets and their methods is given in Supplementary Material 2.SM.4.3).

[INSERT FIGURE 2.15 HERE]

Figure 2.15: Temporal changes in the prevalence of different measurement methods in the International Comprehensive Ocean-Atmosphere Dataset (ICOADS). a) fractional contributions of observations made by different measurement methods: bucket observations (blue), engine room intake (ERI) and hull contact sensor observations (green), moored and drifting buoys (red), and unknown (yellow). b) Global annual average Sea Surface Temperature (SST) anomalies based on different kinds of data: ERI and hull contact sensor (green), bucket (blue), buoy (red), and all (black). Averages are computed over all $5^{\circ} \times 5^{\circ}$ where both ERI/hull and bucket measurements, but not necessarily buoy data, were available. Adapted from Kennedy et al. (2011a).

Buckets of improved design and measurement methods with smaller, on average, biases came into use after 1941 (Figure 2.15, top); average biases were reduced further in recent decades, but not eliminated (Figure 2.15, bottom). Increasing density of SST observations made possible the identification (Reynolds et al., 2002; Reynolds et al., 2010; Kennedy et al., 2012) and partial correction of more recent period biases (Kennedy et al., 2011a). In particular, it is hypothesized that the proximity of the hot engine often biases engine room intake (ERI) measurements warm (Kent et al., 2010). Because of the prevalence of the ERI measurements among SST data from ships, the ship SSTs are biased warm by 0.12°C – 0.18°C on average

compared to the buoy data (Reynolds et al., 2010; Kennedy et al., 2011a; Kennedy et al., 2012). An assessment of the potential impact of modern biases can be ascertained by considering the difference between HadSST3 (bias corrections applied throughout) and HadSST2 (bucket corrections only) global means (Figure 2.16): it is particularly prominent in 1945–1970 period, when rapid changes in prevalence of ERI and bucket measurements during and after the World War II affect HadSST2 due to the uncorrected measurement biases (Thompson et al., 2008), while these are corrected in HadSST3. Nevertheless, for periods longer than a century the effect of HadSST3-HadSST2 differences on linear trend slopes is small relative to the trend uncertainty (Table 2.5). Some degree of independent check on the validity of HadSST3 adjustments comes from a comparison to sub-surface temperature data (Gouretski et al., 2012; Section 3.2).

Table 2.5: Trend estimates and 90% confidence intervals (Box 2.2) for two subsequent versions of the HadSST dataset over five common periods. HadSST2 has been used in AR4; HadSST3 is used in this chapter.

Dataset	Trends in °C per decade				
	1880–2012	1901–2012	1901–1950	1951–2012	1979–2012
HadSST3 (Kennedy et al., 2011a)	0.054 ± 0.012	0.067 ± 0.013	0.117 ± 0.028	0.074 ± 0.027	0.124 ± 0.030
HadSST2 (Rayner et al., 2006)	0.051 ± 0.015	0.069 ± 0.012	0.084 ± 0.055	0.098 ± 0.017	0.121 ± 0.033

[INSERT FIGURE 2.16 HERE]

Figure 2.16: Global annual average Sea Surface Temperature (SST) and Night Marine Air Temperature (NMAT) relative to a 1961–1990 climatology from gridded datasets of SST observations (HadSST2 and its successor HadSST3), the raw SST measurement archive (ICOADS, v2.5) and night marine air temperatures dataset HadNMAT2 (Kent et al., 2013). HadSST2 and HadSST3 both are based on SST observations from versions of the ICOADS dataset, but differ in degree of measurement bias correction.

The traditional approach to modeling random error of in situ SST data assumed the independence of individual measurements. Kent and Berry (2008) identified the need to account for error correlation for measurements from the same “platform” (i.e., an individual ship or buoy), but change from platform to platform in a random fashion. Kennedy et al. (2011b) achieved that by introducing platform-dependent biases, which are constant within the same platform, but change randomly from one platform to another. Accounting for such correlated errors in HadSST3 resulted in estimated error for global and hemispheric monthly means that are more than twice the estimates given by HadSST2. The uncertainty in many, but not all, components of the HadSST3 product is represented by the ensemble of its realizations (Figure 2.17).

Datasets of Marine Air Temperatures (MAT) have traditionally been restricted to night-time series only (NMAT datasets) due to the direct solar heating effect on the daytime measurements, although corrected daytime MAT records for 1973-present are already available (Berry and Kent, 2009). Other major biases, affecting both night-time and daytime MAT are due to increasing deck height with the general increase in the size of ships over time and non-standard measurement practices. Recently these biases were re-examined and explicit uncertainty calculation undertaken for NMAT by Kent et al. (2013), resulting in the HadNMAT2 dataset.

2.4.2.1.2 Satellite SST data records

Satellite SST datasets are based on measuring electromagnetic radiation that left ocean surface and got transmitted through the atmosphere. Because of complexity of processes involved, the majority of such data has to be calibrated on the basis of in situ observations. The resulting datasets, however, provide a description of global SST fields with a level of spatial detail unachievable by in situ data only. The principal Infra-Red (IR) sensor is the Advanced Very High Resolution Radiometer (AVHRR) series. Since AR4, the AVHRR time series has been reprocessed consistently back to March 1981 (Casey et al., 2010) to create the AVHRR Pathfinder v5.2 dataset. Passive microwave datasets of SST are available since 1997 equatorward of 40° and near-globally since 2002 (Wentz et al., 2000; Gentemann et al., 2004). They are generally less accurate than IR-based SST datasets, but their superior coverage in areas of persistent cloudiness provides SST estimates where the IR record has none (Reynolds et al., 2010).

The (Advanced) Along Track Scanning Radiometer ((A)ATSR) series of three sensors was designed for climate monitoring of SST; their combined record starts in August 1991 and exceeds two decades (it stopped

with the demise of the ENVISAT platform in 2012). The (A)ATSRs are ‘dual-view’ IR radiometers intended to allow atmospheric effects removal without the use of in situ observations. Since AR4, ATSR observations have been reprocessed with new estimation techniques (Embury and Merchant, 2011). The resulting SST products seem to be more accurate than many in situ observations (Embury et al., 2011). In terms of monthly global means, the agreement is illustrated in Figure 2.17. By analyzing AATSR and in situ data together, Kennedy et al. (2012) verified and extended existing models for biases and random errors of in situ data.

[INSERT FIGURE 2.17 HERE]

Figure 2.17: Global monthly mean Sea Surface Temperature (SST) anomalies relative to a 1961–1990 climatology from satellites (ATSRs) and in situ records (HadSST3). Black lines: the 100-member HadSST3 ensemble. Red lines: ATSR-based night-time subsurface temperature at 0.2m depth ($SST_{0.2m}$) estimates from the ATSR Reprocessing for Climate (ARC) project. Retrievals based on three spectral channels (D3, solid line) are more accurate than retrievals based on only two (D2, dotted line). Contributions of the three different ATSR missions to the curve shown are indicated at the bottom. The in situ and satellite records were co-located within $5^\circ \times 5^\circ$ monthly grid boxes: only those where both datasets had data for the same month were used in the comparison. Adapted from Merchant et al. (2012).

2.4.2.2 Interpolated SST Products and Trends

SST datasets form a major part of global surface temperature analyses considered in this assessment report. To use an SST dataset as a boundary condition for atmospheric reanalyses products (Box 2.3) or in atmosphere-only climate simulations (considered in Chapter 9 onwards), gridded datasets with complete coverage over the global ocean are typically needed. These are usually based on a special form of kriging (optimal interpolation) procedure that retains large-scale correlation structures and can accommodate very sparse data coverage. For the pre-satellite era (generally, before October 1981) only in situ data are used; for the latter period some products also use AVHRR data. Figure 2.18 compares interpolated SST datasets that extend back to the 19th century with the uninterpolated HadSST3 and HadNMAT2 products. Linear trend estimates for global mean SSTs from those products updated through 2012 are presented in Table 2.6. Differences between the trends from different datasets are larger when the calculation period is shorter (1979–2012) or has lower quality data (1901–1950); these are mainly due to different data coverage of underlying observational datasets and bias correction methods used in these products.

[INSERT FIGURE 2.18 HERE]

Figure 2.18: Global annual average Sea Surface Temperature (SST) and Night Marine Air Temperature (NMAT) relative to a 1961–1990 climatology from state of the art datasets. Spatially interpolated products are shown by solid lines; non-interpolated products by dashed lines.

Table 2.6: Trend estimates and 90% confidence intervals (Box 2.2) for interpolated SST datasets (uninterpolated state-of-the-art HadSST3 dataset is included for comparison). Dash indicates not enough data available for trend calculation.

Dataset	Trends in °C per decade

In summary, it is certain that global average Sea Surface Temperatures (SSTs) have increased since the beginning of the 20th century. Since AR4, major improvements in availability of metadata and data completeness have been made, and a number of new global SST records have been produced. Intercomparisons of new SST data records obtained by different measurement methods, including satellite data, have resulted in better understanding of uncertainties and biases in the records. While these innovations have helped highlight and quantify uncertainties and affect our understanding of the character of changes since the mid-20th century, they do not alter the conclusion that global SSTs have increased both since the 1950s and since the late 19th century.

2.4.3 Global Combined Land and Sea Surface Temperature

AR4 concluded that the GMST had increased, with the last 50 years increasing at almost double the rate of the last 100 years. Subsequent developments in LSAT and SST have led to better understanding of the data and their uncertainties as discussed in preceding sections. This improved understanding has led to revised global products.

Changes have been made to all three GMST datasets that were used in AR4 (Hansen et al., 2010; Morice et al., 2012; Vose et al., 2012b). These are now in somewhat better agreement with each other over recent years, in large part because HadCRUT4 now better samples the NH high latitude land regions (Jones et al., 2012; Morice et al., 2012) which comparisons to reanalyses had shown led to a propensity for HadCRUT3 to under-estimate recent warming (Simmons et al., 2010). Starting in the 1980s each decade has been significantly warmer than all preceding decades since the 1850s in HadCRUT4, a dataset that explicitly quantifies a large number of sources of uncertainty (Figure 2.19). Each of the last three decades is also the warmest in the other two GMST datasets, but these have substantially less mature and complete uncertainty estimates, precluding such an assessment of significance of their decadal differences. The GISS and MLOST datasets fall outside the 90% CI of HadCRUT4 for several decades in the twentieth century (Figure 2.19). These decadal differences could reflect residual biases in one or more dataset, an incomplete treatment of uncertainties in HadCRUT4.1, or a combination of these effects (Box 2.1). The datasets utilize different LSAT (Section 2.4.1) and SST (Section 2.4.2) component records (Supplementary Material 2.SM.4.3.4) that in the case of SST differ somewhat in their multi-decadal trend behaviour (Table 2.6 compare HadSST3 and ERSSTv3b).

All ten of the warmest years have occurred since 1997, with 2010 and 2005 effectively tied for the warmest year on record in all three products. However, uncertainties on individual annual values are sufficiently large that the ten warmest years are statistically indistinguishable from one another. The global-mean trends are significant for all datasets and multi-decadal periods considered in Table 2.7. Using HadCRUT4 and its uncertainty estimates, the warming from 1850–1900 (early-industrial) to 1986–2005 (reference period for the modelling chapters and Annex I) is $0.61^{\circ}\text{C} \pm 0.06^{\circ}\text{C}$ (90% confidence interval) (Supplementary Material 2.SM.4.3.3).

Table 2.7: Same as Table 2.4, but for Global Mean Surface Temperature (GMST) over five common periods.

Dataset	Trends in $^{\circ}\text{C}$ per decade				
	1880–2012	1901–2012	1901–1950	1951–2012	1979–2012
HadCRUT4 (Morice et al., 2012)	0.062 ± 0.012	0.075 ± 0.013	0.107 ± 0.026	0.106 ± 0.027	0.155 ± 0.033
NCDC MLOST (Vose et al., 2012b)	0.064 ± 0.015	0.081 ± 0.013	0.097 ± 0.040	0.118 ± 0.021	0.151 ± 0.037
GISS (Hansen et al., 2010)	0.065 ± 0.015	0.083 ± 0.013	0.090 ± 0.034	0.124 ± 0.020	0.161 ± 0.033

[INSERT FIGURE 2.19 HERE]

Figure 2.19: Decadal Global Mean Surface Temperature (GMST) anomalies (white vertical lines in grey blocks) and their uncertainties (90% confidence intervals as grey blocks) based upon the Land-Surface Air Temperature (LSAT) and Sea Surface Temperature (SST) combined HadCRUT4 (v4.1.1.0) ensemble (Morice et al., 2012). Anomalies are relative to a 1961–1990 climatology. 1850s indicates the period 1850–1859, and so on. NCDC MLOST and GISS dataset best-estimates are also shown.

Differences between datasets are much smaller than both interannual variability and the long-term trend (Figure 2.20). Since 1901 almost the whole globe has experienced surface warming (Figure 2.21). Warming has not been linear; most warming occurred in two periods: around 1900 to around 1940 and around 1970 onwards (Figure 2.22). Shorter periods are noisier and so proportionately less of the sampled globe exhibits statistically significant trends at the grid box level (Figure 2.22). The two periods of global mean warming exhibit very distinct spatial signatures. The early 20th century warming was largely a NH mid- to high-latitude phenomenon, whereas the more recent warming is more global in nature. These distinctions may yield important information as to causes (Chapter 10). Differences between datasets are larger in earlier periods (Figures 2.19, 2.20), particularly prior to the 1950s when observational sampling is much more geographically incomplete (and many of the well sampled areas may have been globally unrepresentative

(Bronnimann, 2009)), data errors and subsequent methodological impacts are larger (Thompson et al., 2008), and different ways of accounting for data void regions are more important (Vose et al., 2005b).

[INSERT FIGURE 2.20 HERE]

Figure 2.20: Annual Global Mean Surface Temperature (GMST) anomalies relative to a 1961–1990 climatology from the latest version of the three combined Land-Surface Air Temperature (LSAT) and Sea Surface Temperature (SST) datasets (HadCRUT4, GISS and NCDC MLOST). Published dataset uncertainties are not included for reasons discussed in Box 2.1.

[INSERT FIGURE 2.21 HERE]

Figure 2.21: Trends in Global Mean Surface Temperature (GMST) from the three datasets of Figure 2.20 for 1901–2012. White areas indicate incomplete or missing data. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). Differences in coverage primarily reflect the degree of interpolation to account for data void regions undertaken by the dataset providers ranging from none beyond grid box averaging (HadCRUT4) to substantial (GISS).

[INSERT FIGURE 2.22 HERE]

Figure 2.22: Trends in Global Mean Surface Temperature (GMST) from NCDC MLOST for three non-consecutive shorter periods (1911–1940; 1951–1980; 1981–2012). White areas indicate incomplete or missing data. Trends and significance have been calculated as in Figure 2.22.

Much interest has focussed on the period since 1998 and an apparent flattening ('hiatus') in trends, most marked in NH winter (Cohen et al., 2012). Various investigators have pointed out the limitations of such short-term trend analysis in the presence of auto-correlated series variability and that several other similar length phases of no warming exist in all the observational records and in climate model simulations (Easterling and Wehner, 2009; Peterson et al., 2009; Liebmann et al., 2010; Foster and Rahmstorf, 2011; Santer et al., 2011). This issue is discussed in the context of model behaviour, forcings and natural variability in Box 9.2 and Section 10.3.1. Regardless, all global combined land and sea surface temperature datasets exhibit a statistically nonsignificant warming trend over 1998–2012 ($0.042^{\circ}\text{C} \pm 0.093^{\circ}\text{C}$ per decade (HadCRUT4); $0.037^{\circ}\text{C} \pm 0.085^{\circ}\text{C}$ per decade (NCDC MLOST); $0.069^{\circ}\text{C} \pm 0.082^{\circ}\text{C}$ per decade (GISS)). An average of the trends from these three data sets yields an estimated change for the 1998–2012 period of 0.05°C [–0.05 to +0.15] per decade.

In summary, it is certain that globally averaged near surface temperatures have increased since the late 19th century. Each of the past three decades has been warmer than all the previous decades in the instrumental record, and the decade of the 2000s has been the warmest. The global combined land and ocean temperature data show an increase of about 0.89°C (0.69°C – 1.08°C) over the period 1901–2012 and about 0.72°C (0.49°C – 0.89°C) over the period 1951–2012 when described by a linear trend. Despite the robust multi-decadal timescale warming, there exists substantial multi-annual variability in the rate of warming with several periods exhibiting almost no linear trend (including the warming hiatus since 1998).

2.4.4 Upper Air Temperature

AR4 summarized that globally the troposphere had warmed at a rate greater than the GMST over the radiosonde record, while over the shorter satellite era the GMST and tropospheric warming rates were indistinguishable. Trends in the tropics were more uncertain than global trends although even this region was concluded to be warming. Globally, the stratosphere was reported to be cooling over the satellite era starting in 1979. New advances since AR4 have highlighted the substantial degree of uncertainty in both satellite and balloon-borne radiosonde records and lead to some revisions and improvements in existing products and the creation of a number of new data products.

2.4.4.1 Advances in Multi-Decadal Observational Records

The major global radiosonde records extend back to 1958 with temperatures, measured as the balloon ascends, reported at mandatory pressure levels. Satellites have monitored tropospheric and lower stratospheric temperature trends since late 1978 through the Microwave Sounding Unit (MSU) and its follow-on Advanced Microwave Sounding Unit (AMSU) since 1998. These measures of upwelling radiation

represent bulk (volume averaged) atmospheric temperature (Figure 2.23). The ‘Mid-Tropospheric’ (MT) MSU channel that most directly corresponds to the troposphere has 10–15% of its signal from both the skin temperature of the Earth’s surface and the stratosphere. Two alternative approaches have been suggested for removing the stratospheric component based upon differencing of view angles (LT) and statistical recombination (*G) with the ‘Lower Stratosphere’ (LS) channel (Spencer and Christy, 1992; Fu et al., 2004). The MSU satellite series also included a Stratospheric Sounding Unit (SSU) that measured at higher altitudes (Seidel et al., 2011).

[INSERT FIGURE 2.23 HERE]

Figure 2.23: Vertical weighting functions for those satellite temperature retrievals discussed in this chapter (modified from Seidel et al. (2011)). The dashed line indicates the typical maximum altitude achieved in the historical radiosonde record. The three SSU channels are denoted by the designated names 25, 26 and 27. LS (Lower Stratosphere) and MT (Mid Troposphere) are two direct MSU measures and LT (Lower Troposphere) and *G (Global Troposphere) are derived quantities from one or more of these that attempt to remove the stratospheric component from MT.

At the time of AR4 there were only two ‘global’ radiosonde datasets that included treatment of homogeneity issues: RATPAC (Free et al., 2005) and HadAT (Thorne et al., 2005). Three additional estimates have appeared since AR4 based on novel and distinct approaches. A group at the University of Vienna have produced RAOBCORE and RICH (Haimberger, 2007; Haimberger et al., 2008, 2012) using ERA reanalysis products (Box 2.3). Sherwood and colleagues developed an iterative universal kriging approach for radiosonde data to create IUK (Sherwood et al., 2008) and concluded that non-climatic data issues leading to spurious cooling remained in the deep tropics even after homogenisation. The HadAT group created an automated version, undertook systematic experimentation and concluded that the parametric uncertainty (Box 2.1) was of the same order of magnitude as the apparent climate signal (McCarthy et al., 2008; Titchner et al., 2009; Thorne et al., 2011). A similar ensemble approach has also been applied to the RICH product (Haimberger et al., 2012). These various ensembles and new products exhibit more tropospheric warming / less stratospheric cooling than pre-existing products at all levels. Globally the radiosonde records all imply the troposphere has warmed and the stratosphere cooled since 1958 but with uncertainty that grows with height and is much greater outside the better-sampled NH extra-tropics (Thorne et al., 2011; Haimberger et al., 2012), where it is of the order 0.1°C per decade.

For MSU, AR4 considered estimates produced from three groups: UAH (University of Alabama in Huntsville); RSS (Remote Sensing Systems) and VG2 (now no longer updated). A new product has been created by NOAA labelled STAR, using a fundamentally distinct approach for the critical inter-satellite warm target calibration step (Zou et al., 2006a). STAR exhibits more warming / less cooling at all levels than UAH and RSS. For MT and LS, Zou and Wang (2010) concluded that this does not primarily relate to use of their inter-satellite calibration technique but rather differences in other processing steps. RSS also produced a parametric uncertainty ensemble (Box 2.1) employing a Monte-Carlo approach allowing methodological inter-dependencies to be fully expressed (Mears et al., 2011). For large-scale trends dominant effects were inter-satellite offset determinations and, for tropospheric channels, diurnal drift. Uncertainties were concluded to be of the order 0.1°C per decade at the global mean for both tropospheric channels (where it is of comparable magnitude to the long-term trends) and the stratospheric channel.

SSU provides the only long-term near-global temperature data above the lower stratosphere, with the series terminating in 2006. Some AMSU-A channels have replaced this capability and efforts to understand the effect of changed measurement properties have been undertaken (Kobayashi et al., 2009). Until recently only one SSU dataset existed (Nash and Edge, 1989), updated by Randel et al. (2009). Liu and Weng (2009) have produced an intermediate analysis for Channels 25 and 26 (but not channel 27). Wang et al. (2012g) building upon insights from several of these recent studies have produced a more complete analysis. Differences between the independent estimates are much larger than differences between MSU records or radiosonde records at lower levels, with substantial inter-decadal time series behaviour departures, zonal trend structure, and global trend differences of the order 0.5°C per decade (Seidel et al., 2011; Thompson et al., 2012; Wang et al., 2012g). Although all SSU datasets agree that the stratosphere is cooling, there is therefore *low confidence* in the details above the lower stratosphere.

In summary, many new datasets have been produced since AR4 from radiosondes and satellites with renewed interest in satellite measurements above the lower stratosphere. Several studies have attempted to

quantify the parametric uncertainty (Box 2.1) more rigorously. These various datasets and analyses have served to highlight the degree of uncertainty in the data and derived products.

2.4.4.2 *Intercomparisons of Various Long-Term Radiosonde and MSU Products*

Since AR4 there have been a large number of intercomparisons between radiosonde and MSU datasets. Interpretation is complicated, as most studies considered dataset versions that have since been superseded. Several studies compared UAH and RSS products to local, regional or global raw / homogenized radiosonde data (Christy and Norris, 2006; Christy et al., 2007; Randall and Herman, 2008; Christy and Norris, 2009; Christy et al., 2010; Christy et al., 2011; Mears et al., 2012; Po-Chedley and Fu, 2012). Early studies focussed upon the time of transition from NOAA-11 to NOAA-12 (early 1990s), which indicated an apparent issue in RSS. Christy et al. (2007) noted that this coincided with the Mount Pinatubo eruption and that RSS was the only product, either surface or tropospheric, that exhibited tropical warming immediately after the eruption when cooling would be expected. Using reanalysis data Bengtsson and Hodges (2011) also found evidence of a potential jump in RSS in 1993 over the tropical oceans. Mears et al. (2012) cautioned that an El Niño event quasi-simultaneous with Pinatubo complicates interpretation. They also highlighted several other periods of disagreement between radiosonde records and MSU records. All MSU records were most uncertain when satellite orbits are drifting rapidly (Christy and Norris, 2006, 2009). Mears et al. (2011) found that trend differences between RSS and other datasets could not be explained in many cases by parametric uncertainties in RSS alone. It was repeatedly cautioned that there were potential common biases (of varying magnitude) between the different MSU records or between the different radiosonde records which complicate intercomparisons (Christy and Norris, 2006, 2009; Mears et al., 2012).

In summary, assessment of the large body of studies comparing various long-term radiosonde and MSU products since AR4 is hampered by dataset version changes, and inherent data uncertainties. These factors substantially limit the ability to draw robust and consistent inferences from such studies about the true long-term trends or the value of different data products.

2.4.4.3 *Additional Evidence from Other Technologies and Approaches*

Global Positioning System (GPS) radio occultation (RO) currently represents the only self-calibrated SI traceable raw satellite measurements (Anthes et al., 2008; Anthes, 2011). The fundamental observation is time delay of the occulted signal's phase traversing the atmosphere. The time delay is a function of several atmospheric physical state variables. Subsequent analysis converts the time delay to temperature and other parameters, which inevitably adds some degree of uncertainty to the derived temperature data. Intercomparisons of GPS-RO products show that differences are largest for derived geophysical parameters (including temperature), but are still small relative to other observing technologies (Ho et al., 2012). Comparisons to MSU and radiosondes (Kuo et al., 2005; Ho et al., 2007; He et al., 2009; Ho et al., 2009b; Ho et al., 2009a; Baringer et al., 2010; Sun et al., 2010; Ladstadter et al., 2011) show substantive agreement in interannual behaviour, but also some multi-year drifts that require further examination before this additional data source can usefully arbitrate between different MSU and radiosonde trend estimates.

Atmospheric winds are driven by thermal gradients. Radiosonde winds are far less affected by time-varying biases than their temperatures (Gruber and Haimberger, 2008; Sherwood et al., 2008; Section 2.7.3). Allen and Sherwood (2007) initially used radiosonde wind to infer temperatures within the Tropical West Pacific warm pool region, then extended this to a global analysis (Allen and Sherwood, 2008) yielding a distinct tropical upper tropospheric warming trend maximum within the vertical profile, but with large uncertainty. Winds can only quantify relative changes and require an initialization (location and trend at that location) (Allen and Sherwood, 2008). The large uncertainty range was predominantly driven by this initialization choice, a finding later confirmed by Christy et al. (2010), who in addition questioned the stability given the sparse geographical sampling, particularly in the tropics, and possible systematic sampling effects amongst other potential issues. Initializing closer to the tropics tended to reduce or remove the appearance of a tropical upper tropospheric warming trend maximum (Allen and Sherwood, 2008; Christy et al., 2010). There is only *low confidence* in trends inferred from 'thermal winds' given the relative immaturity of the analyses and their large uncertainties.

In summary, new technologies and approaches have emerged since AR4. However, these new technologies and approaches either constitute too short a record or are too immature to inform assessments of long-term trends at the present time.

2.4.4.4 Synthesis of Free Atmosphere Temperature Estimates

Global-mean lower tropospheric temperatures have increased since the mid-20th century (Figure 2.24, bottom). Structural uncertainties (Box 2.1) are larger than at the surface but it can still be concluded that globally the troposphere has warmed (Table 2.8). On top of this long-term trend are super-imposed short-term variations that are highly correlated with those at the surface but of somewhat greater amplitude. Global mean lower stratospheric temperatures have decreased since the mid-20th century punctuated by short-lived warming events associated with explosive volcanic activity (Figure 2.24a). However, since the mid-1990s little net change has occurred. Cooling rates are on average greater from radiosonde datasets than MSU datasets. This *very likely* relates to widely recognized cooling biases in radiosondes (Mears et al., 2006) which all dataset producers explicitly caution are *likely* to remain to some extent in their final products (Free and Seidel, 2007; Haimberger et al., 2008; Sherwood et al., 2008; Thorne et al., 2011).

[INSERT FIGURE 2.24 HERE]

Figure 2.24: Global annual average lower stratospheric (top) and lower tropospheric (bottom) temperature anomalies relative to a 1981–2010 climatology from different datasets. STAR does not produce a lower tropospheric temperature product. Note that the y-axis resolution differs between the two panels.

Table 2.8: Trend estimates and 90% confidence intervals (Box 2.2) for radiosonde and MSU dataset global average values over the radiosonde (1958–2012) and satellite periods (1979–2012). LT indicates Lower Troposphere, MT indicates Mid Troposphere and LS indicates Lower Stratosphere (Figure 2.23). Satellite records only start in 1979 and STAR do not produce an LT product.

Dataset	Trends in °C per decade					
	1958–2012			1979–2012		
	LT	MT	LS	LT	MT	LS
HadAT2 (Thorne et al., 2005)	0.159 ± 0.038	0.095 ± 0.034	−0.339 ± 0.086	0.162 ± 0.047	0.079 ± 0.057	−0.436 ± 0.204
RAOBCORE 1.5 (Haimberger et al., 2012)	0.156 ± 0.031	0.109 ± 0.029	−0.186 ± 0.087	0.139 ± 0.049	0.079 ± 0.054	−0.266 ± 0.227
RICH-obs (Haimberger et al., 2012)	0.162 ± 0.031	0.102 ± 0.029	−0.285 ± 0.087	0.158 ± 0.046	0.081 ± 0.052	−0.331 ± 0.241
RICH-tau (Haimberger et al., 2012)	0.168 ± 0.032	0.111 ± 0.030	−0.280 ± 0.085	0.160 ± 0.046	0.083 ± 0.052	−0.345 ± 0.238
RATPAC (Free et al., 2005)	0.136 ± 0.028	0.076 ± 0.028	−0.338 ± 0.092	0.128 ± 0.044	0.039 ± 0.051	−0.468 ± 0.225
UAH (Christy et al., 2003)				0.138 ± 0.043	0.043 ± 0.042	−0.372 ± 0.201
RSS (Mears and Wentz, 2009a, 2009b)				0.131 ± 0.045	0.079 ± 0.043	−0.268 ± 0.177
STAR (Zou and Wang, 2011)					0.123 ± 0.047	−0.320 ± 0.175

In comparison to the surface (Figure 2.22), tropospheric layers exhibit smoother geographic trends (Figure 2.25) with warming dominating cooling north of approximately 45°S and greatest warming in high northern latitudes. The lower stratosphere cooled almost everywhere but this cooling exhibits substantial large-scale structure. Cooling is greatest in the highest southern latitudes and smallest in high northern latitudes. There are also secondary stratospheric cooling maxima in the mid-latitude regions of each hemisphere.

[INSERT FIGURE 2.25 HERE]

Figure 2.25: Trends in MSU upper air temperature over 1979–2012 from UAH (left hand panels) and RSS (right hand panels) and for LS (top row) and LT (bottom row). Data are temporally complete within the sampled domains for each dataset. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval).

Available global and regional trends from radiosondes since 1958 (Figure 2.26) show agreement that the troposphere has warmed and the stratosphere cooled. While there is little ambiguity in the sign of the changes, the rate and vertical structure of change are distinctly dataset-dependent, particularly in the stratosphere. Differences are greatest in the tropics and SH extra-tropics where the historical radiosonde data coverage is poorest. Not shown in the figure for clarity are estimates of parametric dataset uncertainties or trend-fit uncertainties—both of which are of the order of at least 0.1°C per decade (Section 2.4.4.1).

[INSERT FIGURE 2.26 HERE]

Figure 2.26: Trends in upper air temperature for all available radiosonde data products that contain records for 1958–2012 for the globe (top) and tropics (20°N–20°S) and extra-tropics (bottom). The bottom panel trace in each case is for trends on distinct pressure levels. Note that the pressure axis is not linear. The top panel points show MSU layer equivalent measure trends. MSU layer equivalents have been processed using the method of Thorne et al. (2005). No attempts have been made to sub-sample to a common data mask.

Differences in trends between available radiosonde datasets are greater during the satellite era than for the full radiosonde period of record in all regions and at most levels (Figure 2.27, cf. Figure 2.26). The RAOBCORE product exhibits greater vertical trend gradients than other datasets and it has been posited that this relates to its dependency upon reanalysis fields (Sakamoto and Christy, 2009; Christy et al., 2010). MSU trend estimates in the troposphere are generally bracketed by the radiosonde range. In the stratosphere MSU deep layer estimates tend to show slightly less cooling. Over both 1958–2011 and 1979–2011 there is some evidence in the radiosonde products taken as a whole that the tropical tropospheric trends increase with height. But the magnitude and the structure is highly dataset-dependent.

[INSERT FIGURE 2.27 HERE]

Figure 2.27: As Figure 2.26 except for the satellite era 1979–2012 period and including MSU products (RSS, STAR and UAH).

In summary, based upon multiple independent analyses of measurements from radiosondes and satellite sensors it is *virtually certain* that globally the troposphere has warmed and the stratosphere has cooled since the mid-20th century. Despite unanimous agreement on the sign of the trends, substantial disagreement exists among available estimates as to the rate of temperature changes, particularly outside the Northern Hemisphere extra-tropical troposphere, which has been well sampled by radiosondes. Hence there is only *medium confidence* in the rate of change and its vertical structure in the Northern Hemisphere extra-tropical troposphere and *low confidence* elsewhere.

[START FAQ 2.1 HERE]**FAQ 2.1: How do We Know the World has Warmed?**

Evidence for a warming world comes from multiple independent climate indicators, from high up in the atmosphere to the depths of the oceans. They include changes in surface, atmospheric, and oceanic temperatures, glaciers, snow cover, sea ice, sea level, and atmospheric water vapour. Scientists from all over the world have independently verified this evidence many times. That the world has warmed since the nineteenth century is unequivocal.

Discussion about climate warming often centres on potential residual biases in temperature records from land-based weather stations. These records are very important, but they only represent one indicator of changes in the climate system. Broader evidence for a warming world comes from a wide range of independent physically consistent measurements of many other, strongly interlinked, elements of the climate system (FAQ 2.1, Figure 1).

[INSERT FAQ 2.1, FIGURE 1 HERE]

FAQ 2.1, Figure 1: Independent analyses of many components of the climate system that would be expected to change in a warming world exhibit trends consistent with warming (arrow direction denotes the sign of the change), as shown in FAQ 2.1, Figure 2.

A rise in global average surface temperatures is the best-known indicator of climate change. Although each year and even decade is not always warmer than the last, global surface temperatures have warmed substantially since 1900.

Warming land temperatures correspond closely with the observed warming trend over the oceans. Warming oceanic air temperatures, measured from aboard ships, and temperatures of the sea surface itself also coincide, as borne out by many independent analyses.

The atmosphere and ocean are both fluid bodies, so warming at the surface should also be seen in the lower atmosphere, and deeper down into the upper oceans, and observations confirm that this is indeed the case. Analyses of measurements made by weather balloon radiosondes and satellites consistently show warming of the troposphere, the active weather layer of the atmosphere. More than 90% of the excess energy absorbed by the climate system since at least the 1970s has been stored in the oceans as can be seen from global records of ocean heat content going back to the 1950s.

As the oceans warm, the water itself expands. This expansion is one of the main drivers of the independently observed rise in sea levels over the past century. Melting of glaciers and ice sheets also contribute, as do changes in storage and usage of water on land.

A warmer world is also a moister one, because warmer air can hold more water vapour. Global analyses show that specific humidity, which measures the amount of water vapour in the atmosphere, has increased over both the land and the oceans.

The frozen parts of the planet—known collectively as the cryosphere—affect, and are affected by, local changes in temperature. The amount of ice contained in glaciers globally has been declining every year for more than 20 years, and the lost mass contributes, in part, to the observed rise in sea level. Snow cover is sensitive to changes in temperature, particularly during the spring, when snow starts to melt. Spring snow cover has shrunk across the NH since the 1950s. Substantial losses in Arctic sea ice have been observed since satellite records began, particularly at the time of the minimum extent, which occurs in September at the end of the annual melt season. By contrast, the increase in Antarctic sea ice has been smaller.

Individually, any single analysis might be unconvincing, but analysis of these different indicators and independent datasets has led many independent research groups to *all* reach the same conclusion. From the deep oceans to the top of the troposphere, the evidence of warmer air and oceans, of melting ice and rising seas all points unequivocally to one thing: the world has warmed since the late 19th century (FAQ 2.1, Figure 2).

[INSERT FAQ 2.1, FIGURE 2 HERE]

FAQ 2.1, Figure 2: Multiple independent indicators of a changing global climate. Each line represents an independently-derived estimate of change in the climate element. In each panel all datasets have been normalized to a common period of record. A full detailing of which source datasets go into which panel is given in the Supplementary Material 2.SM.5.

[END FAQ 2.1 HERE]

2.5 Changes in Hydrological Cycle

This section covers the main aspects of the hydrological cycle, including large-scale average precipitation, stream flow and runoff, soil moisture, atmospheric water vapour, and clouds. Meteorological drought is assessed in Section 2.6. Ocean precipitation changes are assessed in Section 3.4.3 and changes in the area covered by snow in Section 4.5.

2.5.1 Large Scale Changes in Precipitation

2.5.1.1 Global Land Areas

AR4 concluded that precipitation has generally increased over land north of 30°N over the period 1900–2005 but downward trends dominate the tropics since the 1970s. AR4 included analysis of both the GHCN (Vose et al., 1992) and CRU (Mitchell and Jones, 2005) gauge-based precipitation datasets for the globally averaged annual precipitation over land. For both datasets the overall linear trend from 1900 to 2005 (1901–2002 for CRU) was positive but not statistically significant (Table 3.4 from AR4). Other periods covered in AR4 (1951–2005 and 1979–2005) showed a mix of negative and positive trends depending on the dataset.

Since AR4, existing datasets have been updated and a new dataset developed. Figure 2.28 shows the century-scale variations and trends on globally and zonally averaged annual precipitation using five datasets: GHCN V2 (updated through 2011; Vose et al., 1992), Global Precipitation Climatology Project V2.2 (GPCP) combined raingauge-satellite product (Adler et al., 2003), CRU TS 3.10.01 (updated from Mitchell and Jones, 2005), Global Precipitation Climatology Centre V6 (GPCC) dataset (Becker et al., 2013) and a reconstructed dataset by Smith et al. (2012). Each data product incorporates a different number of station series for each region. The Smith et al. product is a statistical reconstruction using Empirical Orthogonal Functions, similar to the NCDC MLOST global temperature product (Section 2.4.3) that does provide coverage for most of the global surface area although only land is included here. The datasets based on in situ observations only start in 1901, but the Smith et al. dataset ends in 2008, while the other 3 datasets contain data until 2010.

For the longest common period of record (1901–2008) the GHCN and GPCC datasets show statistically significant but opposite trends in globally averaged precipitation, with the Smith et al. and CRU datasets showing small non-significant declines (Table 2.9). Global trends for the shorter period (1951–2008) also show a mix of statistically non-significant positive and negative trends amongst the three datasets. These differences among datasets, particularly for the early part of the 20th century indicate that long-term increases in global precipitation discussed in AR4 are uncertain, owing to issues in data coverage in the early part of the 20th century (Wan et al., 2013).

[INSERT FIGURE 2.28 HERE]

Figure 2.28: Annual precipitation anomalies averaged over land areas for four latitudinal bands and the globe from five global precipitation datasets relative to a 1981–2000 climatology.

Table 2.9: Trend estimates and 90% confidence intervals (Box 2.2) for annual precipitation for each time series in Figure 2.28 over two common periods of record.

Dataset	Area	Trends in mm yr ⁻¹ per decade	
		1901–2008	1951–2008
CRU TS 3.10.01 (updated from Mitchell and Jones, 2005)	Global	–0.337 ± 1.670	2.036 ± 4.260
GHCN V2 (updated through 2011; Vose et al., 1992)	Global	2.081 ± 1.662	–2.767 ± 3.919
GPCC V6 (Becker et al., 2013)	Global	–2.610 ± 1.497	–1.861 ± 4.010
Smith et al. (2012)	Global	–0.392 ± 1.497	1.792 ± 3.707

In summary, *confidence* in precipitation change averaged over global land areas is *low* prior to 1950 and *medium* afterwards because of insufficient data, particularly in the earlier part of the record. Available globally incomplete records show mixed and nonsignificant long-term trends in reported global mean changes. Further, when virtually all the land area is filled in using a reconstruction method, the resulting time series shows little change in land-based precipitation since 1900.

2.5.1.2 Spatial Variability of Observed Trends

The latitude band plots in Figure 2.28 suggest that precipitation over tropical land areas (30°S–30°N) has increased over the last decade reversing the drying trend that occurred from the mid-1970s to mid-1990s. As a result the period 1951–2008 shows no significant overall trend in tropical land precipitation (Table 2.10).

Longer term trends (1901–2008) in the tropics, shown in Table 2.10, are also non-significant for each of the four datasets. The mid-latitudes of the NH (30°N–60°N) show an overall increase in precipitation from 1901 to 2008 with statistically significant trends for each dataset. For the shorter period (1951–2008) the trends are also positive but non-significant for two of the four datasets. For the high latitudes of the NH (60°N–90°N) the GHCN dataset shows a significant increase for the 1951–2008 period, whereas the other three datasets show no significant change (Table 2.10). Fewer data from high latitude stations make these trends less certain. Because of insufficient data, longer trends for the high latitudes are not available. In the mid-latitudes of the SH (60°S–30°S) there is evidence of long-term increases with three datasets showing significant trends for the 1901–2008 period. For the 1951–2008 period changes in SH mid-latitude precipitation are less certain with only one dataset showing a significant trend towards drying. All datasets show an abrupt decline in SH mid-latitude precipitation in the early 2000s (Figure 2.28) consistent with enhanced drying that has very recently recovered. These results for latitudinal changes are consistent with the global satellite observations for the 1979–2008 period (Allan et al., 2010) and land-based gauge measurements for the 1950–1999 period (Zhang et al., 2007a) which both show that precipitation has increased over wet regions of the tropics and NH mid-latitudes, and decreased over dry regions of the subtropics.

Table 2.10: Trend estimates and 90% confidence intervals (Box 2.2) for annual precipitation for each time series in Figure 2.28 over two periods. Dashes indicate not enough data available for trend calculation. For the latitudinal band 90°S–60°S not enough data exists for each product in either period.

Dataset	Trends in mm yr ⁻¹ per decade		
	Area	1901–2008	1951–2008
CRU TS 3.10.01 (updated from Mitchell and Jones, 2005)	60°N–90°N		-0.188 ± 0.405
	30°N–60°N	2.770 ± 1.906	5.652 ± 3.725
	30°S–30°N	-2.010 ± 3.729	-9.528 ± 10.872
	60°S–30°S	2.964 ± 2.853	-2.747 ± 7.962
GHCN V2 (updated through 2011; Vose et al., 1992)	60°N–90°N		4.518 ± 2.640
	30°N–60°N	3.234 ± 1.097	1.385 ± 1.980
	30°S–30°N	1.014 ± 3.002	-5.147 ± 7.275
	60°S–30°S	-0.565 ± 2.265	-8.009 ± 5.632
GPCC V6 (Becker et al., 2013)	60°N–90°N		-0.029 ± 0.424
	30°N–60°N	3.135 ± 1.049	1.500 ± 1.926
	30°S–30°N	-0.477 ± 3.348	-4.162 ± 9.646
	60°S–30°S	2.403 ± 2.006	-0.510 ± 5.451
Smith et al. (2012)	60°N–90°N		0.305 ± 0.487
	30°N–60°N	1.444 ± 0.502	0.969 ± 0.881
	30°S–30°N	0.429 ± 1.476	0.665 ± 4.753
	60°S–30°S	2.944 ± 1.397	0.784 ± 3.310

In AR4, maps of observed trends of annual precipitation for 1901–2005 were calculated using GHCN interpolated to a 5° × 5° latitude/longitude grid. Trends (in % per decade) were calculated for each grid box and showed statistically significant changes, particularly increases in eastern and northwestern North America, parts of Europe and Russia, southern South America, and Australia, declines in the Sahel region of Africa, and a few scattered declines elsewhere.

Figure 2.29 shows the spatial variability of long-term trends (1901–2010) and more recent trends (1979–2010) over land in annual precipitation using the CRU, GHCN, and GPCC datasets. The trends are computed from land-only grid box time series using each native dataset grid resolution. The patterns of these absolute trends (in mm yr⁻¹ per decade) are broadly similar to the trends (in % per decade) relative to local climatology (Supplementary Material 2.SM.6.1). Increases for the period 1901–2010 are seen in the mid- and higher-latitudes of both the NH and SH consistent with the reported changes for latitudinal bands. At the grid box scale, statistically significant trends occur in most of the same areas, in each dataset. The GPCC map shows the most areas with significant trends. Comparing the maps in Figure 2.29, many of the areas that

showed statistically significant long-term trends in AR4 show opposite trends between the 1901–2010 period and the 1979–2010 period (e.g., parts of North America including the western USA, parts of southern South America, southern Africa, northeastern Africa and Spain, Iceland, and Russia). The prominent exception is the Sahel region which for 1979–2010 continues to show an increase, although not as strong as reported in AR4.

[INSERT FIGURE 2.29 HERE]

Figure 2.29: Trends in precipitation over land from the CRU, GHCN and GPCP datasets for 1901–2010 (left hand panels) and 1979–2010 (right hand panels). Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval).

In summary, the land areas of the mid-latitudes of the NH show a *likely* overall increase in precipitation (*medium confidence* since 1901, but *high confidence* after 1951). Since 1951, precipitation in the high-latitudes of the NH also shows increases, but *confidence* is *low* for the changes in this region. There is evidence for increased precipitation in the mid-latitudes of the SH since 1901 (*medium confidence*). It is *likely* there was an abrupt decline in SH mid-latitude precipitation in the early 2000s consistent with enhanced drying that has very recently recovered. Precipitation in the tropical land areas has increased (*medium confidence*) over the last decade, reversing the drying trend that occurred from the mid-1970s to mid-1990s reported in AR4. Consequently, there is little evidence for longer term changes in tropical precipitation over land.

2.5.1.3 Changes in Snowfall

AR4 draws no conclusion on global changes in snowfall. Changes in snowfall are discussed on a region-by-region basis, but mainly focussed on North America and Eurasia. Statistically significant increases were found in most of Canada, parts of northern Europe and Russia. A number of areas showed a decline in the number of snowfall events, especially those where climatological averaged temperatures were close to 0°C and where warming led to earlier onset of spring. Also, an increase in lake-effect snowfall was found for areas near the North American Great Lakes.

Since AR4, most published literature has considered again changes in snowfall in North America. These studies have confirmed that more winter-time precipitation is falling as rain rather than snow in the Western United States (Knowles et al., 2006), the Pacific Northwest and Central United States (Feng and Hu, 2007). Kunkel et al. (2009) analyzed trends using a specially quality-controlled dataset of snowfall observations over the contiguous U.S. and found that snowfall has been declining in the Western U.S., Northeastern U.S. and southern margins of the seasonal snow region, but increasing in the western Great Plains and Great Lakes regions. Snowfall in Canada has increased mainly in the north while a significant decrease was observed in the southwestern part of the country for 1950–2009 (Mekis and Vincent, 2011).

Other regions that have been analyzed include Japan (Takeuchi et al., 2008), where warmer winters in the heavy snowfall areas on Honshu are associated with decreases in snowfall and precipitation in general. Shekar et al. (2010) found declines in total seasonal snowfall along with increases in maximum and minimum temperatures in the western Himalaya. Serquet et al. (2011) analyzed snowfall and rainfall days since 1961 and found the proportion of snowfall days to rainfall days in Switzerland was declining in association with increasing temperatures. Scherrer and Appenzeller (2006) found a trend in a pattern of variability of snowfall in the Swiss Alps that indicated decreasing snow at low altitudes relative to high altitudes, but with large decadal variability in key snow indicators (Scherrer et al., 2013). Van Ommen and Morgan (2010) draw a link between increased snowfall in coastal East Antarctica and increased southwest Western Australia drought. However, Monaghan and Bromwich (2008) found an increase in snow accumulation over all Antarctica from the late 1950s to 1990, then a decline to 2004. Thus snowfall changes in Antarctica remain uncertain.

In summary, in most regions analyzed, it is *likely* that decreasing numbers of snowfall events are occurring where increased winter temperatures have been observed (North America, Europe, Southern and Eastern Asia). Confidence is *low* for the changes in snowfall over Antarctica.

2.5.2 *Streamflow and Runoff*

AR4 concluded that runoff and river discharge generally increased at high latitudes, with some exceptions. No consistent long-term trend in discharge was reported for the world's major rivers on a global scale.

River discharge is unique among water cycle components in that it both spatially and temporally integrates surplus waters upstream within a catchment (Shiklomanov et al., 2010), which makes it well suited for in situ monitoring (Arndt et al., 2010). The most recent comprehensive analyses (Milliman et al., 2008; Dai et al., 2009) do not support earlier work (Labat et al., 2004) that reported an increasing trend in global river discharge associated with global warming during the 20th century. It must be noted that many if not most large rivers, especially those for which a long-term streamflow record exists, have been impacted by human influences such as dam construction or land use, so results must be interpreted with caution. Dai et al. (2009) assembled a dataset of 925 most downstream stations on the largest rivers monitoring 80% of the global ocean draining land areas and capturing 73% of the continental runoff. They found that discharges in about one-third of the 200 largest rivers (including the Congo, Mississippi, Yenisey, Paraná, Ganges, Columbia, Uruguay, and Niger) show statistically significant trends during 1948–2004, with the rivers having downward trends (45) outnumbering those with upward trends (19). Decreases in streamflow were found over many low and mid-latitude river basins such as the Yellow River in northern China since 1960s (Piao et al., 2010) where precipitation has decreased. Increases in streamflow during the latter half of the 20th century also have been reported over regions with increased precipitation, such as parts of the United States (Groisman et al., 2004), and in the Yangtze River in southern China (Piao et al., 2010). In the Amazon basin an increase of discharge extremes is observed over recent decades (Espinoza Villar et al., 2009). For France, Giuntoli et al. (2013) found that the sign of the temporal trends in natural streamflows varies with period studied. In that case study, significant correlations between median to low flows and the Atlantic Multidecadal Oscillation (AMO; Section 2.7.8) result in long quasi-periodic oscillations.

At high latitudes, increasing winter base flow and mean annual stream flow resulting from possible permafrost thawing were reported in Northwest Canada (St. Jacques and Sauchyn, 2009). Rising minimum daily flows also have been observed in northern Eurasian rivers (Smith et al., 2007). For ocean basins other than the Arctic, and for the global ocean as a whole, the data for continental discharge show small or downward trends, which are statistically significant for the Pacific ($-9.4 \text{ km}^3 \text{ yr}^{-1}$). Precipitation is a major driver for the discharge trends and for the large interannual-to-decadal variations (Dai et al., 2009). However, for the Arctic drainage areas, Adam and Lettenmaier (2008) found that upward trends in streamflow are not accompanied by increasing precipitation, especially over Siberia, based on available observations. Zhang et al. (2012a) argued that precipitation measurements are sparse and exhibit large cold-season biases in the Arctic drainage areas and hence there would be large uncertainties using these data to investigate their influence on streamflow.

Recently, Stahl et al. (2010) and Stahl and Tallaksen (2012) investigated streamflow trends based on a dataset of near-natural streamflow records from more than 400 small catchments in 15 countries across Europe for 1962–2004. A regional coherent pattern of annual streamflow trends was revealed with negative trends in southern and eastern regions, and generally positive trends elsewhere. Subtle regional differences in the subannual changes in various streamflow metrics also can be captured in regional studies such as by Monk et al. (2011) for Canadian Rivers.

In summary, the most recent comprehensive analyses lead to the conclusion that *confidence is low* for an increasing trend in global river discharge during the 20th century.

2.5.3 *Evapotranspiration Including Pan Evaporation*

AR4 concluded that decreasing trends were found in records of pan evaporation over recent decades over the USA, India, Australia, New Zealand, China and Thailand and speculated on the causes including decreased surface solar radiation, sunshine duration, increased specific humidity and increased clouds. However, AR4 also reported that direct measurements of evapotranspiration over global land areas are scarce, and concluded that reanalysis evaporation fields are not reliable because they are not well constrained by precipitation and radiation.

Since AR4 gridded datasets have been developed that estimate actual evapotranspiration from either atmospheric forcing and thermal remote sensing, sometimes in combination with direct measurements (e.g., from FLUXNET, a global network of flux towers), or interpolation of FLUXNET data using regression techniques, providing an unprecedented look at global evapotranspiration (Mueller et al., 2011). On a global scale, evapotranspiration over land increased from the early 1980s up to the late 1990s (Wild et al., 2008; Jung et al., 2010; Wang et al., 2010) and Wang et al. (2010) found that global evapotranspiration increased at a rate of 0.6 W m^{-2} per decade for the period 1982–2002. After 1998, a lack of moisture availability in SH land areas, particularly decreasing soil moisture, has acted as a constraint to further increase of global evapotranspiration (Jung et al., 2010).

Zhang et al. (2007b) found decreasing pan evaporation at stations across the Tibetan Plateau, even with increasing air temperature. Similarly, decreases in pan evaporation were also found for northeastern India (Jhajharia et al., 2009) and the Canadian Prairies (Burn and Hesch, 2007). A continuous decrease in reference and pan evaporation for the period 1960–2000 was reported by Xu et al. (2006a) for a humid region in China, consistent with reported continuous increase in aerosol levels over China (Qian et al., 2006; Section 2.2.4). Roderick et al. (2007) examined the relationship between pan evaporation changes and many of the possible causes listed above using a physical model and conclude that many of the decreases (USA, China, Tibetan Plateau, Australia) cited above are related to declining wind speeds and to a lesser extent decreasing solar radiation. Fu et al. (2009) provided an overview of pan evaporation trends and concluded the major possible causes, changes in wind speed, humidity, and solar radiation, have been occurring, but that the importance of each is regionally dependent.

The recent increase in incoming shortwave radiation in regions with decreasing aerosol concentrations (Section 2.2.3) can explain positive evapotranspiration trends only in the humid part of Europe. In semi-arid and arid regions, trends in evapotranspiration largely follow trends in precipitation (Jung et al., 2010). Trends in surface winds (Section 2.7.2) and CO_2 (Section 2.2.1.1.1) also alter the partitioning of available energy into evapotranspiration and sensible heat. While surface wind trends may explain pan evaporation trends over Australia (Rayner, 2007; Roderick et al., 2007), their impact on actual evapotranspiration is limited due to the compensating effect of boundary-layer feedbacks (van Heerwaarden et al., 2010). In vegetated regions, where a large part of evapotranspiration comes from transpiration through plants' stomata, rising CO_2 concentrations can lead to reduced stomatal opening and evapotranspiration (Idso and Brazel, 1984; Leakey et al., 2006). Additional regional effects that impact evapotranspiration trends are lengthening of the growing season and land use change.

In summary, there is *medium confidence* that pan evaporation continued to decline in most regions studied since AR4 related to changes in wind speed, solar radiation and humidity. On a global scale, evapotranspiration over land increased (*medium confidence*) from the early 1980s up to the late 1990s. After 1998, a lack of moisture availability in SH land areas, particularly decreasing soil moisture, has acted as a constraint to further increase of global evapotranspiration.

2.5.4 Surface Humidity

AR4 reported widespread increases in surface air moisture content since 1976, along with near-constant relative humidity over large scales though with some significant changes specific to region, time of day or season.

In good agreement with previous analysis from Dai (2006), Willett et al. (2008) show widespread increasing specific humidity across the globe from the homogenised gridded monthly mean anomaly product HadCRUH (1973–2003). Both Dai and HadCRUH products that are blended land and ocean data products end in 2003 but HadISDH (1973–2012) (Willett et al., 2013) and the NOCS product (Berry and Kent, 2009) are available over the land and ocean respectively through 2012. There are some small isolated but coherent areas of drying over some of the more arid land regions (Figure 2.30a). Moistening is largest in the tropics (Table 2.11) and the summer hemisphere over both land and ocean. Large uncertainty remains over the SH where data are sparse. Global specific humidity is sensitive to large scale phenomena such as ENSO (Figure 2.30b; Box 2.5). It is strongly correlated with land surface temperature averages over the 23 Giorgi and Francisco (2000) regions for the period 1973–1999 and mostly exhibits increases at or above the increase expected from the Clausius-Clapeyron relation (about $7\% \text{ }^\circ\text{C}^{-1}$; Annex III: Glossary) with *high confidence*

(Willett et al., 2010). Land surface humidity trends are similar in ERA-Interim to observed estimates of homogeneity-adjusted datasets (Simmons et al., 2010; Figure 2.30b).

[INSERT FIGURE 2.30 HERE]

Figure 2.30: a) Trends in surface specific humidity from HadISDH and NOCS over 1973–2012. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). b) Global annual average anomalies in land surface specific humidity from Dai (2006; red), HadCRUH (Willett et al., 2013; orange), HadISDH (Willett et al., 2013; black), and ERA-Interim (Simmons et al., 2010; blue). Anomalies are relative to the 1979–2003 climatology.

Table 2.11: Trend estimates and 90% confidence intervals (Box 2.2) for surface humidity over two periods.

		Trends in % per decade	
	Dataset	1976–2003	1973–2012
Land	HadISDH (Willett et al., 2008)	0.127 ± 0.037	0.091 ± 0.023
	HadCRUH_land (Willett et al., 2008)	0.128 ± 0.043	
	Dai_land (Dai, 2006)	0.099 ± 0.046	
Ocean	NOCS (Berry and Kent, 2009)	0.114 ± 0.064	0.090 ± 0.033
	HadCRUH_marine (Willett et al., 2008)	0.065 ± 0.049	
	Dai_marine (Dai, 2006)	0.058 ± 0.044	

Since 2000 surface specific humidity over land has remained largely unchanged (Figure 2.30) whereas land areas have on average warmed slightly (Figure 2.14) implying a reduction in land region relative humidity. This may be linked to the greater warming of the land surface relative to the ocean surface (Joshi et al., 2008). The marine specific humidity (Berry and Kent, 2009), like that over land, shows widespread increases that correlate strongly with SST. However, there is a marked decline in marine relative humidity around 1982. This is reported in Willett et al. (2008) where its origin is concluded to be a non-climatic data issue owing to a change in reporting practice for dewpoint temperature.

In summary, it is *very likely* that global near surface air specific humidity has increased since the 1970s. However, during recent years the near surface moistening over land has abated (*medium confidence*). As a result, fairly widespread decreases in relative humidity near the surface are observed over the land in recent years.

2.5.5 Tropospheric Humidity

As reported in AR4, observations from radiosonde and GPS measurements over land, and satellite measurements over ocean indicate increases in tropospheric water vapour at near-global spatial scales which are consistent with the observed increase in atmospheric temperature over the last several decades. Tropospheric water vapour plays an important role in regulating the energy balance of the surface and top-of-atmosphere, provides a key feedback mechanism and is essential to the formation of clouds and precipitation.

2.5.5.1 Radiosonde

Radiosonde humidity data for the troposphere were used sparingly in AR4, noting a renewed appreciation for biases with the operational radiosonde data that had been highlighted by several major field campaigns and intercomparisons. Since AR4 there have been three distinct efforts to homogenize the tropospheric humidity records from operational radiosonde measurements (Durre et al., 2009; McCarthy et al., 2009; Dai et al., 2011) (Supplementary Material 2.SM.6.1, Table 2.SM.9). Over the common period of record from 1973 onwards, the resulting estimates are in substantive agreement regarding specific humidity trends at the largest geographical scales. On average, the impact of the correction procedures is to remove an artificial temporal trend towards drying in the raw data and indicate a positive trend in free tropospheric specific humidity over the period of record. In each analysis, the rate of increase in the free troposphere is concluded

to be largely consistent with that expected from the Clausius-Clapeyron relation (about 7%/°C). There is no evidence for a significant change in free tropospheric relative humidity, although a decrease in relative humidity at lower levels is observed (Section 2.5.5). Indeed, McCarthy et al. (2009) show close agreement between their radiosonde product at the lowest levels and HadCRUH (Willett et al., 2008).

2.5.5.2 GPS

Since the early 1990s, estimates of column integrated water vapour have been obtained from ground-based Global Positioning System (GPS) receivers. An international network started with about 100 stations in 1997 and has currently been expanded to over 500 (primarily land-based) stations. Several studies have compiled GPS water vapour datasets for climate studies (Jin et al., 2007; Wang et al., 2007; Wang and Zhang, 2008, 2009). Using such data, Mears et al. (2010) demonstrated general agreement of the interannual anomalies between ocean-based satellite and land-based GPS column integrated water vapour data. The interannual water vapour anomalies are closely tied to the atmospheric temperature changes in a manner consistent with that expected from the Clausius-Clapeyron relation. Jin et al. (2007) found an average column integrated water vapour trend of about 2 kg m⁻² per decade during 1994–2006 for 150 (primarily land-based) stations over the globe, with positive trends at most NH stations and negative trends in the SH. However, given the short length (about 10 years) of the GPS records, the estimated trends are very sensitive to the start and end years and the analyzed time period (Box 2.2).

2.5.5.3 Satellite

AR4 reported positive decadal trends in lower and upper tropospheric water vapour based upon satellite observations for the period 1988–2004. Since AR4, there has been continued evidence for increases in lower tropospheric water vapour from microwave satellite measurements of column integrated water vapour over oceans (Santer et al., 2007; Wentz et al., 2007) and globally from satellite measurements of spectrally-resolved reflected solar radiation (Mieruch et al., 2008). The interannual variability and longer-term trends in column-integrated water vapour over oceans are closely tied to changes in SST at the global scale and interannual anomalies show remarkable agreement with low level specific humidity anomalies from HadCRUH (O’Gorman et al., 2012). The rate of moistening at large spatial scales over oceans is close to that expected from the Clausius-Clapeyron relation (about 7% per °C) with invariant relative humidity (Figure 2.31). Satellite measurements also indicate that the globally-averaged upper tropospheric relative humidity has changed little over the period 1979–2010 while the troposphere has warmed, implying an increase in the mean water vapour mass in the upper troposphere (Shi and Bates, 2011).

[INSERT FIGURE 2.31 HERE]

Figure 2.31: a) Trends in column integrated water vapour over ocean surfaces from Special Sensor Microwave Imager, (Wentz et al., 2007) for the period 1988–2010. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). b) Global annual average anomalies in column integrated water vapour averaged over ocean surfaces. Anomalies are relative to the 1988–2007 average.

Interannual variations in temperature and upper tropospheric water vapour from infrared satellite data are consistent with a constant RH behavior at large spatial scales (Dessler et al., 2008; Gettelman and Fu, 2008; Chung et al., 2010). On decadal time-scales, increased greenhouse gas concentrations reduce clear-sky outgoing long-wave radiation (Allan, 2009; Chung and Soden, 2010), thereby influencing inferred relationships between moisture and temperature. Using Meteosat infrared radiances, Brogniez et al. (2009) demonstrated that interannual variations in free tropospheric humidity over subtropical dry regions are heavily influenced by meridional mixing between the deep tropics and the extra tropics. Regionally, upper tropospheric humidity changes in the tropics were shown to relate strongly to the movement of the ITCZ based upon microwave satellite data (Xavier et al., 2010). Shi and Bates (2011) found an increase in upper tropospheric humidity over the equatorial tropics from 1979 to 2008. However there was no significant trend found in tropical-mean or global-mean averages, indicating that on these time and space scales the upper troposphere has seen little change in relative humidity over the past 30 years. While microwave satellite measurements have become increasingly relied upon for studies of upper tropospheric humidity, the absence of a homogenized dataset across multiple satellite platforms presents some difficulty in documenting coherent trends from these records (John et al., 2011).

2.5.5.4 Reanalyses.

Using NCEP reanalyses for the period 1973–2007, Paltridge et al. (2009) found negative trends in specific humidity above 850 hPa over both the tropics and southern midlatitudes, and above 600 hPa in the NH midlatitudes. However, as noted in AR4, reanalysis products suffer from time dependent biases and have been shown to simulate unrealistic trends and variability over the ocean (Mears et al., 2007; John et al., 2009) (Box 2.3). Some reanalysis products do reproduce observed variability in low level humidity over land (Simmons et al., 2010), more complete assessments of multiple reanalysis products yield substantially different and even opposing trends in free tropospheric specific humidity (Chen et al., 2008; Dessler and Davis, 2010). Consequently, reanalysis products are still considered to be unsuitable for the analysis of tropospheric water vapour trends (Sherwood et al., 2010).

In summary, radiosonde, GPS and satellite observations of tropospheric water vapour indicate *very likely* increases at near global scales since the 1970s occurring at a rate that is generally consistent with the Clausius-Clapeyron relation (about 7% °C⁻¹) and the observed increase in atmospheric temperature. Significant trends in tropospheric relative humidity at large spatial scales have not been observed, with the exception of near-surface air over land where relative humidity has decreased in recent years (Section 2.5.5).

2.5.6 Clouds

2.5.6.1 Surface Observations

AR4 reported that surface-observed total cloud cover may have increased over many land areas since the middle of the 20th century, including the USA, the former USSR, Western Europe, midlatitude Canada, and Australia. A few regions exhibited decreases, including China and central Europe. Trends were less globally consistent since the early 1970s, with regional reductions in cloud cover were reported for western Asia and Europe but increases over the USA.

Analyses since AR4 have indicated decreases in cloud occurrence/cover in recent decades over Poland (Wibig, 2008), China and Tibet (Duan and Wu, 2006; Endo and Yasunari, 2006; Xia, 2010b), in particular for upper level clouds (Warren et al., 2007) and also over Africa, Eurasia and in particular South America (Warren et al., 2007). Increased frequency of overcast conditions has been reported for some regions, such as Canada from 1953 to 2002 (Milewska, 2004), with no statistically significant trends evident over Australia (Jovanovic et al., 2011) and North America (Warren et al., 2007). A global analysis of surface observations spanning the period 1971–2009 (Eastman and Warren, 2012) indicates a small decline in total cloud cover of ~0.4% per decade which is largely attributed to declining mid- and high-level cloud cover and is most prominent in the middle latitudes.

Regional variability in surface-observed cloudiness over the ocean appeared more credible than zonal and global mean variations in AR4. Multidecadal changes in upper-level cloud cover and total cloud cover over particular areas of the tropical Indo-Pacific Ocean were consistent with island precipitation records and SST variability. This has been extended more recently by Deser et al. (2010a), who found that an eastward shift in tropical convection and total cloud cover from the western to central equatorial Pacific occurred over the 20th century and attributed it to a long-term weakening of the Walker circulation (Section 2.7.5). Eastman et al. (2011) report that, after the removal of apparently spurious globally coherent variability, cloud cover decreased in all subtropical stratocumulus regions from 1954 to 2008.

2.5.6.2 Satellite Observations

Satellite cloud observations offer the advantage of much better spatial and temporal coverage compared to surface observations. However they require careful efforts to identify and correct for temporal discontinuities in the datasets associated with orbital drift, sensor degradation, and inter-satellite calibration differences. AR4 noted that there were substantial uncertainties in decadal trends of cloud cover in all satellite datasets available at the time and concluded that there was no clear consensus regarding the decadal changes in total cloud cover. Since AR4 there has been continued effort to assess the quality of and develop improvements to

multi-decadal cloud products from operational satellite platforms (Evan et al., 2007; O'Dell et al., 2008; Heidinger and Pavolonis, 2009).

Several satellite datasets offer multi-decadal records of cloud cover (Stubenrauch et al., 2013). AR4 noted that there were discrepancies in global cloud cover trends between ISCCP and other satellite data products, notably a large downward trend of global cloudiness in ISCCP since the late 1980s, which is inconsistent with PATMOS-x and surface observations (Baringer et al., 2010). Recent work has confirmed the conclusion of AR4, that much of the downward trend in ISCCP is spurious and an artefact of changes in satellite viewing geometry (Evan et al., 2007). An assessment of long-term variations in global-mean cloud amount from nine different satellite datasets by Stubenrauch et al. (2013) found differences between datasets were comparable in magnitude to the interannual variability (2.5–3.5%). Such inconsistencies result from differences in sampling as well as changes in instrument calibration and inhibit an accurate assessment of global-scale cloud cover trends.

Satellite observations of low-level marine clouds suggest no long-term trends in cloud liquid water path or optical properties (O'Dell et al., 2008; Rausch et al., 2010). On regional scales, trends in cloud properties over China have been linked to changes in aerosol concentrations (Qian et al., 2009; Bennartz et al., 2011) (Section 2.2.3).

In summary, surface-based observations show region- and height-specific variations and trends in cloudiness but there remains substantial ambiguity regarding global-scale cloud variations and trends, especially from satellite observations. While trends of cloud cover are consistent between independent datasets in certain regions, substantial ambiguity and therefore *low confidence* remains in the observations of global-scale cloud variability and trends.

2.6 Changes in Extreme Events

AR4 highlighted the importance of understanding changes in extreme climate events (Annex III: Glossary) because of their disproportionate impact on society and ecosystems compared to changes in mean climate (see also IPCC Working Group II). More recently a comprehensive assessment of observed changes in extreme events was undertaken by the IPCC Special Report on Managing the Risks of Extreme Events and Disasters to Advance Climate Change Adaptation (SREX) (Seneviratne et al., 2012; Section 1.3.3).

Data availability, quality and consistency especially affect the statistics of extremes and some variables are particularly sensitive to changing measurement practices over time. For example, historical tropical cyclone records are known to be heterogeneous due to changing observing technology and reporting protocols (Section 14.6.1) and when records from multiple ocean basins are combined to explore global trends, because data quality and reporting protocols vary substantially between regions (Knapp and Kruk, 2010). Similar problems have been discovered when analysing wind extremes, because of the sensitivity of measurements to changing instrumentation and observing practice (e.g., Smits et al., 2005; Wan et al., 2010).

Numerous regional studies indicate that changes observed in the frequency of extremes can be explained or inferred by shifts in the overall probability distribution of the climate variable (Griffiths et al., 2005; Ballester et al., 2010; Simolo et al., 2011). However, it should be noted that these studies refer to counts of threshold exceedance—frequency, duration—which closely follow mean changes. Departures from high percentiles/return periods (intensity, severity, magnitude) are highly sensitive to changes in the shape and scale parameters of the distribution (Schar et al., 2004; Clark et al., 2006; Della-Marta et al., 2007a; Della-Marta et al., 2007b; Fischer and Schar, 2010) and geographical location. Debate continues over whether variance as well as mean changes are affecting global temperature extremes (Hansen et al., 2012; Rhines and Huybers, 2013) as illustrated in Figure 1.8 and FAQ 2.2, Figure 1. In the following sections the conclusions from both AR4 and SREX are reviewed along with studies subsequent to those assessments.

2.6.1 Temperature Extremes

AR4 concluded that it was *very likely* that a large majority of global land areas had experienced decreases in indices of cold extremes and increases in indices of warm extremes, since the middle of the 20th century, consistent with warming of the climate. In addition, globally averaged multi-day heat events had *likely*

exhibited increases over a similar period. SREX updated AR4 but came to similar conclusions while using the revised AR5 uncertainty guidance (Seneviratne et al., 2012). Further evidence since then indicates that the *level of confidence* that the majority of warm and cool extremes show warming remains *high*.

A large amount of evidence continues to support the conclusion that most global land areas analysed have experienced significant warming of both maximum and minimum temperature extremes since about 1950 (Donat et al., 2013c). Changes in the occurrence of cold and warm days (based on daily maximum temperatures) are generally less marked (Figure 2.32). The ENSO (Box 2.5) influences both maximum and minimum temperature variability especially around the Pacific Rim (e.g., Kenyon and Hegerl, 2008; Alexander et al., 2009) but often affecting cold and warm extremes differently. Different datasets using different gridding methods and/or input data (Supplementary Material 2.SM.7) indicate large coherent trends in temperature extremes globally, associated with warming (Figure 2.32). The level of quality control varies between these datasets. For example, HadEX2 (Donat et al., 2013c) uses more rigorous quality control which leads to a reduced station sample compared to GHCNDEX (Donat et al., 2013a) or HadGHCND (Caesar et al., 2006). However despite these issues datasets compare remarkably consistently even though the station networks vary through time (Figure 2.32; Table 2.12). Other datasets that have assessed these indices, but cover a shorter period, also agree very well over the period of overlapping data, e.g., HadEX (Alexander et al., 2006) and Duke (Morak et al., 2011; Morak et al., 2013).

Table 2.12: Trend estimates and 90% confidence intervals (Box 2.2) for global values of cold nights (TN10p), cold days (TX10p), warm nights (TN90p) and warm days (TX90p) over the periods 1951–2010 and 1979–2010 (see Box 2.4, Table 1 for more information on indices).

Dataset	Trends in days per decade							
	TN10p		TX10p		TN90p		TX90p	
	1951–2010	1979–2010	1951–2010	1979–2010	1951–2010	1979–2010	1951–2010	1979–2010
HadEX2 (Donat et al., 2013c)	-3.9 ± 0.6	-4.2 ± 1.2	-2.5 ± 0.7	-4.1 ± 1.4	4.5 ± 0.9	6.8 ± 1.8	2.9 ± 1.2	6.3 ± 2.2
HadGHCND (Caesar et al., 2006)	-4.5 ± 0.7	-4.0 ± 1.5	-3.3 ± 0.8	-5.0 ± 1.6	5.8 ± 1.3	8.6 ± 2.3	4.2 ± 1.8	9.4 ± 2.7
GHCNDEX (Donat et al., 2013a)	-3.9 ± 0.6	-3.9 ± 1.3	-2.6 ± 0.7	-3.9 ± 1.4	4.3 ± 0.9	6.3 ± 1.8	2.9 ± 1.2	6.1 ± 2.2

The shift in the distribution of night-time temperatures appears greater than daytime temperatures although whether distribution changes are simply linked to increases in the mean or other moments is an active area of research (Ballester et al., 2010; Simolo et al., 2011; Donat and Alexander, 2012; Hansen et al., 2012). Indeed, all datasets examined (Duke, GHCNDEX, HadEX, HadEX2 and HadGHCND), indicate a faster increase in minimum temperature extremes than maximum temperature extremes. While diurnal temperature range (DTR) declines have only been assessed with *medium confidence* (Section 2.4.1.2), *confidence* of accelerated increases in minimum temperature extremes compared to maximum temperature extremes is *high* due to the more consistent patterns of warming in minimum temperature extremes globally.

Regional changes in a range of climate indices are assessed in Table 2.13. These indicate *likely* increases across most continents in unusually warm days and nights and/or reductions in unusually cold days and nights including frosts. Some regions have experienced close to a doubling of the occurrence of warm and a halving of the occurrence of cold nights e.g., parts of the Asia-Pacific region (Choi et al., 2009) and parts of Eurasia (Klein Tank et al., 2006; Donat et al., 2013a; Donat et al., 2013c) since the mid-20th century. Changes in both local and global SST patterns (Section 2.4.2) and large scale circulation patterns (Section 2.7) have been shown to be associated with regional changes in temperature extremes (Barrucand et al., 2008; Scaife et al., 2008; Alexander et al., 2009; Li et al., 2012), particularly in regions around the Pacific Rim (Kenyon and Hegerl, 2008). Globally, there is evidence of large-scale warming trends in the extremes of temperature, especially minimum temperature, since the beginning of the 20th century (Donat et al., 2013c).

[INSERT TABLE 2.13 HERE]

Table 2.13: Regional observed changes in a range of climate indices since the middle of the 20th century. Assessments are based on a range of ‘global’ studies and assessments (Groisman et al., 2005; Alexander et al., 2006; Caesar et al., 2006; Sheffield and Wood, 2008; Dai, 2011a; Dai, 2011b; Seneviratne et al., 2012; Sheffield et al., 2012; Dai, 2013; Donat et al., 2013a; Donat et al., 2013c; van der Schrier et al., 2013) and selected regional studies as indicated. Bold text indicates where the assessment is somewhat different to SREX Table 3-2. In each such case a footnote explains why the assessment is different. See also Figures 2.32 and 2.33.

There are some exceptions to this large-scale warming of temperature extremes including central North America, eastern USA (Alexander et al., 2006; Kunkel et al., 2008; Peterson et al., 2008) and some parts of South America (Alexander et al., 2006; Rusticucci and Renom, 2008; Skansi et al., 2013) which indicate changes consistent with cooling in these locations. However, these exceptions appear to be mostly associated with changes in maximum temperatures (Donat et al., 2013c). The so-called ‘warming hole’ in central North America and eastern USA, where temperatures have cooled relative to the significant warming elsewhere in the region, is associated with observed changes in the hydrological cycle and land-atmosphere interaction (Pan et al., 2004; Portmann et al., 2009a; Portmann et al., 2009b; Misra et al., 2012) and decadal and multi-decadal variability linked with the Atlantic and Pacific Oceans (Meehl et al., 2012; Weaver, 2012).

[INSERT FIGURE 2.32 HERE]

Figure 2.32: Trends in annual frequency of extreme temperatures over the period 1951–2010, for: (a) cold nights (TN10p), (b) cold days (TX10p), (c) warm nights (TN90p) and (d) warm days (TX90p) (Box 2.4, Table 1). Trends were calculated only for grid boxes that had at least 40 years of data during this period and where data ended no earlier than 2003. Grey areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). The data source for trend maps is HadEX2 (Donat et al., 2013c) updated to include the latest version of the European Climate Assessment dataset (Klok and Tank, 2009). Beside each map are the near-global time series of annual anomalies of these indices with respect to 1961–1990 for three global indices datasets: HadEX2 (red); HadGHCND (Caesar et al., 2006; blue) and updated to 2010 and GHCNDEX (Donat et al., 2013a; green). Global averages are only calculated using grid boxes where all three datasets have at least 90% of data over the time period. Trends are significant (i.e., a trend of zero lies outside the 90% confidence interval) for all the global indices shown.

Since AR4 many studies have analysed local to regional changes in multi-day temperature extremes in more detail, specifically addressing different heat wave aspects such as frequency, intensity, duration and spatial extent (Box 2.4, FAQ 2.2). Several high-profile heat waves have occurred in recent years (e.g., in Europe in 2003 (Beniston, 2004), Australia in 2009 (Pezza et al., 2012), Russia in 2010 (Barriopedro et al., 2011; Dole et al., 2011; Trenberth and Fasullo, 2012a) and USA in 2011/2012 (Hoerling et al., 2012) (Section 10.6.2) which have had severe impacts (see WGII). Heat waves are often associated with quasi-stationary anticyclonic circulation anomalies that produce prolonged hot conditions at the surface (Black and Sutton, 2007; Garcia-Herrera et al., 2010), but long-term changes in the persistence of these anomalies are still relatively poorly understood (Section 2.7). Heat waves can also be amplified by pre-existing dry soil conditions in transitional climate zones (Ferranti and Viterbo, 2006; Fischer et al., 2007; Seneviratne et al., 2010; Mueller and Seneviratne, 2012) and the persistence of those soil-moisture anomalies (Lorenz et al., 2010). Dry soil-moisture conditions are either induced by precipitation deficits (Della-Marta et al., 2007b; Vautard et al., 2007), or evapotranspiration excesses (Black and Sutton, 2007; Fischer et al., 2007), or a combination of both (Seneviratne et al., 2010). This amplification of soil moisture-temperature feedbacks is suggested to have partly enhanced the duration of extreme summer heat waves in southeastern Europe during the latter part of the 20th century (Hirschi et al., 2011), with evidence emerging of a signature in other moisture-limited regions (Mueller and Seneviratne, 2012).

Table 2.13 shows that there has been a *likely* increasing trend in the frequency of heatwaves since the middle of the 20th century in Europe and Australia and across much of Asia where there are sufficient data. However *confidence* on a global scale is *medium* due to lack of studies over Africa and South America but also in part due to differences in trends depending on how heatwaves are defined (Perkins et al., 2012). Using monthly means as a proxy for heatwaves Coumou et al. (2013) and Hansen et al. (2012) indicate that record breaking temperatures in recent decades substantially exceed what would be expected by chance but caution is required when making inferences between these studies and those that deal with multi-day events and/or use more complex definitions for heatwave events. There is also evidence in some regions that periods prior to the 1950s had more heatwaves (e.g., over the USA, the decade of the 1930s stands out and is also associated with extreme drought conditions (Peterson et al., 2013) while conversely in other regions

heatwave trends may have been underestimated due to poor quality and/or consistency of data (e.g., Della-Marta et al. (2007a) over Western Europe; Kuglitsch et al. (2009; 2010) over the Mediterranean). Recent available studies also suggest that the number of cold spells has reduced significantly since the 1950s (Donat et al., 2013a; Donat et al., 2013c).

In summary, new analyses continue to support the AR4 and SREX conclusions that since about 1950 it is *very likely* that the numbers of cold days and nights have decreased and the numbers of warm days and nights have increased overall on the global scale, i.e., for land areas with sufficient data. It is *likely* that such changes have also occurred across most of North America, Europe, Asia and Australia. There is *low to medium confidence* in historical trends in daily temperature extremes in Africa and South America as there is either insufficient data or trends vary across these regions. This combined with issues with defining events, leads to the assessment that there is *medium confidence* that globally the length and frequency of warm spells, including heat waves, has increased since the middle of the 20th century although it is *likely* that heatwave frequency has increased during this period in large parts of Europe, Asia and Australia.

2.6.2 Extremes of the Hydrological Cycle

In Section 2.5 mean state changes in different aspects of the hydrological cycle are discussed. In this section we focus on the more extreme aspects of the cycle including extreme rainfall, severe local weather events like hail, flooding and droughts. Extreme events associated with tropical and extratropical storms are discussed in Sections 2.6.3 and 2.6.4 respectively.

2.6.2.1 Precipitation Extremes

AR4 concluded that substantial increases are found in heavy precipitation events. It was *likely* that annual heavy precipitation events had disproportionately increased compared to mean changes between 1951 and 2003 over many mid-latitude regions, even where there had been a reduction in annual total precipitation. Rare precipitation (such as the highest annual daily precipitation total) events were *likely* to have increased over regions with sufficient data since the late 19th century. SREX supported this view, as have subsequent analyses, but noted large spatial variability within and between regions (Table 3.2 of Seneviratne et al., 2012).

Given the diverse climates across the globe it has been difficult to provide a universally valid definition of 'extreme precipitation'. However, Box 2.4 Table 1 indicates some of the common definitions that are used in the scientific literature. In general, statistical tests indicate changes in precipitation extremes are consistent with a wetter climate (Section 7.6.5), although with a less spatially coherent pattern of change than temperature, in that there are large areas that show increasing trends and large areas that show decreasing trends and a lower level of statistical significance than for temperature change (Alexander et al., 2006; Donat et al., 2013a; Donat et al., 2013c). Using R95p and SDII indices (Box 2.4), Figures 2.33a and 2.33b show these areas for heavy precipitation amounts and precipitation intensity where sufficient data are available in the HadEX2 dataset (Donat et al., 2013c) although there are more areas showing significant increases than decreases. While changes in large-scale circulation patterns have a substantial influence on precipitation extremes globally (Alexander et al., 2009; Kenyon and Hegerl, 2010), Westra et al. (2013) showed, using in situ data over land, that trends in the wettest day of the year indicate more increases than would be expected by chance. Over the tropical oceans satellite measurements show an increase in the frequency of the heaviest rainfall during warmer (El Niño) years (Allan and Soden, 2008).

Regional trends in precipitation extremes since the middle of the 20th century are varied (Table 2.13). In most continents *confidence* in trends is not higher than *medium* except in North America and Central America and Europe where there have been *likely* increases in either the frequency or intensity of heavy precipitation. This assessment increases to *very likely* for central North America. For North America it is also *likely* that increases have occurred during the whole of the 20th century (Pryor et al., 2009; Donat et al., 2013c; Villarini et al., 2013). For South America the most recent integrative studies indicate heavy rain events are increasing in frequency and intensity over the continent as a whole (Donat et al., 2013c; Skansi et al., 2013). For Europe and the Mediterranean, the assessment masks some regional and seasonal variation. For example, much of the increase reported in Table 2.13 is found in winter although with decreasing trends in some other regions such as northern Italy, Poland and some Mediterranean coastal sites (Pavan et al.,

2008; Lupikasza, 2010; Toreti et al., 2010). There are mixed regional trends across Asia and Oceania but with some indication that increases are being observed in more regions than decreases while recent studies focused on Africa, in general, have not found significant trends in extreme precipitation (see Chapter 14 for more on regional variations and trends).

The above studies generally use indices which reflect ‘moderate’ extremes e.g., events occurring as often as 5% or 10% of the time (Box 2.4). Only a few regions have sufficient data to assess trends in rarer precipitation events reliably, e.g., events occurring on average once in several decades. Using Extreme Value Theory, DeGaetano (2009) showed a 20% reduction in the return period for extreme precipitation events over large parts of the contiguous USA from 1950 to 2007. For Europe from 1951 to 2010, Van den Besselaar et al. (2012) reported a median reduction in 5 to 20 year return periods of 21%, with a range between 2% and 58% depending on the subregion and season. This decrease in waiting times for rare extremes is qualitatively similar to the increase in moderate extremes for these regions reported above, and also consistent with earlier local results for the extreme tail of the distribution reported in AR4.

The above studies refer to daily precipitation extremes, although rainfall will often be limited to part of the day only. The literature on sub-daily scales is too limited for a global assessment although it is clear that analysis and framing of questions regarding sub-daily precipitation extremes is becoming more critical (Trenberth, 2011). Available regional studies have shown results that are even more complex than for daily precipitation and with variations in the spatial patterns of trends depending on event formulation and duration. However regional studies show indications of more increasing than decreasing trends (Sen Roy, 2009; for India) (Sen Roy and Rouault, 2013; for South Africa) (Westra and Sisson, 2011; for Australia). Some studies present evidence of scaling of sub-daily precipitation with temperature that is outside that expected from the Clausius-Clapeyron relation (about 7% °C⁻¹) (Lenderink and Van Meijgaard, 2008; Haerter et al., 2010; Jones et al., 2010; Lenderink et al., 2011; Utsumi et al., 2011), but scaling beyond that expected from thermodynamic theories is controversial (Section 7.6.5).

In summary, further analyses continue to support the AR4 and SREX conclusions that it is *likely* that since 1951 there have been statistically significant increases in the number of heavy precipitation events (e.g., above the 95th percentile) in more regions than there have been statistically significant decreases, but there are strong regional and subregional variations in the trends. In particular, many regions present statistically non-significant or negative trends, and, where seasonal changes have been assessed, there are also variations between seasons (e.g., more consistent trends in winter than in summer in Europe). The overall most consistent trends towards heavier precipitation events are found in central North America (*very likely* increase) but assessment for Europe shows *likely* increases in more regions than decreases.

2.6.2.2 Floods

AR4 WGI Chapter 3 (Trenberth et al., 2007) did not assess changes in floods but AR4 WGII concluded that there was not a general global trend in the incidence of floods (Kundzewicz et al., 2007). SREX went further to suggest that there was low agreement and thus *low confidence* at the global scale regarding changes in the magnitude or frequency of floods or even the sign of changes.

AR5 WGII assess floods in regional detail accounting for the fact that trends in floods are strongly influenced by changes in river management (see also Section 2.5.2). While the most evident flood trends appear to be in northern high latitudes, where observed warming trends have been largest, in some regions no evidence of a trend in extreme flooding has been found, e.g., over Russia based on daily river discharge (Shiklomanov et al., 2007). Other studies for Europe (Hannaford and Marsh, 2008; Renard et al., 2008; Petrow and Merz, 2009; Stahl et al., 2010) and Asia (Jiang et al., 2008; Delgado et al., 2010) show evidence for upward, downward or no trend in the magnitude and frequency of floods, so that there is currently no clear and widespread evidence for observed changes in flooding except for the earlier spring flow in snow-dominated regions (Seneviratne et al., 2012).

In summary, there continues to be a lack of evidence and thus *low confidence* regarding the sign of trend in the magnitude and/or frequency of floods on a global scale.

2.6.2.3 Droughts

AR4 concluded that droughts had become more common, especially in the tropics and sub-tropics since about 1970. SREX provided a comprehensive assessment of changes in observed droughts (Section 3.5.1 and Box 3.3 of SREX), updated the conclusions provided by AR4 and stated that the type of drought considered and the complexities in defining drought (Annex III: Glossary) can substantially affect the conclusions regarding trends on a global scale (Chapter 10). Based on evidence since AR4, SREX concluded that there were not enough direct observations of dryness to suggest *high confidence* in observed trends globally, although there was *medium confidence* that since the 1950s some regions of the world have experienced more intense and longer droughts. The differences between AR4 and SREX are primarily due to analyses post-AR4, differences in how both assessments considered drought and updated IPCC uncertainty guidance.

There are very few direct measurements of drought related variables, such as soil moisture (Robock et al., 2000), so drought proxies (e.g., PDSI, SPI, SPEI; Box 2.4) and hydrological drought proxies (e.g., Vidal et al., 2010; Dai, 2011b) are often used to assess drought. The chosen proxy (e.g., precipitation, evapotranspiration, soil moisture, or streamflow) and time scale can strongly affect the ranking of drought events (Sheffield et al., 2009; Vidal et al., 2010). Analyses of these indirect indices come with substantial uncertainties. For example, PDSI may not be comparable across climate zones. A self-calibrating (sc-) PDSI can replace the fixed empirical constants in PDSI with values representative of the local climate (Wells et al., 2004). Furthermore, for studies using simulated soil moisture, the type of potential evapotranspiration model used can lead to significant differences in the estimation of the regions affected and the areal extent of drought (Sheffield et al., 2012), but the overall effect of a more physically realistic parameterisation is debated (van der Schrier et al., 2013).

Because drought is a complex variable and can at best be incompletely represented by commonly used drought indices, discrepancies in the interpretation of changes can result. For example, Sheffield and Wood (2008) found decreasing trends in the duration, intensity and severity of drought globally. Conversely, Dai (2011a; Dai, 2011b) found a general global increase in drought, although with substantial regional variation and individual events dominating trend signatures in some regions (e.g., the 1970s prolonged Sahel drought and the 1930s drought in the USA and Canadian Prairies). Studies subsequent to these continue to provide somewhat different conclusions on trends in global droughts and/or dryness since the middle of the 20th century (Sheffield et al., 2012; Dai, 2013; Donat et al., 2013c; van der Schrier et al., 2013).

Van der Schrier et al. (2013) using monthly sc-PDSI found no strong case either for notable drying or moisture increase on a global scale over the periods 1901–2009 or 1950–2009 and this largely agrees with the results of Sheffield et al. (2012) over the latter period. A comparison between the sc-PDSI calculated by van der Schrier et al. (2013) and that of Dai (2011a) shows that the dominant mode of variability is very similar, with a temporal evolution suggesting a trend toward drying. However, the same analysis for the 1950–2009 period shows an initial increase in drying in the Van der Schrier et al. dataset, followed by a decrease from the mid-1980s onwards, while the Dai data show a continuing increase until 2000. The difference in trends between the sc-PDSI dataset of Van der Schrier et al. and Dai appears to be due to the different calibration periods used, the shorter 1950–1979 period in the latter study resulting in higher index values from 1980 onwards, although the associated spatial patterns are similar. In addition, the observed precipitation forcing dataset differs between studies, with van der Schrier et al. (2013) and Sheffield et al. (2012) using CRU TS 3.10.01 (updated from Mitchell and Jones, 2005). This dataset uses fewer stations and has been wetter than some other precipitation products in the last couple of decades (Figure 2.29, Table 2.9), although the best dataset to use is still an open question. Despite this, a measure of sc-PDSI with potential evapotranspiration estimated using the Penman-Montieth equation shows an increase in the percentage of land area in drought since 1950 (Sheffield et al., 2012; Dai, 2013), while van der Schrier et al. (2013) also finds a slight increase in the percentage of land area in severe drought using the same measure. This is qualitatively consistent with the trends in surface soil moisture found for the shorter period 1988–2010 by Dorigo et al. (2012) using a new multi-satellite dataset and changes in observed streamflow (Dai, 2011b). However all these studies draw somewhat different conclusions and the compelling arguments both for (Dai, 2011b; Dai, 2013) and against (Sheffield et al., 2012; van der Schrier et al., 2013) a significant increase in the land area experiencing drought has hampered global assessment.

Studies that support an increasing trend towards the land area affected by drought seem to be at odds with studies that look at trends in dryness (i.e., lack of rainfall). For example, Donat et al. (2013c) found that the annual maximum number of consecutive dry days has declined since the 1950s in more regions than it has increased (Figure 2.33c). However, only regions in Russia and the USA indicate significant changes and there is a lack of information for this index over large regions, especially Africa. Most other studies focussing on global dryness find similar results, with decadal variability dominating longer-term trends (Frich et al., 2002; Alexander et al., 2006; Donat et al., 2013a). However, Giorgi et al. (2011) indicate that ‘hydroclimatic intensity’ (Box 2.4, Chapter 7), a measure which combines both dry spell length and precipitation intensity, has increased over the latter part of the 20th century in response to a warming climate. They show that positive trends (reflecting an increase in the length of drought and/or extreme precipitation events) are most marked in Europe, India, parts of South America and East Asia although trends appear to have decreased (reflecting a decrease in the length of drought and/or extreme precipitation events) in Australia and northern South America (Figure 2.33c). Data availability, quality and length of record remain issues in drawing conclusions on a global scale, however.

Despite differences between the conclusions drawn by global studies, there are some areas in which they agree. Table 2.13 indicates that there is *medium confidence* of an increase in dryness or drought in Eastern Asia with *high confidence* that this is the case in the Mediterranean and west Africa. There is also *high confidence* of decreases in dryness or drought in central North America and north-west Australia.

[INSERT FIGURE 2.33 HERE]

Figure 2.33: Trends in (a) annual amount of precipitation from days >95th percentile (R95p) (b) daily precipitation intensity (SDII) and (c) frequency of the annual maximum number of consecutive dry days (CDD) (Box 2.4, Table 1). Trends are shown as relative values for better comparison across different climatic regions. Trends were calculated only for grid boxes that had at least 40 years of data during this period and where data ended no earlier than 2003. Grey areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). The data source for trend maps is HadEX2 (Donat et al., 2013a) updated to include the latest version of the European Climate Assessment dataset (Klok and Tank, 2009). (d) Trends (normalized units) in hydroclimatic intensity (HY-INT: a multiplicative measure of length of dry spell and precipitation intensity) over the period 1976–2000 (adapted from Giorgi et al. (2011)). An increase (decrease) in HY-INT reflects an increase (decrease) in the length of drought and /or extreme precipitation events.

In summary, the current assessment concludes that there is not enough evidence at present to suggest more than *low confidence* in a global-scale observed trend in drought or dryness (lack of rainfall) since the middle of the 20th century, due to lack of direct observations, geographical inconsistencies in the trends, and dependencies of inferred trends on the index choice. Based on updated studies, AR4 conclusions regarding global increasing trends in drought since the 1970s were probably overstated. However, it is *likely* that the frequency and intensity of drought has increased in the Mediterranean and West Africa and decreased in central North America and north-west Australia since 1950.

2.6.2.4 Severe Local Weather Events

Another extreme aspect of the hydrological cycle is severe local weather phenomena such as hail or thunder storms. These are not well observed in many parts of the world, since the density of surface meteorological observing stations is too coarse to measure all such events. Moreover, homogeneity of existing reporting is questionable (Verbout et al., 2006; Doswell et al., 2009). Alternatively, measures of severe thunderstorms or hailstorms can be derived by assessing the environmental conditions that are favourable for their formation but this method is very uncertain (Seneviratne et al., 2012). SREX highlighted studies such as Brooks and Dotzek (2008) who found significant variability but no clear trend in the past 50 years in severe thunderstorms in a region east of the Rocky Mountains in the United States, Cao (2008) who found an increasing frequency of severe hail events in Ontario, Canada during the period 1979–2002 and Kunz et al. (2009) who found that hail days significantly increased during the period 1974–2003 in southwest Germany. Hailpad studies from Italy (Eccel et al., 2012) and France (Berthet et al., 2011) suggest slight increases in larger hail sizes and a correlation between the fraction of precipitation falling as hail with average summer temperature while in Argentina between 1960–2008 the annual number of hail events was found to be increasing in some regions and decreasing in others (Mezher et al., 2012). In China between 1961 and 2005, the number of hail days has been found to generally decrease, with the highest occurrence between 1960 and 1980 but with a sharp drop since the mid-1980s (CMA, 2007; Xie et al., 2008). However there is little

consistency in hail size changes in different regions of China since 1980 (Xie et al., 2010). Remote sensing offers a potential alternative to surface-based meteorological networks for detecting changes in small scale severe weather phenomenon such as proxy measurements of lightning from satellites (Zipser et al., 2006) but there remains little convincing evidence that changes in severe thunderstorms or hail have occurred since the middle of the 20th century (Brooks, 2012).

In summary, there is *low confidence* in observed trends in small-scale severe weather phenomena such as hail and thunderstorms because of historical data inhomogeneities and inadequacies in monitoring systems.

2.6.3 Tropical Storms

AR4 concluded that it was *likely* that an increasing trend had occurred in intense tropical cyclone activity since 1970 in some regions but that there was no clear trend in the annual numbers of tropical cyclones. Subsequent assessments, including SREX and more recent literature indicate that it is difficult to draw firm conclusions with respect to the confidence levels associated with observed trends prior to the satellite era and in ocean basins outside of the North Atlantic.

Section 14.6.1 discusses changes in tropical storms in detail. Current datasets indicate no significant observed trends in global tropical cyclone frequency over the past century and it remains uncertain whether any reported long-term increases in tropical cyclone frequency are robust, after accounting for past changes in observing capabilities (Knutson et al., 2010). Regional trends in tropical cyclone frequency and the frequency of very intense tropical cyclones have been identified in the North Atlantic and these appear robust since the 1970s (Kossin et al. 2007) (*very high confidence*). However, argument reigns over the cause of the increase and on longer time scales the fidelity of these trends is debated (Landsea et al., 2006; Holland and Webster, 2007; Landsea, 2007; Mann et al., 2007b) with different methods for estimating undercounts in the earlier part of the record providing mixed conclusions (Chang and Guo, 2007; Mann et al., 2007a; Kunkel et al., 2008; Vecchi and Knutson, 2008, 2011). No robust trends in annual numbers of tropical storms, hurricanes and major hurricanes counts have been identified over the past 100 years in the North Atlantic basin. Measures of land-falling tropical cyclone frequency (Figure 2.34) are generally considered to be more reliable than counts of all storms which tend to be strongly influenced by those that are weak and/or short-lived. Callaghan and Power (2011) find a statistically significant decrease in Eastern Australia land-falling tropical cyclones since the late 19th century although including 2010/2011 season data this trend becomes non-significant (i.e., a trend of zero lies just inside the 90% confidence interval). Significant trends are not found in other oceans on shorter timescales (Chan and Xu, 2009; Kubota and Chan, 2009; Mohapatra et al., 2011; Weinkle et al., 2012), although Grinsted et al. (2012) find a significant positive trend in eastern USA using tide-gauge data from 1923–2008 as a proxy for storm surges associated with land-falling hurricanes. Differences between tropical cyclone studies highlight the challenges that still lie ahead in assessing long-term trends.

[INSERT FIGURE 2.34 HERE]

Figure 2.34: Normalized 5-year running means of the number of (a) adjusted land falling eastern Australian tropical cyclones (adapted from Callaghan and Power (2011) and updated to include 2010/2011 season) and (b) unadjusted land falling U.S. hurricanes (adapted from Vecchi and Knutson (2011) and (c) land-falling typhoons in China (adapted from CMA, 2011). Vertical axis ticks represent one standard deviation, with all series normalized to unit standard deviation after a 5-year running mean was applied.

Arguably, storm frequency is of limited usefulness if not considered in tandem with intensity and duration measures. Intensity measures in historical records are especially sensitive to changing technology and improving methodology. However over the satellite era, increases in the intensity of the strongest storms in the Atlantic appear robust (Kossin et al., 2007; Elsner et al., 2008) but there is limited evidence for other regions and the globe. Time series of cyclone indices such as power dissipation, an aggregate compound of tropical cyclone frequency, duration, and intensity that measures total wind energy by tropical cyclones, show upward trends in the North Atlantic and weaker upward trends in the western North Pacific since the late 1970s (Emanuel, 2007), but interpretation of longer-term trends is again constrained by data quality concerns (Landsea et al., 2011).

In summary, this assessment does not revise the SREX conclusion of *low confidence* that any reported long-term (centennial) increases in tropical cyclone activity are robust, after accounting for past changes in

observing capabilities. More recent assessments indicate that it is *unlikely* that annual numbers of tropical storms, hurricanes and major hurricanes counts have increased over the past 100 years in the North Atlantic basin. Evidence however is for a *virtually certain* increase in the frequency and intensity of the strongest tropical cyclones since the 1970s in that region.

2.6.4 Extratropical Storms

AR4 noted a *likely* net increase in frequency/intensity of NH extreme extratropical cyclones and a poleward shift in storm tracks since the 1950s. SREX further consolidated the AR4 assessment of poleward shifting storm tracks, but revised the assessment of the confidence levels associated with regional trends in the intensity of extreme extratropical cyclones.

Studies using reanalyses continue to support a northward and eastward shift in the Atlantic cyclone activity during the last 60 years with both more frequent and more intense wintertime cyclones in the high-latitude Atlantic (Schneider et al., 2007; Raible et al., 2008; Vilibic and Sepic, 2010) and fewer in the mid-latitude Atlantic (Wang et al., 2006b; Raible et al., 2008). Some studies show an increase in intensity and number of extreme Atlantic cyclones (Paciorek et al., 2002; Lehmann et al., 2011) while others show opposite trends in eastern Pacific and North America (Gulev et al., 2001). Comparisons between studies are hampered because of the sensitivities in identification schemes and/or different definitions for extreme cyclones (Ulbrich et al., 2009; Neu et al., 2012). The fidelity of research findings also rests largely with the underlying reanalyses products that are used (Box 2.3). See also Section 14.6.2.

Over longer periods studies of severe storms or storminess have been performed for Europe where long running in situ pressure and wind observations exist. Direct wind speed measurements however either have short records or are hampered by inconsistencies due to changing instrumentation and observing practice over time (Smits et al., 2005; Wan et al., 2010). In most cases, therefore wind speed or storminess proxies are derived from in situ pressure measurements or reanalyses data, the quality and consistency of which vary. In situ observations indicate no clear trends over the past century or longer (Hanna et al., 2008; Matulla et al., 2008; Allan et al., 2009; Barring and Fortuniak, 2009) with substantial decadal and longer fluctuations but with some regional and seasonal trends (Wang et al., 2009c; Wang et al., 2011). Figure 2.35 shows some of these changes for boreal winter using geostrophic wind speeds indicating that decreasing trends outnumber increasing trends (Wang et al., 2011) although with few that are statistically significant. While Donat et al. (2011) and Wang et al. (2012h) find significant increases in both the strength and frequency of wintertime storms for large parts of Europe using the 20th century Reanalysis (Compo et al., 2011), there is debate over whether this is an artefact of the changing number of assimilated observations over time (Cornes and Jones, 2011; Krueger et al., 2013) even though Wang et al. (2012h) find good agreement between the 20th century Reanalysis trends and those derived from geostrophic wind extremes in the North Sea region.

[INSERT FIGURE 2.35 HERE]

Figure 2.35: 99th percentiles of geostrophic wind speeds for winter (DJF). Triangles show regions where geostrophic wind speeds have been calculated from in situ surface pressure observations. Within each pressure triangle, Gaussian low-pass filtered curves and estimated linear trends of the 99th percentile of these geostrophic wind speeds for winter are shown. The ticks of the time (horizontal) axis range from 1875 to 2005, with an interval of 10 years. Disconnections in lines show periods of missing data. Red (blue) trend lines indicate upward (downward) significant trends (i.e., a trend of zero lies outside the 95% confidence interval). From Wang et al. (2011).

SREX noted that available studies using reanalyses indicate a decrease in extratropical cyclone activity (Zhang et al., 2004) and intensity (Zhang et al., 2004; Wang et al., 2009d) over the last 50 years has been reported for northern Eurasia (60°N–40°N) linked to a possible northward shift with increased cyclone frequency in the higher latitudes and decrease in the lower latitudes. The decrease at lower latitudes was also found in East Asia (Wang et al., 2012h) and is also supported by a study of severe storms by Zou et al. (2006b) who used sub-daily in situ pressure data from a number of stations across China.

SREX also notes that, based on reanalyses, North American cyclone numbers have increased over the last 50 years, with no statistically significant change in cyclone intensity (Zhang et al., 2004). Hourly SLP data from Canadian stations showed that winter cyclones have become significantly more frequent, longer lasting, and stronger in the lower Canadian Arctic over the last 50 years (1953–2002), but less frequent and weaker in the south, especially along the southeast and southwest Canadian coasts (Wang et al., 2006a). Further south, a

tendency toward weaker low-pressure systems over the past few decades was found for U.S. east coast winter cyclones using reanalyses, but no statistically significant trends in the frequency of occurrence of systems (Hirsch et al., 2001).

Using the 20th century Reanalysis (Compo et al., 2011), Wang et al. (2012h) found substantial increases in extratropical cyclone activity in the SH (20°S–90°S). However, for southeast Australia, a decrease in activity is found and this agrees well with geostrophic wind extremes derived from in situ surface pressure observations (Alexander et al., 2011). This strengthens the evidence of a southward shift in storm tracks previously noted using older reanalyses products (Fyfe, 2003; Hope et al., 2006). Frederiksen and Frederiksen (2007) linked the reduction in cyclogenesis at 30°S and southward shift to a decrease in the vertical mean meridional temperature gradient. There is some inconsistency among reanalysis products for the SH regarding trends in the frequency of intense extratropical cyclones (Lim and Simmonds, 2007; Pezza et al., 2007; Lim and Simmonds, 2009) although studies tend to agree on a trend towards more intense systems, even when inhomogeneities associated with changing numbers of observations have been taken into account (Wang et al., 2012h). However further undetected contamination of these trends due to issues with the reanalyses products cannot be ruled out (Box 2.3) and this lowers our confidence in long-term trends. Links between extratropical cyclone activity and large scale variability are discussed in Section 2.7 and Section 14.6.2.

Studies that have examined trends in wind extremes from observations or regional reanalysis products tend to point to declining trends in extremes in mid-latitudes (Pirazzoli and Tomasin, 2003; Smits et al., 2005; Pryor et al., 2007; Zhang et al., 2007b) and increasing trends in high latitudes (Lynch et al., 2004; Turner et al., 2005; Hundecha et al., 2008; Stegall and Zhang, 2012). Other studies have compared the trends from observations with reanalysis data and reported differing or even opposite trends in the reanalysis products (Smits et al., 2005; McVicar et al., 2008). On the other hand, declining trends reported by Xu et al. (2006b) over China between 1969 and 2000 were generally consistent with trends in NCEP reanalysis. Trends extracted from reanalysis products must be treated with caution however, although usually with later generation products providing improvements over older products (Box 2.3).

In summary, *confidence* in large scale changes in the intensity of extreme extratropical cyclones since 1900 is *low*. There is also *low confidence* for a clear trend in storminess proxies over the last century due to inconsistencies between studies or lack of long-term data in some parts of the world (particularly in the SH). Likewise, *confidence* in trends in extreme winds is *low*, due to quality and consistency issues with analysed data.

[START BOX 2.4 HERE]

Box 2.4: Extremes Indices

As SREX highlighted, there is no unique definition of what constitutes a climate extreme in the scientific literature given variations in regions and sectors affected (Stephenson et al., 2008). Much of the available research is based on the use of so-called ‘extremes indices’ (Zhang et al., 2011). These indices can either be based on the probability of occurrence of given quantities or on absolute or percentage threshold exceedances (relative to a fixed climatological period) but also include more complex definitions related to duration, intensity and persistence of extreme events. For example, the term ‘heat wave’ can mean very different things depending on the index formulation for the application for which it is required (Perkins and Alexander, 2012).

Box 2.4, Table 1 lists a number of specific indices that appear widely in the literature and have been chosen to provide some consistency across multiple chapters in AR5 (along with the location of associated figures and text). These indices have been generally chosen for their robust statistical properties and their applicability across a wide range of climates. Another important criterion is that data for these indices are broadly available over both space and time. The existing near-global land-based datasets cover at least the post-1950 period but for regions such as Europe, North America, parts of Asia and Australia much longer analyses are available. The same indices used in observational studies (this chapter) are also used to diagnose climate model output (Chapters 9, 10, 11 and 12).

Box 2.4, Table 1: Definitions of extreme temperature and precipitation indices used in IPCC. After Zhang et al. (2011). The most common units are shown but these may be shown as normalized or relative depending on application in different chapters.

Index	Descriptive name	Definition	Units	Figures/Tables	Section
TXx	Warmest daily Tmax	Seasonal/annual maximum value of daily max temperature	°C	Box 2.4, Figure 1, Figures 9.37, 10.17, 12.13	Box 2.4, 9.5.4.1, 10.6.1.1, 12.4.3.3

The types of indices discussed here do not include indices such as NINO3 representing positive and negative phases of the ENSO (Box 2.5), nor do they include extremes such as 1 in 100 year events. Typically extreme indices assessed here reflect more ‘moderate’ extremes, e.g., events occurring as often as 5% or 10% of the time (Box 2.4, Table 1). Predefined extreme indices are usually easier to obtain than the underlying daily

climate data, which are not always freely exchanged by meteorological services. However some of these indices do represent rarer events e.g., annual maxima or minima. Analyses of these and rarer extremes (e.g., with longer return period thresholds) are making their way into a growing body of literature which, for example, are using Extreme Value Theory (Coles, 2001) to study climate extremes (Zwiers and Kharin, 1998; Brown et al., 2008; Sillmann et al., 2011; Zhang et al., 2011; Kharin et al., 2013).

Extreme indices are more generally defined for daily temperature and precipitation characteristics (Zhang et al., 2011) although research is developing on the analysis of sub-daily events but mostly only on regional scales (Sen Roy, 2009; Shiu et al., 2009; Jones et al., 2010; Jakob et al., 2011; Lenderink et al., 2011; Shaw et al., 2011). Temperature and precipitation indices are sometimes comined to investigate ‘extremeness’ (e.g., hydroclimatic intensity, HY-INT; Giorgi et al., 2011) and/or the areal extent of extremes (e.g., the Climate Extremes Index (CEI) and its variants (Gleason et al., 2008; Gallant and Karoly, 2010; Ren et al., 2011). Indices rarely include other weather and climate variables, such as wind speed, humidity, or physical impacts (e.g., streamflow) and phenomena. Some examples are available in the literature for wind-based (Della-Marta et al., 2009) and pressure-based (Beniston, 2009) indices, for health-relevant indices combining temperature and relative humidity characteristics (Differbaugh et al., 2007; Fischer and Schar, 2010) and for a range of dryness or drought indices (e.g., Palmer Drought Severity Index (PDSI) Palmer, 1965; Standardised Precipitation Index (SPI), Standardised Precipitation Evapotranspiration Index (SPEI) Vicente-Serrano et al., 2010) and wetness indices (e.g., Standardized Soil Wetness Index (SSWI); Vidal et al., 2010).

In addition to the complication of defining an index, the results depend also on the way in which indices are calculated (to create global averages for example). This is due to the fact that different algorithms may be employed to create grid box averages from station data, or that extremes indices may be calculated from gridded daily data or at station locations and then gridded. All of these factors add uncertainty to the calculation of an extreme. For example, the spatial patterns of trends in the hottest day of the year differ slightly between datasets although when globally averaged, trends are similar over the second half of the 20th century (Box 2.4, Figure 1). Further discussion of the parametric and structural uncertainties in datasets is given in Box 2.1.

[INSERT BOX 2.4, FIGURE 1 HERE]

Box 2.4, Figure 1: Trends in the warmest day of the year using different datasets for the period 1951–2010. The datasets are (a) HadEX2 (Donat et al., 2013c) updated to include the latest version of the European Climate Assessment dataset (Klok and Tank, 2009), (b) HadGHCND (Caesar et al., 2006) using data updated to 2010 (Donat et al., 2013a), and (c) Globally averaged annual warmest day anomalies for each dataset. Trends were calculated only for grid boxes that had at least 40 years of data during this period and where data ended no earlier than 2003. Grey areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). Anomalies are only calculated using grid boxes where both datasets have data and where 90% of data are available.

[START FAQ 2.2 HERE]

FAQ 2.2: Have there been any Changes in Climate Extremes?

There is strong evidence that warming has lead to changes in temperature extremes—including heat waves—since the mid-20th century. Increases in heavy precipitation have probably also occurred over this time, but vary by region. However, for other extremes, such as tropical cyclone frequency, we are less certain, except in some limited regions, that there have been discernable changes over the observed record.

From heat waves to cold snaps or droughts to flooding rains, recording and analysing climate extremes poses unique challenges, not just because these events are rare, but also because they invariably happen in conjunction with disruptive conditions. Furthermore, there is no consistent definition in the scientific literature of what constitutes an extreme climatic event, and this complicates comparative global assessments.

Although, in an absolute sense, an extreme climate event will vary from place to place—a hot day in the tropics, for instance, may be a different temperature to a hot day in the mid-latitudes—international efforts to monitor extremes have highlighted some significant global changes.

For example, using consistent definitions for cold (<10th percentile) and warm (>90th percentile) days and nights it is found that warm days and nights have increased and cold days and nights have decreased for most regions of the globe; a few exceptions being central and eastern North America, and southern South America but mostly only related to daytime temperatures. Those changes are generally most apparent in minimum temperature extremes e.g., warm nights. Data limitations make it difficult to establish a causal link to increases in average temperatures, but FAQ 2.2, Figure 1 indicates that daily global temperature extremes have indeed changed. Whether these changes are simply associated with the average of daily temperatures increasing (the dashed lines in FAQ 2.2, Figure 1) or whether other changes in the distribution of daytime and night-time temperatures have occurred is still under debate.

Warm spells or heat waves i.e., periods containing consecutive extremely hot days or nights have also been assessed, but there are fewer studies of heat wave characteristics than those that compare changes in merely warm days or nights. Most global land areas with available data have experienced more heat waves since the middle of the 20th century. One exception is the south-eastern United States, where heat wave frequency and duration measures generally show decreases. This has been associated with a so-called ‘warming hole’ in this region, where precipitation has also increased, and may be related to interactions between the land and the atmosphere, and long-term variations in the Atlantic and Pacific Oceans. However large regions, particularly in Africa and South America have limited information on changes in heatwaves.

For regions such as Europe, where historical temperature reconstructions exist going back several hundreds of years, indications are that some regions have experienced a disproportionate number of extreme heat waves in recent decades.

[INSERT FAQ 2.2, FIGURE 1 HERE]

FAQ 2.2, Figure 1: Distribution of (a) daily minimum and (b) daily maximum temperature anomalies relative to a 1961–1990 climatology for two periods: 1951–1980 (blue) and 1981–2010 (red) using the HadGHCND dataset. The shaded blue and red areas represent the coldest 10% and warmest 10% respectively of (a) nights and (b) days during the 1951–1980 period. The darker shading indicates by how much the number of the coldest days and nights has reduced (dark blue) and by how much the number of the warmest days and nights has increased (dark red) during the 1981–2010 period compared to the 1951–1980 period.

Changes in extremes for other climate variables are generally less coherent than those observed for temperature, due to data limitations and inconsistencies between studies, regions and/or seasons. However, increases in precipitation extremes, for example, are consistent with a warmer climate. Analyses of land areas with sufficient data indicate increases in the frequency and intensity of extreme precipitation events in recent decades, but results vary strongly between regions and seasons. For instance, evidence is most compelling for increases in heavy precipitation in North America, Central America and Europe, but in some other regions—such as southern Australia and western Asia—there is evidence of decreases. Likewise, drought studies do not agree on the sign of the global trend, with regional inconsistencies in trends also dependent on how droughts are defined. However, indications exist that droughts have increased in some regions (e.g., the Mediterranean) and decreased in others (e.g., central North America) since the middle of the 20th century.

Considering other extremes, such as tropical cyclones, the latest assessments show that due to problems with past observing capabilities, it is difficult to make conclusive statements about long-term trends. There is very strong evidence, however, that storm activity has increased in the North Atlantic since the 1970s.

Over periods of a century or more, evidence suggests slight decreases in the frequency of tropical cyclones making landfall in the North Atlantic and the South Pacific, once uncertainties in observing methods have been considered. Little evidence exists of any longer-term trend in other ocean basins. For extratropical cyclones, a poleward shift is evident in both hemispheres over the past 50 years, with further but limited evidence of a decrease in wind storm frequency at mid-latitudes. Several studies suggest an increase in intensity, but data sampling issues hamper these assessments.

[INSERT FAQ 2.2, FIGURE 2 HERE]

FAQ 2.2, Figure 2: Trends in the frequency (or intensity) of various climate extremes (arrow direction denotes the sign of the change) since the middle of the 20th century (except for North Atlantic storms where the period covered is from the 1970s).

FAQ 2.2, Figure 2 summarizes some of the observed changes in climate extremes. Overall, the most robust global changes in climate extremes are seen in measures of daily temperature, including to some extent, heat waves. Precipitation extremes also appear to be increasing, but there is large spatial variability, and observed trends in droughts are still uncertain except in a few regions. While robust increases have been seen in tropical cyclone frequency and activity in the North Atlantic since the 1970s, the reasons for this are still being debated. There is limited evidence of changes in extremes associated with other climate variables since the mid-20th century.

[END FAQ 2.2 HERE]

2.7 Changes in Atmospheric Circulation and Patterns of Variability

Changes in atmospheric circulation and indices of climate variability, as expressed in Sea Level Pressure (SLP), wind, Geopotential Height (GPH), and other variables were assessed in AR4. Substantial multi-decadal variability was reported in the large-scale atmospheric circulation over the Atlantic and the Pacific. With respect to trends, a decrease was found in tropospheric GPH over high latitudes of both hemispheres and an increase over the mid-latitudes in boreal winter for the period 1979–2001. These changes were found to be associated with an intensification and poleward displacement of Atlantic and southern midlatitude jet streams and enhanced storm track activity in the NH from the 1960s to at least the 1990s. Changes in the North Atlantic Oscillation (NAO) and the Southern Annular Mode (SAM) towards their positive phases were observed, but it was noted that the NAO returned to its long-term mean state from the mid-1990s to the early 2000s.

Since AR4, more and improved observational datasets and reanalysis datasets (Box 2.3) have been published. Uncertainties and inaccuracies in all datasets are better understood (Box 2.1). The studies since AR4 assessed in this section support the poleward movement of circulation features since the 1970s and the change in the SAM. At the same time, large decadal-to-multidecadal variability in atmospheric circulation is found that partially offsets previous trends in other circulation features such as the NAO or the Pacific Walker circulation.

This section assesses observational evidence for changes in atmospheric circulation in fields of SLP, GPH, and wind, in circulation features (such as the Hadley and Walker circulation, monsoons, or jet streams; Annex III: Glossary), as well as in circulation variability modes. Regional climate effects of the circulation changes are discussed in Chapter 14.

2.7.1 Sea Level Pressure

AR4 concluded that SLP in December to February decreased between 1948 and 2005 in the Arctic, Antarctic and North Pacific. More recent studies using updated data for the period 1949–2009 (Gillett and Stott, 2009) also find decreases in SLP in the high latitudes of both hemispheres in all seasons and increasing SLP in the tropics and subtropics most of the year. However, due to decadal variability SLP trends are sensitive to the choice of the time period (Box 2.2), and they depend on the dataset.

The spatial distribution of SLP represents the distribution of atmospheric mass, which is the surface imprint of the atmospheric circulation. Barometric measurements are made in weather stations or on board ships. Fields are produced from the observations by interpolation or using data assimilation into weather models. One of the most widely used observational datasets is HadSLP2 (Allan and Ansell, 2006), which integrates 2228 historical global terrestrial stations with marine observations from the ICOADS on a $5^\circ \times 5^\circ$ grid. Other observation products (e.g., Trenberth and Paolino, 1980; for the extratropical NH) or reanalyses are also widely used to address changes in SLP. Although the quality of SLP data is considered good, there are discrepancies between gridded SLP datasets in regions with sparse observations, e.g., over Antarctica (Jones and Lister, 2007).

Van Haren et al. (2012) found a strong SLP decrease over the Mediterranean in January to March from 1961 to 2000. For the more recent period (1979–2012) trends in SLP, consistent across different datasets (shown in Figure 2.36 for ERA-Interim), are negative in the tropical and northern subtropical Atlantic during most of the year as well as, in May to October, in northern Siberia. Positive trends are found year-round over the North and South Pacific and South Atlantic. Trends in the equatorial Pacific zonal SLP gradient during the 20th century (e.g., Vecchi et al., 2006; Power and Kociuba, 2011a, 2011b) are discussed in Section 2.7.5.

[INSERT FIGURE 2.36 HERE]

Figure 2.36: Trends in (left) Sea Level Pressure (SLP), (middle) 500 hPa geopotential height (GPH), and (right) 100 hPa GPH in (top) November to April 1979/1980 to 2011/2012 and (bottom) May to October 1979 to 2011 from ERA-Interim data. Trends are only shown if significant (i.e., a trend of zero lies outside the 90% confidence interval).

The position and strength of semi-permanent pressure centres show no clear evidence for trends since 1951. However, prominent variability is found on decadal time scales (Figure 2.37). Consistent across different datasets, the Azores high and the Icelandic low in boreal winter, as captured by the high and low SLP contours, were both small in the 1960s and 1970s, large in the 1980s and 1990s, and again smaller in the 2000s. Favre and Gershunov (2006) find an eastward shift of the Aleutian low from the mid-1970s to 2001, which persisted during the 2000s (Figure 2.37). The Siberian High exhibits pronounced decadal-to-multidecadal variability (Panagiotopoulos et al., 2005; Huang et al., 2010), with a recent (1998 to 2012) strengthening and northwestward expansion (Zhang et al., 2012b). In boreal summer, the Atlantic and Pacific high-pressure systems extended more westward in the 1960s and 1970s than later. On interannual time scales, variations in pressure centres are related to modes of climate variability. Trends in the indices that capture the strength of these modes are reported in Section 2.7.8, their characteristics and impacts are discussed in Chapter 14.

[INSERT FIGURE 2.37 HERE]

Figure 2.37: Decadal averages of Sea Level Pressure (SLP) from the 20th century Reanalysis (20CR) for (left) November of previous year to April and (right) May to October shown by two selected contours: 1004 hPa (dashed lines) and 1020.5 hPa (solid lines). Topography above 2 km above mean sea level in 20CR is shaded in dark grey.

In summary, sea level pressure has *likely* decreased from 1979 to 2012 over the tropical Atlantic and increased over large regions of the Pacific and South Atlantic, but trends are sensitive to the time period analysed due to large decadal variability.

2.7.2 Surface Wind Speed

AR4 concluded that mid-latitude westerly winds have generally increased in both hemispheres. Because of shortcomings in the observations, SREX stated that *confidence* in surface wind trends is *low*. Further studies assessed here confirm this assessment.

Surface wind measurements over land and ocean are based on largely separate observing systems. Early marine observations were based on ship speed through the water or sails carried or on visual estimates of sea state converted to the wind speed using the Beaufort scale. Anemometer measurements were introduced starting in the 1950s. The transition from Beaufort to measured winds introduced a spurious trend, compounded by an increase in mean anemometer height over time (Kent et al., 2007; Thomas et al., 2008). ICOADS release 2.5 (Woodruff et al., 2011) contains information on measurement methods and wind measurement heights, permitting adjustment for these effects. The ICOADS-based dataset WASWind (1950–2010; Tokinaga and Xie, 2011a) and the interpolated product NOCS v.2.0 (1973–present; Berry and Kent, 2011) include such corrections, among other improvements.

Marine surface winds are also measured from space using various microwave range instruments: scatterometers and synthetic aperture radars retrieve wind vectors, while altimeters and passive radiometers measure wind speed only (Bourassa et al., 2010). The latter type provides the longest continuous record, starting in July 1987. Satellite-based interpolated marine surface wind datasets use objective analysis methods to blend together data from different satellites and atmospheric reanalyses. The latter provide wind directions as in Blended Sea Winds (BSW, Zhang et al., 2006), or background fields as in Cross-Calibrated Multi-Platform winds (CCMP, Atlas et al., 2011) and OAFflux (Yu and Weller, 2007). CCMP uses additional

dynamical constraints, in situ data and a recently homogenized dataset of SSM/I observations (Wentz et al., 2007), among other satellite sources.

Figure 2.38 compares 1988–2010 linear trends in surface wind speeds from interpolated datasets based on satellite data, from interpolated and non-interpolated datasets based on in situ data, and from atmospheric reanalyses. Note that these trends over a 23-year-long period primarily reflect decadal variability in winds, rather than long-term climate change (Box 2.2). Kent et al. (2012) recently intercompared several of these datasets and found large differences. The differences in trend patterns in Figure 2.38 are large as well. Nevertheless, some statistically significant features are present in most datasets, including a pattern of positive and negative trend bands across the North Atlantic Ocean (Section 2.7.6.2.) and positive trends along the west coast of North America. Strengthening of the Southern Ocean winds, consistent with the increasing trend in the SAM (Section 2.7.8) and with the observed changes in wind stress fields described in Section 3.4.4, can be seen in satellite-based analyses and atmospheric reanalyses in Figure 2.38. Alternating Southern Ocean trend signs in the NOCS v.2.0 panel are due to interpolation of very sparse in situ data (cf. the panel for the uninterpolated WASWind product).

Surface winds over land have been measured with anemometers on a global scale for decades, but until recently the data have been rarely used for trend analysis. Global datasets lack important meta information on instrumentation and siting (McVicar et al., 2012). Long, homogenized instrumental records are rare (e.g., Usbeck et al., 2010; Wan et al., 2010). Moreover, wind speed trends are sensitive to the anemometer height (Troccoli et al., 2012). Winds near the surface can be derived from reanalysis products (Box 2.3), but discrepancies are found when comparing trends therein with trends for land stations (Smits et al., 2005; McVicar et al., 2008).

Over land, a weakening of seasonal and annual mean as well as maximum winds is reported for many regions from around the 1960s or 1970s to the early 2000s (a detailed review is given in McVicar et al. (2012)), including China and the Tibetan region (Xu et al., 2006b; Guo et al., 2010) (but levelling off since 2000; Lin et al., 2012), western and southern Europe (e.g., Earl et al., 2013), much of the USA (Pryor et al., 2007), Australia (McVicar et al., 2008), and southern and western Canada (Wan et al., 2010). Increasing wind speeds were found at high latitudes in both hemispheres, namely in Alaska from 1921 to 2001 (Lynch et al., 2004), in the central Canadian Arctic and Yukon from the 1950 to the 2000s (Wan et al., 2010), and in coastal Antarctica over the second half of the 20th century (Turner et al., 2005). A global review of 148 studies showed that near-surface terrestrial wind speeds are declining in the Tropics and the mid latitudes of both hemispheres at a rate of -0.14 m s^{-1} per decade (McVicar et al., 2012). Vautard et al. (2010), analysing a global land surface wind dataset from 1979 to 2008, found negative trends on the order of -0.1 m s^{-1} per decade over large portions of Northern Hemispheric land areas. The wind speed trend pattern over land inferred from their data (1988–2010, Figure 2.38) has many points with magnitudes much larger than those in the reanalysis products, which appear to underestimate systematically the wind speed over land, as well as in coastal regions (Kent et al., 2012).

[INSERT FIGURE 2.38 HERE]

Figure 2.38: Trends in surface wind speed for 1988–2010. Shown in the top row are datasets based on the satellite wind observations: (a) Cross-Calibrated Multi-Platform wind product (CCMP, Atlas et al., 2011); (b) wind speed from the Objectively Analyzed Air-Sea Heat Fluxes dataset, release 3 (OAFlux); (c) Blended Sea Winds (BSW, Zhang et al., 2006); in the middle row are datasets based on surface observations: (d) wind speed from the Surface Flux Dataset, v.2, from NOC, Southampton, U.K. (Berry and Kent, 2009); (e) Wave- and Anemometer-based Sea Surface Wind (WASWind, (Tokinaga and Xie, 2011a)); (f) Surface Winds on the Land (Vautard et al., 2010); and in the bottom row are surface wind speeds from atmospheric reanalyses: (g) ERA-Interim; (h) NCEP-NCAR, v.1 (NNR); and (i) 20th century Reanalysis (20CR, Compo et al., 2011). Wind speeds correspond to 10 m heights in all products. Land station winds (panel f) are also for 10 m (but anemometer height is not always reported) except for the Australian data where they correspond to 2 m height. To improve readability of plots, all datasets (including land station data) were averaged to the $4^\circ \times 4^\circ$ uniform longitude-latitude grid. Trends were computed for the annually averaged timeseries of $4^\circ \times 4^\circ$ cells. For all datasets except land station data, an annual mean was considered available only if monthly means for no less than eight months were available in that calendar year. Trend values were computed only if no less than 17 years had values and at least one year was available among the first and last three years of the period. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval).

In summary, *confidence* is *low* in changes in surface wind speed over the land and over the oceans due to remaining uncertainties in datasets and measures used.

2.7.3 Upper-Air Winds

In contrast to surface winds, winds above the planetary boundary layer have received little attention in AR4. Radiosondes and pilot balloon observations are available from around the 1930s (Stickler et al., 2010). Temporal inhomogeneities in radiosonde wind records are less common, but also less studied, than those in radiosonde temperature records (Gruber and Haimberger, 2008; Section 2.4.4.3). Upper air winds can also be derived from tracking clouds or water vapour in satellite imagery (Menzel, 2001) or from measurements using wind profilers, air craft, or thermal observations, all of which serve as an input to reanalyses (Box 2.3).

In the past few years, interest in an accurate depiction of upper air winds has grown, since they are essential for estimating the state and changes of the general atmospheric circulation and for explaining changes in the surface winds (Vautard et al., 2010). Allen and Sherwood (2008), analysing wind shear from radiosonde data, found significant positive zonal mean wind trends in the northern extratropics in the upper troposphere and stratosphere and negative trends in the tropical upper troposphere for the period 1979–2005. Vautard et al. (2010) find increasing wind speed in radiosonde observations in the lower and middle troposphere from 1979 to 2008 over Europe and North America and decreasing wind speeds over Central and Eastern Asia. However, systematic global trend analyses of radiosonde winds are rare, prohibiting an assessment of upper-air wind trends (specific features such as monsoons, jet streams and storms are discussed in Sections 2.7.5, 2.7.6 and 2.6, respectively).

In summary, upper-air winds are less studied than other aspects of the circulation, and less is known about the quality of data products, hence *confidence* in upper-air wind trends is *low*.

2.7.4 Tropospheric Geopotential Height and Tropopause

AR4 concluded that over the NH between 1960 and 2000, boreal winter and annual means of tropospheric GPH decreased over high latitudes and increased over the mid-latitudes. AR4 also reported an increase in tropical tropopause height and a slight cooling of the tropical cold-point tropopause.

Changes in GPH, which can be addressed using radiosonde data or reanalysis data (Box 2.3), reflect SLP and temperature changes in the atmospheric levels below. The spatial gradients of the trend indicate changes in the upper-level circulation. As for SLP, tropospheric GPH trends strongly depend on the period analysed due to pronounced decadal variability. For the 1979–2012 period, trends for 500 hPa GPH from the ERA-Interim reanalysis (Figure 2.36) as well as for other reanalyses show a significant decrease only at southern high latitudes in November to April, but significant positive GPH trends in the subtropics and northern high latitudes. Hence the change in the time period leads to a different trend pattern as compared to AR4. The seasonality and spatial dependence of 500 hPa GPH trends over Antarctica was highlighted by Neff et al. (2008), based upon radiosonde data over the period 1957–2007.

Minimum temperatures near the tropical tropopause (and therefore tropical tropopause height) are important as they affect the water vapour input into the stratosphere (Section 2.2.2.1). Studies since AR4 confirm the increase in tropopause height (Wang et al., 2012c). For tropical tropopause temperatures, studies based on radiosonde data and reanalyses partly support a cooling between the 1990s and the early 2000s (Randel et al., 2006; Randel and Jensen, 2013), but uncertainties in long-term trends of the tropical cold-point tropopause temperature from radiosondes (Wang et al., 2012c; Randel and Jensen, 2013) and reanalyses (Gettelman et al., 2010) are large and *confidence* is therefore *low*.

In summary, tropospheric geopotential height *likely* decreased from 1979 to 2012 at southern high latitudes in austral summer and increased in the subtropics and northern high latitudes. *Confidence* in trends of the tropical cold-point tropopause is *low* due to remaining uncertainties in the data.

2.7.5 Tropical Circulation

In AR4, large interannual variability of the Hadley and Walker circulation was highlighted, as well as the difficulty in addressing changes in these features in the light of discrepancies between datasets. AR4 also found that rainfall in many monsoon systems exhibits decadal changes, but that data uncertainties restrict confidence in trends. SREX also attributed *low confidence* to observed trends in monsoons.

Observational evidence for trends and variability in the strength of the Hadley and Walker circulations (Annex III: Glossary), the monsoons, and the width of the tropical belt is based on radiosonde and reanalyses data (Box 2.3). Additionally, changes in the tropical circulation imprint on other fields that are observed from space (e.g., total ozone, outgoing long-wave radiation). Changes in the average state of the tropical circulation are constrained to some extent by changes in the water cycle (Held and Soden, 2006; Schneider et al., 2010). Changes in the monsoon systems are expressed through altered circulation, moisture transport and convergence, and precipitation. Only a few monsoon studies address circulation changes, while most work focuses on precipitation.

Several studies report a weakening of the global monsoon circulations as well as a decrease of global land monsoon rainfall or of the number of precipitation days over the past 40–50 years (Zhou et al., 2008, see also SREX; Liu et al., 2011). Concerning the East Asian Monsoon, a year-round decrease is reported for wind speeds over China at the surface and in the lower troposphere based on surface observations and radiosonde data (Guo et al., 2010; Jiang et al., 2010; Vautard et al., 2010; Xu et al., 2010). The changes in wind speed are concomitant with changes in pressure centres such as a westward extension of the Western Pacific Subtropical High (Gong and Ho, 2002; Zhou et al., 2009b). A weakening of the East Asian summer monsoon since the 1920s is also found in SLP gradients (Zhou et al., 2009a). However, trends derived from wind observations and circulation trends from reanalysis data carry large uncertainties (Figure 2.38), and monsoon rainfall trends depend, e.g., on the definition of the monsoon area (Hsu et al., 2011). For instance, using a new definition of monsoon area, an increase in northern hemispheric and global summer monsoon (land and ocean) precipitation is reported from 1979 to 2008 (Hsu et al., 2011; Wang et al., 2012a).

The additional datasets that became available since AR4 confirm the large interannual variability of the Hadley and Walker circulation. The strength of the northern Hadley circulation (Figure 2.39) in boreal winter and of the Pacific Walker circulation in boreal fall and winter is largely related to the ENSO (Box 2.5). This association dominates interannual variability and affects trends. Datasets do not agree well with respect to trends in the Hadley circulation (Figure 2.39). Two widely used reanalysis datasets, NNR and ERA-40, both have demonstrated shortcomings with respect to tropical circulation; hence their increases in the Hadley circulation strength since the 1970s might be artificial (Mitas and Clement, 2005; Song and Zhang, 2007; Hu et al., 2011; Stachnik and Schumacher, 2011). Later generation reanalysis datasets including ERA-Interim (Bronnimann et al., 2009; Nguyen et al., 2013) as well as satellite humidity data (Sohn and Park, 2010) also suggest a strengthening from the mid 1970s to present, but the magnitude is strongly dataset dependent.

[INSERT FIGURE 2.39 HERE]

Figure 2.39: a) Indices of the strength of the northern Hadley circulation in December to March (Ψ_{\max} is the maximum of the meridional mass stream function at 500 hPa between the equator and 40°N. b) Indices of the strength of the Pacific Walker circulation in September to January ($\Delta\omega$ is the difference in the vertical velocity between [10°S to 10°N, 180°W to 100°W] and [10°S to 10°N, 100°E to 150°E] as in Oort and Yienger (1996), Δc is the difference in cloud cover between [6°N–12°S, 165°E–149°W] and [18°N–6°N, 165°E–149°W] as in Deser et al. (2010a), v_E is the effective wind index from SSM/I satellite data, updated from Sohn and Park (2010), u is the zonal wind at 10 m averaged in the region [10°S–10°N, 160°E–160°W], ΔSLP is the SLP difference between [5°S–5°N, 160°W–80°W] and [5°S–5°N, 80°E–160°E] as in Vecchi et al. (2006)). Reanalysis datasets include 20CR, NCEP/NCAR, ERA-Interim, JRA-25, MERRA, and CFSR, except for the zonal wind at 10 m (20CR, NCEP/NCAR, ERA-Interim), where available until January 2013. ERA-40 and NCEP2 are not shown as they are outliers with respect to the strength trend of the northern Hadley circulation (Mitas and Clement, 2005; Song and Zhang, 2007; Hu et al., 2011; Stachnik and Schumacher, 2011). Observation datasets include HadSLP2 (Section 2.7.1), ICOADS (Section 2.7.2, only 1957–2009 data are shown) and WASWIND (Section 2.7.2), reconstructions are from Bronnimann et al. (2009). Where more than one time series was available, anomalies from the 1980/1981 to 2009/2010 mean values of each series are shown.

Consistent changes in different observed variables suggest a weakening of the Pacific Walker circulation during much of the 20th century that has been largely offset by a recent strengthening. A weakening is indicated by trends in the zonal SLP gradient across the equatorial Pacific (Section 2.7.1, Table 2.14) from

1861 to 1992 (Vecchi et al., 2006), or from 1901 to 2004 (Power and Kociuba, 2011b). Boreal spring and summer contribute most strongly to the centennial trend (Nicholls, 2008; Karnauskas et al., 2009), as well as to the trend in the second half of the 20th century (Tokinaga et al., 2012). For boreal fall and winter, when the circulation is strongest, no trend is found in the Pacific Walker circulation based on the vertical velocity at 500 hPa from reanalyses (Compo et al., 2011), equatorial Pacific 10 m zonal winds, or SLP in Darwin (Nicholls, 2008; Figure 2.39). However, there are inconsistencies between ERA-40 and NNR (Chen et al., 2008). Deser et al. (2010a) find changes in marine air temperature and cloud cover over the Pacific that are consistent with a weakening of the Walker circulation during most of the 20th century (Section 2.5.7.1 and Yu and Zwiers, 2010). Tokinaga et al. (2012) find robust evidence for a weakening of the Walker circulation (most notably over the Indian Ocean) from 1950 to 2008 based on observations of cloud cover, surface wind, and SLP. Since the 1980s or 1990s, however, trends in the Pacific Walker circulation have reversed (Figure 2.39; Luo et al., 2012). This is evident from changes in SLP (see equatorial SOI trends in Table 2.14 and Box 2.5, Figure 1), vertical velocity (Compo et al., 2011), water vapour flux from satellite and reanalysis data (Sohn and Park, 2010), or sea level height (Merrifield, 2011). It is also consistent with the SST trend pattern since 1979 (Meng et al., 2012, see also Figure 2.22).

Observed changes in several atmospheric parameters suggest that the width of the tropical belt has increased at least since 1979 (Seidel et al., 2008; Forster et al., 2011; Hu et al., 2011). Since AR4, wind, temperature, radiation, and ozone information from radiosondes, satellites, and reanalyses had been used to diagnose the tropical belt width and estimate their trends. Annual mean time series of the tropical belt width from various sources are shown in Figure 2.40.

[INSERT FIGURE 2.40 HERE]

Figure 2.40: Annual average tropical belt width (left) and tropical edge latitudes in each hemisphere (right). The tropopause (red), Hadley cell (blue), and jet stream (green) metrics are based on reanalyses (NCEP/NCAR, ERA-40, JRA25, ERA-Interim, CFSR, and MERRA, see Box 2.3); outgoing longwave radiation (orange) and ozone (black) metrics are based on satellite measurements. The ozone metric refers to equivalent latitude (Hudson et al., 2006; Hudson, 2012). Adapted and updated from Seidel et al. (2008) using data presented in Davis and Rosenlof (2011) and Hudson (2012). Where multiple datasets are available for a particular metric, all are shown as light solid lines, with shading showing their range and a heavy solid line showing their median.

Since 1979 the region of low column ozone values typical of the tropics has expanded in the NH (Hudson et al., 2006; Hudson, 2012). Based on radiosonde observations and reanalyses, the region of the high tropical tropopause has expanded since 1979, and possibly since 1960 (Seidel and Randel, 2007; Birner, 2010; Lucas et al., 2012), although widening estimates from different reanalyses and using different methodologies show a range of magnitudes (Seidel and Randel, 2007; Birner, 2010).

Several lines of evidence indicate that climate features at the edges of the Hadley cell have also moved poleward since 1979. Subtropical jet metrics from reanalysis zonal winds (Strong and Davis, 2007; Archer and Caldeira, 2008b, 2008a; Strong and Davis, 2008) and layer-average satellite temperatures (Fu et al., 2006; Fu and Lin, 2011) also indicate widening, although 1979–2009 wind-based trends (Davis and Rosenlof, 2011) are not statistically significant. Changes in subtropical outgoing longwave radiation, a surrogate for high cloud, also suggest widening (Hu and Fu, 2007), but the methodology and results are disputed (Davis and Rosenlof, 2011). Widening of the tropical belt is also found in precipitation patterns (Hu and Fu, 2007; Davis and Rosenlof, 2011; Hu et al., 2011; Kang et al., 2011; Zhou et al., 2011), including in SH regions (Cai et al., 2012).

The qualitative consistency of these observed changes in independent datasets suggests a widening of the tropical belt between at least 1979 and 2005 (Seidel et al., 2008), and possibly longer. Widening estimates range between around 0° and 3° latitude per decade, but their uncertainties have been only partially explored (Birner, 2010; Davis and Rosenlof, 2011).

In summary, large interannual-to-decadal variability is found in the strength of the Hadley and Walker circulation. The *confidence* in trends in the strength of the Hadley circulation is *low* due to uncertainties in reanalysis datasets. Recent strengthening of the Pacific Walker circulation has largely offset the weakening trend from the 19th century to the 1990s. Several lines of independent evidence indicate a widening of the tropical belt since the 1970s. The suggested weakening of the East Asian monsoon has *low confidence*, given the nature and quality of the evidence.

2.7.6 *Jets, Storm Tracks and Weather Types*

2.7.6.1 *Midlatitude and Subtropical Jets and storm track position*

AR4 reported a poleward displacement of Atlantic and southern polar front jet streams from the 1960s to at least the mid-1990s and a poleward shift of the northern hemispheric storm tracks. However, it was also noted that uncertainties are large and that NNR and ERA-40 disagree in important aspects. SREX also reported a poleward shift of NH and SH storm tracks. Studies since AR4 confirm that in the NH, the jet core has been migrating towards the pole since the 1970s, but trends in the jet speed are uncertain. Additional studies assessed here further support the poleward shift of the North Atlantic storm track from the 1950s to the early 2000s.

Subtropical and midlatitude jet streams are three-dimensional entities that vary meridionally, zonally, and vertically. The position of the midlatitude jet streams is related to the position of the midlatitude storm tracks; regions of enhanced synoptic activity due to the passage of cyclones (Section 2.6). Jet stream winds can be determined from radiosonde measurements of GPH using quasi-geostrophic flow assumptions. Using reanalysis datasets (Box 2.3), it is possible to track 3-dimensional jet variations by identifying a surface of maximum wind (SMW), although a high vertical resolution is required for identification of jets.

Various new analyses based on NCEP/NCAR and ERA-40 reanalyses as well as MSU/AMSU lower stratospheric temperatures (Section 2.4.4) confirm that the jet streams (midlatitude and subtropical) have been moving poleward in most regions in the NH over the last three decades (Fu et al., 2006; Hu and Fu, 2007; Strong and Davis, 2007; Archer and Caldeira, 2008a; Fu and Lin, 2011) but no clear trend is found in the SH (Swart and Fyfe, 2012). There is inconsistency with respect to jet speed trends based upon whether one uses an SMW-based or isobaric-based approach (Strong and Davis, 2007; Archer and Caldeira, 2008b, 2008a; Strong and Davis, 2008) and the choice of analysis periods due to inhomogeneities in reanalyses (Archer and Caldeira, 2008a). In general, jets have become more common (and jet speeds have increased) over the western and central Pacific, eastern Canada, the North Atlantic and Europe (Strong and Davis, 2007; Barton and Ellis, 2009), trends that are concomitant with regional increases in GPH gradients and circumpolar vortex contraction (Frauenfeld and Davis, 2003; Angell, 2006). From a climate dynamics perspective, these trends are driven by regional patterns of tropospheric and lower stratospheric warming or cooling and thus are coupled to large-scale circulation variability.

The North Atlantic storm track is closely associated with the NAO (Schneidereit et al., 2007). Studies based on ERA-40 reanalysis (Schneidereit et al., 2007), SLP measurements from ships (Chang, 2007), sea level time series (Vilibic and Sepic, 2010), and cloud analyses (Bender et al., 2012) support a poleward shift and intensification of the North Atlantic cyclone tracks from the 1950s to the early 2000s (Sorteberg and Walsh, 2008; Cornes and Jones, 2011).

2.7.6.2 *Weather Types and Blocking*

In AR4, weather types were not assessed as such, but an increase in blocking frequency in the Western Pacific and a decrease in North Atlantic were noted.

Changes in the frequency of weather types are of interest since weather extremes are often associated with specific weather types. For instance, persistent blocking of the westerly flow was essential in the development of the 2010 heat wave in Russia (Dole et al., 2011) (Sections 9.5.2.2. and Box 14.2). Synoptic classifications or statistical clustering (Philipp et al., 2007) are commonly used to classify the weather on a given day. Feature-based methods are also used (Crocini-Maspoli et al., 2007a). All these methods require daily SLP or upper-level fields.

Trends in synoptic weather types have been best analysed for Central Europe since the mid-20th century, where several studies describe an increase in westerly or cyclonic weather types in winter but an increase of anticyclonic, dry weather types in summer (Philipp et al., 2007; Werner et al., 2008; Trnka et al., 2009). An eastward shift of blocking events over the North Atlantic (fewer blocking over Greenland and more frequent blocking over the eastern North Atlantic) and the North Pacific was found by Davini et al. (2012) using

NCEP/NCAR reanalysis since 1951 and by Croci-Maspoli et al. (2007a) in ERA-40 reanalysis during the period 1957–2001. Mokhov et al. (2013) find an increase in blocking duration over the NH year-round since about 1990 in a study based on NCEP/NCAR reanalysis data from 1969–2011. For the SH, Dong et al. (2008) found a decrease in number of blocking days but increase in intensity of blocking over the period 1948–1999. Differences in blocking index definitions, the sensitivity of some indices to changes in the mean field, and strong interannual variability in all seasons (Kreienkamp et al., 2010), partly related to circulation variability modes (Croci-Maspoli et al., 2007b), complicate a global assessment of blocking trends.

In summary, there is evidence for a poleward shift of storm tracks and jet streams since the 1970s. Based on the consistency of these trends with the widening of the tropical belt (Section 2.7.5), trends that are based on many different datasets, variables, and approaches, it is *likely* that circulation features have moved poleward since the 1970s. Methodological differences between studies mean there is low confidence in characterizing the global nature of any change in blocking.

2.7.7 Stratospheric Circulation

Changes in the polar vortices were assessed in AR4. A significant decrease in lower-stratospheric GPH in summer over Antarctica since 1969 was found, whereas trends in the Northern Polar Vortex were considered uncertain due to its large variability.

The most important characteristics of the stratospheric circulation for climate and for trace gas distribution are the winter and spring polar vortices and Sudden Stratospheric Warmings (rapid warmings of the middle stratosphere that may lead to a collapse of the Polar Vortex), the Quasi-Biennial Oscillation (an oscillation of equatorial zonal winds with a downward phase propagation), and the Brewer-Dobson circulation (BDC, the meridional overturning circulation transporting air upward in the tropics, poleward to the winter hemisphere, and downward at polar and subpolar latitudes; Annex III: Glossary). Radiosonde observations, reanalysis datasets, and space-borne temperature or trace gas observations are used to address changes in the stratospheric circulation, but all of these sources of information carry large trend uncertainties.

The AR4 assessment was further corroborated in Forster et al. (2011) and in updated 100 hPa GPH trends from ERA-Interim reanalysis (Box 2.3, Figure 2.36). There is *high confidence* that lower stratospheric GPH over Antarctica has decreased in spring and summer at least since 1979. Cohen et al. (2009) reported an increase in the number of Arctic sudden stratospheric warmings during the last two decades. However, interannual variability in the Arctic Polar Vortex is large, uncertainties in reanalysis products are high (Tegtmeier et al., 2008), and trends depend strongly on the time period analysed (Langematz and Kunze, 2008).

The BDC is only indirectly observable via wave activity diagnostics (which represent the main driving mechanism of the BDC), via temperatures or via the distribution of trace gases, which may allow the determination of the ‘age of air’ (i.e., the time an air parcel has resided in the stratosphere after its entry from the troposphere). Randel et al. (2006), found a sudden decrease in global lower stratospheric water vapour and ozone around 2001 that is consistent with an increase in the mean tropical upwelling, i.e., the tropical branch of the BDC (Rosenlof and Reid, 2008; Section 2.2.2.1; Lanzante, 2009; Randel and Jensen, 2013). On the other hand, Engel et al. (2009) found no statistically significant change in the age of air in the 24–35 km layer over the NH midlatitudes from measurements of chemically inert trace gases from 1975 to 2005. However, this does not rule out trends in the lower stratospheric branch of the BDC or trends in mid to low latitude mixing (Bonisch et al., 2009; Ray et al., 2010). All of these methods are subject to considerable uncertainties, and they might shed light only on some aspects of the BDC. *Confidence* in trends in the BDC is therefore *low*.

In summary, it is *likely* that lower-stratospheric geopotential height over Antarctica has decreased in spring and summer at least since 1979. Due to uncertainties in the data and approaches used, *confidence* in trends in the Brewer-Dobson circulation is *low*.

2.7.8 Changes in Indices of Climate Variability

AR4 assessed changes in indices of climate variability. The NAO and SAM were found to exhibit positive trends (strengthened midlatitude westerlies) from the 1960s to 1990s, but the NAO has returned to its long-term mean state since then.

Indices of climate variability describe the state of the climate system with regards to individual modes of climate variability. Together with corresponding spatial patterns, they summarize large fractions of spatio-temporal climate variability. Inferences about significant trends in indices are generally hampered by relative shortness of climate records, their uncertainties, and the presence of large variability on decadal and multidecadal time scales.

Table 2.14 summarizes observed changes in well-known indices of climate variability (see Box 2.5, Table 1 for precise definitions). Even the indices that explicitly include detrending of the entire record (e.g., Deser et al., 2010b), can exhibit statistically significant trends over shorter sub-periods. Confidence intervals in Table 2.14 that do not contain zero indicate trend significance at 10% level; however, the trends significant at 5% and 1% level are emphasized in the discussion below. Chapter 14 discusses the main features and physical meaning of individual climate modes.

The NAO index reached very low values in the winter of 2010 (Osborn, 2011). As a result, with the exception of the PC-based NAO index, which still shows a 5%-significant positive trend from 1951 to present, other NAO or NAM indices do not show significant trends of either sign for the periods presented in Table 2.14. In contrast, the SAM maintained the upward trend (Table 2.14). Fogt et al. (2009) found a positive trend in the SAM index from 1957 to 2005. Visbeck (2009), in a station-based index, found an increase in recent decades (1970s to 2000s).

The observed detrended multidecadal SST anomaly averaged over the North Atlantic Ocean area is often called Atlantic Multidecadal Oscillation Index (AMO, see Box 2.5, Table 1, Figure 1). The warming trend in the “revised” AMO index since 1979 is significant at 1% level (Table 2.14) but cannot be readily interpreted because of the difficulty with reliable removal of the SST warming trend from it (Deser et al., 2010b).

On decadal and inter-decadal timescales the Pacific climate shows an irregular oscillation with long periods of persistence in individual stages and prominent shifts between them. PDO, IPO and NPI indices characterize this variability for both hemispheres and agree well with each other (Box 2.5, Figure 1). While AR4 noted climate impacts of the 1976–1977 PDO phase transition, the shift in the opposite direction, both in PDO and IPO, may have occurred at the end of 1990s (Cai and van Rensch, 2012; Dai, 2012). Significance of 1979–2012 trends in PDO and NPI then would be an artefact of this change; incidentally, no significant trends in these indices was seen for longer periods (Table 2.14). Nevertheless, Pacific changes since the 1980s (positive for NPI and negative for PDO and IPO) are consistent with the observed sea level pressure changes (Section 2.7.1) and with reversing trends in the Walker Circulation (Section 2.7.5), reported to be slowing down during much of the 20th century but sped up again since the 1990s. Equatorial SOI shows an increasing trend since 1979 at 1% significance; more traditionally defined SOI indices do not show significant trends (Table 2.14).

NINO3.4 and NINO3 show a century-scale warming trend significant at 5% level, if computed from the ERSSTv3b dataset (Section 2.4.2) but not if calculated from other datasets (Table 2.14). Furthermore, the sign (and significance) of the trend in east-west SST gradient across the Pacific remains ambiguous (Vecchi and Soden, 2007; Bunge and Clarke, 2009; Karnauskas et al., 2009; Deser et al., 2010a) (Section 14.4.1).

Table 2.14: Trends for selected indices listed in Box 2.5, Table 1. Each index was standardized for its longest available period contained within the 1870–2012 interval. Standardization was done on the DJFM means for the NAO, NAM, and PNA, on seasonal anomalies for PSA1,2, and on monthly anomalies for all other indices. Standardized monthly and seasonal anomalies were further averaged to annual means. Trend values computed for annual or DJFM means are given in standard deviation per decade with their 90% confidence intervals. Index records where the source is not explicitly indicated were computed from either HadISST1 (for SST-based indices), or HadSLP2r (for SLP-based indices), or NNR fields of 500 hPa or 850 hPa geopotential height. CoA stands for ‘Centers of Action’ index definitions. Linear trends for 1870–2012 were removed from ATL3, BMI, and DMI.

Notes:

(a) Trend values significant at the 5% level

(b) Trend values significant at the 1% level

In addition to changes in the mean values of climate indices, changes in the associated spatial patterns are also possible. In particular, the diversity of detail of different ENSO events and possible distinction between their “flavors” have received significant attention (Section 14.4.2). These efforts also intensified the discussion of useful ENSO indices in the literature. Starting from the work of Trenberth and Stepaniak (2001), who proposed to characterize the evolution of ENSO events with the Trans-Niño Index (TNI), which is virtually uncorrelated with the standard ENSO index NINO3.4, other alternative ENSO indices have been introduced and proposals were made for classifying ENSO events according to the indices they primarily maximize. While a traditional, ‘canonical’ El Niño event type (Rasmusson and Carpenter, 1982) is viewed as the ‘eastern Pacific’ type, some of the alternative indices purport to identify events that have central Pacific

maxima and are called dateline El Niño (Larkin and Harrison, 2005), Modoki (Ashok et al., 2007), or Central Pacific El Niño (Kao and Yu, 2009). However, no consensus has been reached regarding the appropriate classification of ENSO events. Takahashi et al. (2011) and Ren and Jin (2011) have presented many of the popular ENSO indices as elements in a two-dimensional linear space spanned by a pair of such indices. ENSO indices that involve Central and Western Pacific SST (NINO4, EMI, TNI) show no significant trends.

Significant positive PNA trends and negative and positive trends in the first and second PSA modes respectively are observed over the last 60 years (Table 2.14). However, the level of significance of these trends depends on the index definition and on the dataset used. The positive trend in the Atlantic Ocean ‘Niño’ mode (AONM) index and in ATL3 are due to the east-intensified warming in the Tropical Atlantic that causes the the weakening of the Atlantic equatorial cold tongue: these changes were noticed by Tokinaga and Xie (2011b) with regards to the last 60-year period. The Indian Ocean Basin Mode (IOBM) has a strong warming trend (significant at 1% since the middle of the 20th century). This phenomenon is well-known (Du and Xie, 2008) and its consequences for the regional climate is a subject of active research (Du et al., 2009; Xie et al., 2009).

In summary, large variability on interannual to decadal time scales and remaining differences between datasets precludes robust conclusions on long-term changes in indices of climate variability. The increase in the NAO index from the 1950s to the 1990s has reversed in more recent periods so that *confidence* in long-term trends is *low*. It is *likely* that the SAM index has become more positive since the 1950s.

Box 2.5: Patterns and Indices of Climate Variability

Much of the spatial structure of climate variability can be described as a combination of ‘preferred’ patterns. The most prominent of these are known as modes of climate variability and impact weather and climate on many spatial and temporal scales (Chapter 14). Individual climate modes historically have been identified through spatial teleconnections: correlations between regional climate variations at widely separated, geographically fixed spatial locations. An index describing temporal variations of the climate mode in question can be formed, e.g., by adding climate anomalies calculated from meteorological records at stations exhibiting the strongest correlation with the mode and subtracting anomalies at stations exhibiting anticorrelation. By regressing climate records from other places on this index, one derives a spatial climate pattern characterizing this mode. Patterns of climate variability have also been derived using a variety of mathematical techniques such as principal component analysis (PCA). These patterns and their indices are useful both because they efficiently describe climate variability in terms of a few preferred modes and also because they can provide clues about how the variability is sustained (Box 14.1 provides formal definitions of these terms).

Box 2.5, Table 1 lists some prominent modes of large-scale climate variability and indices used for defining them. Changes in these indices are associated with large-scale climate variations on interannual and longer time scales. With some exceptions, indices shown have been used by a variety of authors. They are defined relatively simply from raw or statistically analyzed observations of a single climate variable, which has a history of surface observations. For most of these indices at least a century-long record is available for climate research.

[INSERT BOX 2.5, TABLE 1 HERE]

Box 2.5, Table 1: Established indices of climate variability with global or regional influence. Z500, Z700, and Z850 denote geopotential height at the 500, 700 and 850 hPa levels, respectively. Subscript s and a denote "standardized" and "anomalies", respectively. Further information is given in Supplementary Material 2.SM.8. Climate impacts of these modes are listed in Box 14.1.

Most climate modes are illustrated by several indices (Box 2.5, Figure 1), which often behave similarly to each other. Spatial patterns of sea surface temperature (SST) or sea level pressure (SLP) associated with these climate modes are illustrated in Box 2.5, Figure 2. They can be interpreted as a change in the SST or SLP field associated with one standard deviation change in the index.

[INSERT BOX 2.5, FIGURE 1 HERE]

Box 2.5, Figure 1: Some indices of climate variability, as defined in Box 2.5, Table 1, plotted in the 1870–2012 interval. Where ‘HadISST1’, ‘HadSLP2r’, or ‘NNR’ are indicated, the indices were computed from the Sea Surface Temperature (SST) or Sea Level Pressure (SLP) values of the former two datasets or from 500 or 850 hPa geopotential height fields from the NNR. Dataset references given in the panel titles apply to all indices shown in that panel. Where no dataset is specified, a publicly available version of an index from the authors of a primary reference given in Box 2.5, Table 1 was used. All indices were standardized with regard to 1971–2000 period except for NINO3.4 (centralized for 1971–2000) and AMO indices (centralized for 1901–1970). Indices marked as “detrended” had their linear trend for 1870–2012 removed. All indices are shown as 12-month running means except when the temporal resolution is explicitly indicated (e.g., ‘DJFM’ for December-to-March averages) or smoothing level (e.g., 11-year LPF for a low-pass filter with half-power at 11 years).

[INSERT BOX 2.5, FIGURE 2 HERE]

Box 2.5, Figure 2: Spatial patterns of climate modes listed in Box 2.5, Table 1. All patterns shown here are obtained by regression of either Sea Surface Temperature (SST) or Sea Level Pressure (SLP) fields on the standardized index of a climate mode. For each climate mode one of the specific indices shown in Box 2.5, Figure 1 was used, as identified in the panel subtitles. SST and SLP fields are from HadISST1 and HadSLP2r datasets (interpolated gridded products based on datasets of historical observations). Regressions were done on monthly means for all patterns except for NAO and PNA, which were done with the DJFM means, and for PSA1 and PSA2, where seasonal means were used. Each regression was done for the longest period within the 1870–2012 interval when the index was available. For each pattern the time series was linearly de-trended over the entire regression interval. All patterns are shown by color plots, except for PSA2, which is shown by white contours over the PSA1 color plot (contour steps are 0.5 hPa, zero contour is skipped, negative values are indicated by dash).

The difficulty of identifying a universally ‘best’ index for any particular climate mode is due to the fact that no simply defined indicator can achieve a perfect separation of the target phenomenon from all other effects occurring in the climate system. As a result, each index is affected by many climate phenomena whose relative contributions may change with the time period and the dataset used. Limited length and quality of the observational record further compound this problem. Thus the choice of index is always application-specific.

Tables

Table 2.1: Global annual mean surface dry-air mole fractions and their change since 2005 for well-mixed GHG from four measurement networks. Units are ppt except where noted. Uncertainties are 90% confidence intervals. ^aREs (radiative efficiency) and lifetimes (except CH₄ and N₂O, which are from Prather et al., 2012) are from Chapter 8.

Species	Lifetime (yr)	RE (W m ⁻² ppb ⁻¹)	2011 Global Annual Mean			Global Increase from 2005 to 2011		
			UCI	SIO ^b /AGAGE E	NOAA	UCI	SIO ^b /AGAGE	NOAA
CO ₂ (ppm)		1.37 × 10 ⁻⁵		390.48 ± 0.28	390.44 ± 0.16		11.67 ± 0.37	11.66 ± 0.13

Notes:

AGAGE = Advanced Global Atmospheric Gases Experiment; NOAA = National Oceanic and Atmospheric Administration, Earth System Research Laboratory, Global Monitoring Division; SIO = Scripps Institution of Oceanography, University of California, San Diego; UCI = University of California, Irvine, Department of Chemistry. HFC-125 = CHF₂CF₃; HFC-134a = CH₂FCF₃; HFC-143a = CH₃CF₃; HFC-152a = CH₃CHF₂; HFC-23 = CHF₃; CFC-11 = CCl₃F; CFC-12 = CCl₂F₂; CFC-113 = CCIF₂CCl₂F; HCFC-22 = CHClF₂; HCFC-141b = CH₃CCl₂F; HCFC-142b = CH₃CCIF₂.

(a) Each program uses different methods to estimate uncertainties.

(b) SIO reports only CO₂; all other values reported in these columns are from AGAGE. SIO CO₂ program and AGAGE are not affiliated with each other.

Budget lifetimes are shown; for CH₄ and N₂O, perturbation lifetimes (12.4 years for CH₄ and 121 years for N₂O) are used to estimate global warming potentials (Chapter 8)

Year 1750 values determined from air extracted from ice cores are below detection limits for all species except CO₂ (278 ± 2 ppm), CH₄ (722 ± 25 ppb), N₂O (270 ± 7 ppb) and CF₄ (34.7 ± 0.2 ppt). Centennial variations up to 10 ppm CO₂, 40 ppb CH₄, and 10 ppb occur throughout the late-Holocene (Chapter 6).

Table 2.13: Regional observed changes in a range of climate indices since the middle of the 20th century. Assessments are based on a range of ‘global’ studies and assessments (Groisman et al., 2005; Alexander et al., 2006; Caesar et al., 2006; Sheffield and Wood, 2008; Dai, 2011a; Dai, 2011b; Seneviratne et al., 2012; Sheffield et al., 2012; Dai, 2013; Donat et al., 2013a; Donat et al., 2013c; van der Schrier et al., 2013) and selected regional studies as indicated. Bold text indicates where the assessment is somewhat different to SREX Table 3-2. In each such case a footnote explains why the assessment is different. See also Figures 2.32 and 2.33.

Region	Warm Days (e.g., TX90p ^a)	Cold Days (e.g., TX10p ^a)	Warm Nights (e.g., TN90p ^a , TR ^a)	Cold Nights / Frosts (e.g., TN10p ^a , FD ^a)	Heat Waves / Warm Spells ⁸	Extreme Precipitation (e.g., RX1day ^a , R95p ^a , R99p ^a)	Dryness (e.g., CDD ^a) / Drought ¹
North America and Central America	High confidence: <i>Likely</i> overall increase but spatially varying trends ^{1,2}	High confidence: <i>Likely</i> overall decrease but with spatially varying trends ^{1,2}	High confidence: <i>Likely</i> overall increase ^{1,2}	High confidence: <i>Likely</i> overall decrease ^{1,2}	Medium confidence: increases in more regions than decreases ^{1,3} but 1930s dominates longer term trends in the USA ⁴	High confidence: <i>Likely</i> overall increase ^{1,2,5} but some spatial variation High confidence: <i>Very likely</i> increase central North America ^{6,7}	Medium confidence: decrease ¹ but spatially varying trends High confidence^b: <i>Likely</i> decrease central North America⁴
South America	Medium confidence^b: Overall increase⁸	Medium confidence^b: Overall decrease⁸	Medium confidence^b: Overall increase⁸	Medium confidence^b: Overall decrease⁸	Low confidence: insufficient evidence (lack of literature) and spatially varying trends but some evidence of increases in more areas than decreases ⁸	Medium confidence^b: Increases in more regions than decreases^{8,9} but spatially varying trends	Low confidence: Limited literature and spatially varying trends ⁸
Europe and Mediterranean	High confidence: <i>Likely</i> overall increase ^{10,11,12}	High confidence: <i>Likely</i> overall decrease ^{11,12}	High confidence: <i>Likely</i> overall increase ^{11,12}	High confidence: <i>Likely</i> overall decrease ^{10,11,12}	High confidence^b: <i>Likely</i> increases in most regions^{3,13}	High confidence^{b,c}: <i>Likely</i> increases in more regions than decreases^{5,15,16} but regional and seasonal variation	Medium confidence: spatially varying trends High confidence^b: <i>Likely</i> increase in Mediterranean^{17,18}
Africa and Middle East	Low to medium confidence^{b,d}: limited data in many regions but increases in most regions assessed Medium confidence^b:	Low to medium confidence^{b,d}: limited data in many regions but decreases in most regions assessed Medium confidence^b:	Medium confidence^{b,d}: limited data in many regions but increases in most regions assessed Medium confidence^b:	Medium confidence^{b,d}: limited data in many regions but decreases in most regions assessed Medium confidence^b:	Low confidence ^d : insufficient evidence (lack of literature) Medium confidence: increase in North Africa and Middle East and southern	Low confidence ^d : insufficient evidence and spatially varying trends Medium confidence^b: increases in more	Medium confidence ^d : increase ^{19,22,24} High confidence^b: <i>likely</i> increase in West Africa^{25,26} although 1970s Sahel drought dominates

	increase North Africa and Middle East ^{19,20}	decrease North Africa and Middle East ^{19,20}	increase North Africa and Middle East ^{19,20}	decrease North Africa and Middle East ^{19,20}	Africa ^{3,19,21,22}	regions than decreases in southern Africa but spatially varying trends depending on index ^{5,21,22}	the trend
	High confidence ^b : <i>Likely increase southern Africa</i> ^{21,22,23}	High confidence ^b : <i>Likely decrease southern Africa</i> ^{21,22,23}	High confidence ^b : <i>Likely increase southern Africa</i> ^{21,22,23}	High confidence ^b : <i>Likely decrease southern Africa</i> ^{21,22,23}			
Asia (excluding South-east Asia)	High confidence ^{b,e} : <i>Likely overall increase</i> ^{27,28,29,30,31,32}	High confidence ^{b,e} : <i>Likely overall decrease</i> ^{27,28,29,30,31,32}	High confidence ^{b,e} : <i>Likely overall increase</i> ^{27,28,29,30,31,32}	High confidence ^{b,e} : <i>Likely overall decrease</i> ^{27,28,29,30,31,32}	Medium confidence ^{b,e} : Spatially varying trends and insufficient data in some regions High confidence ^{b,c} : <i>Likely more areas of increases than decreases</i> ^{3,28,33}	Low to medium confidence ^{b,e} : Low confidence due to insufficient evidence or spatially varying trends. Medium confidence: increases in more regions than decreases ^{5,34,35,36}	Low to medium confidence ^{b,e} Medium confidence: Increase in eastern Asia ^{36,37}
South-east Asia and Oceania	High confidence ^{b,f} : <i>Likely overall increase</i> ^{27,38,39,40}	High confidence ^{b,f} : <i>Likely overall decrease</i> ^{27,38,39}	High confidence ^{b,f} : <i>Likely overall increase</i> ^{27,38,39,40}	High confidence ^{b,f} : <i>Likely overall decrease</i> ^{27,38,39}	Low confidence (due lack of literature) to high confidence ^{b,f} depending on region High confidence ² : <i>Likely overall increase in Australia</i> ^{3,14,41}	Low confidence (lack of literature) to high confidence ^{b,f} High confidence: <i>Likely decrease in southern Australia</i> ^{42,43} but index and season dependent	Low to medium confidence ^{b,f} : inconsistent trends between studies in SE Asia. Overall increase in dryness in southern and eastern Australia High confidence ^b : <i>Likely increase northwest Australia</i> ^{25,26,44}

1 (a) See Box 2.4, Table 1 for definitions

2 (b) More recent literature updates the assessment from SREX Table 3-2 (including 'global' studies).

3 (c) This represents a measure of the area affected which is different from what was assessed in SREX Table 3-2.

4 (d) This represents a slightly different region than that assessed in SREX Table 3-2 as it includes the Middle East.

5 (e) This represents a slightly different region than that assessed in SREX Table 3-2 as it excludes South-east Asia.

6 (f) This represents a slightly different region than that assessed in SREX Table 3-2 as it combines SE Asia and Oceania.

7 (g) Definitions for warm spells and heat waves vary (Perkins and Alexander, 2012) but here we are commonly assessing the Warm Spell Duration Index (WSDI; Zhang et al., 2011)

8 or other heat wave indices (e.g., HWF, HWM)

1 (Fischer and Schar, 2010; Perkins et al., 2012) that have defined multi-day heat extremes relative to either daily maximum or minimum temperatures (or both) above a high
2 (commonly 90th) percentile relative to a late-20th century reference period.
3 (h) See Box 2.4 and Section 2.6.1 for definitions

1 **Box 2.5, Table 1:** Established indices of climate variability with global or regional influence. Z500, Z700, and Z850 denote geopotential height at the 500, 700 and 850 hPa levels,
 2 respectively. Subscript s and a denote "standardized" and "anomalies", respectively. Further information is given in Supplementary Material 2.SM.8. Climate impacts of these modes
 3 are listed in Box 14.1.
 4

Climate Phenomenon		Index Name	Index Definition	Primary Reference(s)
El Niño – Southern Oscillation (ENSO)	Traditional indices of ENSO-related Tropical Pacific climate variability	NINO1+2	SST _a averaged over [10°S–0°, 90°W–80°W]	Rasmusson and Wallace (1983), Cane (1986)
		NINO3	Same as above but for [5°S–5°N, 150°W–90°W]	
		NINO4	Same as above but for [5°S–5°N, 160°E–150°W]	
		NINO3.4	Same as above but for [5°S–5°N, 170°W–120°W]	Trenberth (1997)
		Troup Southern Oscillation Index (SOI)	Standardized for each calendar month SLP _a difference: Tahiti minus Darwin, x10	Troup (1965)
		SOI	Standardized difference of SLP _{sa} : Tahiti minus Darwin	Trenberth (1984); Ropelewski and Jones (1987)
	Darwin SOI	Darwin SLP _{sa}	Trenberth and Hoar (1996)	
	Equatorial SOI (EQSOI)	Standardized difference of standardized averages of SLP _a over equatorial [5°S–5°N] Pacific Ocean areas: [130°W–80°W] minus [90°E–140°E]	Bell and Halpert (1998)	
	Indices of ENSO events evolution and type	Trans-Niño Index (TNI)	NINO1+2 _s minus NINO4 _s	Trenberth and Stepaniak (2001)
El Niño Modoki Index (EMI)		SST _a [165°E–140°W, 10°S–10°N] minus ½*[110°W–70°W, 15°S–5°N] minus ½*[125°E–145°E, 10°S–20°N]	Ashok et al. (2007)	
Pacific Decadal and Interdecadal Variability	Pacific Decadal Oscillation (PDO)	1st PC of monthly N. Pacific SST _a field [20°N–70°N] with subtracted global mean	Mantua et al. (1997); Zhang et al. (1997)	
	Intedecadal Pacific Oscillation (IPO)	Projection of a global SST _a onto the IPO pattern, which is found as one of the leading Empirical Orthogonal Functions of a low-pass filtered global SST _a field	Folland et al. (1999); Power et al. (1999); Parker et al. (2007)	
	North Pacific Index (NPI)	SLP _a averaged over [30°N–65°N; 160°E–140°W]	Trenberth and Hurrell (1994)	
North Atlantic Oscillation (NAO)	Azores-Iceland NAO Index	SLP _{sa} difference: Lisbon/Ponta Delgada minus Stykkisholmur/ Reykjavik	Hurrell (1995)	
	PC-based NAO Index	Leading PC of SLP _a over the Atlantic sector	Hurrell (1995)	
	Gibraltar – South-west Iceland NAO Index	Standardized for each calendar month SLP _a difference: Gibraltar minus SW Iceland / Reykjavik	Jones et al. (1997)	
Annular modes	Northern Annular Mode (NAM)	PC-based NAM or Arctic Oscillation (AO) index	1st PC of the monthly mean SLP _a poleward of 20°N	Thompson and Wallace (1998, 2000)
	Southern Annular Mode (SAM)	PC-based SAM or Antarctic Oscillation (AAO) index	1st PC of Z850 _a or Z700 _a south of 20°S	Thompson and Wallace (2000)
		Grid-based SAM index: 40°S–70°S difference	Difference between standardized zonally averaged SLP _a at 40°S and 70°S, using gridded SLP fields	Nan and Li (2003)

		Station-based SAM index: 40°S–65°S	Difference in standardized zonal mean SLP _a at 40°S and 65°S, using station data	Marshall (2003)
Pacific/North America (PNA) atmospheric teleconnection		PNA index based on centers of action	$\frac{1}{4}[(20^\circ\text{N}, 160^\circ\text{W}) - (45^\circ\text{N}, 165^\circ\text{W}) + (55^\circ\text{N}, 115^\circ\text{W}) - (30^\circ\text{N}, 85^\circ\text{W})]$ in the Z500 _{sa} field	Wallace and Gutzler (1981)
		PNA from rotated PCA	Rotated PC (RPC) from the analysis of the NH Z500 _a field	Barnston and Livezey (1987).
Pacific/South America (PSA) atmospheric teleconnection		PSA1 and PSA2 mode indices (PC-based)	2nd and 3rd PCs respectively of SH seasonal Z500 _a	Mo and Paegle (2001)
		PSA index (centers of action)	$[-(35^\circ\text{S}, 150^\circ\text{W}) + (60^\circ\text{S}, 120^\circ\text{W}) - (45^\circ\text{S}, 60^\circ\text{W})]$ in the Z500 _a field	Karoly (1989)
			$[(45^\circ\text{S}, 170^\circ\text{W}) - (67.5^\circ\text{S}, 120^\circ\text{W}) + (50^\circ\text{S}, 45^\circ\text{W})]/3$ in the Z500 _a field	Yuan and Li (2008)
Atlantic Ocean Multidecadal Variability		Atlantic Multidecadal Oscillation (AMO) index	10-yr running mean of linearly detrended Atlantic mean SST _a [0°–70°N]	Enfield et al. (2001)
		Revised AMO index	As above, but detrended by subtracting SST _a [60°S–60°N] mean	Trenberth and Shea (2006)
Tropical Atlantic Ocean variability	Atlantic Ocean Niño Mode (AONM)	ATL3	SST _a averaged over [3°S–3°N, 20°W–0°]	Zebiak (1993)
		PC-based AONM	1st PC of the detrended tropical Atlantic monthly SST _a (20°S–20°N)	Deser et al. (2010b)
	Tropical Atlantic Meridional Mode (AMM)	PC-based AMM Index	2nd PC of the detrended tropical Atlantic monthly SST _a (20°S–20°N)	
Tropical Indian Ocean variability	Indian Ocean Basin Mode (IOBM)	Basin mean index (BMI)	SST _a averaged over [40°–110°E, 20°S–20°N]	Yang et al. (2007)
		IOBM, PC-based Index	The 1st PC of the IO detrended SST _a (40°E–110° E, 20°S–20°N)	Deser et al. (2010b)
	Indian Ocean Dipole Mode (IODM)	PC-based IODM index	The 2nd PC of the IO detrended SST _a (40°E–110° E, 20°S–20°N)	
		Dipole Mode Index (DMI)	SST _a difference: [50°E–70°E, 10°S–10°N] minus [90°E–110°E, 10°S–0°]	Saji et al. (1999)

Chapter 2: Observations: Atmosphere and Surface

Coordinating Lead Authors: Dennis L. Hartmann (USA), Albert M.G. Klein Tank (Netherlands), Matilde Rusticucci (Argentina)

Lead Authors: Lisa Alexander (Australia), Stefan Broennimann (Switzerland), Yassine Abdul-Rahman Charabi (Oman), Frank Dentener (EU/Netherlands), Ed Dlugokencky (USA), David Easterling (USA), Alexey Kaplan (USA), Brian Soden (USA), Peter Thorne (USA/Norway/UK), Martin Wild (Switzerland), Panmao Zhai (China)

Contributing Authors: Robert Adler (USA), Richard Allan (UK), Robert Allan (UK), Donald Blake (USA), Owen Cooper (USA), Aiguo Dai (USA), Robert Davis (USA), Sean Davis (USA), Markus Donat (Australia), Vitali Fioletov (Canada), Erich Fischer (Switzerland), Leopold Haimberger (Austria), Ben Ho (USA), John Kennedy (UK), Elizabeth Kent (UK), Stefan Kinne (Germany), James Kossin (USA), Norman Loeb (USA), Cathrine Lund Myhre (Norway), Carl Mears (USA), Christopher Merchant (UK), Steve Montzka (USA), Colin Morice (UK), Joel Norris (USA), David Parker (UK), Bill Randel (USA), Andreas Richter (Germany), Matthew Rigby (UK), Ben Santer (USA), Dian Seidel (USA), Tom Smith (USA), David Stephenson (UK), Ryan Teuling (Netherlands), Junhong Wang (USA), Xiaolan Wang (Canada), Ray Weiss (USA), Kate Willett (UK), Simon Wood (UK)

Review Editors: Jim Hurrell (USA), Jose Marengo (Brazil), Fredolin Tangang (Malaysia), Pedro Viterbo (Portugal)

Date of Draft: 7 June 2013

Figures

Figure 2.1: a) Globally averaged CO₂ dry-air mole fractions from Scripps Institution of Oceanography (SIO) at monthly time resolution based on measurements from Mauna Loa, Hawaii and South Pole (red) and NOAA/ESRL/GMD at quasi-weekly time resolution (blue). SIO values are deseasonalized. b) Instantaneous growth rates for globally averaged atmospheric CO₂ using the same colour code as in (a). Growth rates are calculated as the time derivative of the deseasonalized global averages (Dlugokencky et al., 1994).

Figure 2.2: a) Globally averaged CH₄ dry-air mole fractions from UCI (green; 4 values per year, except prior to 1984, when they are of lower and varying frequency), AGAGE (red; monthly), and NOAA/ESRL/GMD (blue; quasi-weekly). b) Instantaneous growth rate for globally averaged atmospheric CH₄ using the same colour code as in (a). Growth rates were calculated as in Figure 2.1.

Figure 2.3: a) Globally averaged N₂O dry-air mole fractions from AGAGE (red) and NOAA/ESRL/GMD (blue) at monthly resolution. b) Instantaneous growth rates for globally averaged atmospheric N₂O. Growth rates were calculated as in Figure 2.1.

Figure 2.4: Globally averaged dry-air mole fractions at Earth's surface of the major halogen-containing well-mixed GHG. These are derived mainly using monthly mean measurements from the AGAGE and NOAA/ESRL/GMD networks. For clarity, only the most abundant chemicals are shown in different compound classes and results from different networks have been combined when both are available.

Figure 2.5: Water vapour anomalies in the lower stratosphere (~16–19 km) from satellite sensors and in situ measurements normalized to 2000–2011. (a) Monthly mean water vapour anomalies at 83 hPa for 60°S–60°N (blue) determined from HALOE and MLS satellite sensors. (b) Approximately monthly balloon-borne measurements of stratospheric water vapour from Boulder, Colorado at 40°N (green dots; green curve is 15-point running mean) averaged over 16–18 km and monthly means as in (a), but averaged over 30°N–50°N (black).

Figure 2.6: Zonally averaged, annual mean total column ozone in Dobson Units (DU; $1 \text{ DU} = 2.69 \times 10^{16} \text{ O}_3/\text{cm}^2$) from ground-based measurements combining Brewer, Dobson, and filter spectrometer data WOUDC (red), GOME/SCIAMACHY/GOME-2 GSG (green) and merged satellite BUV/TOMS/SBUV/OMI MOD V8 (blue) for a) Non-Polar Global (60°S – 60°N), b) NH (30°N – 60°N), c) Tropics (25°S – 25°N), d) SH (30°S – 60°S) and e) March NH Polar (60°N – 90°N) and October SH Polar (60°S – 90°S). Adapted from Weber et al. (2012; see also for abbreviations).

Figure 2.7: Annual average surface ozone concentrations from regionally representative ozone monitoring sites around the world. a) Europe. b) Asia and North America. c) Remote sites in the Northern and Southern Hemispheres. The station name in the legend is followed by its latitude and height. Time series include data from all times of day and trend lines are linear regressions following the method of Parrish et al. (2012). Trend lines are fit through the full time series at each location, except for Jungfrauoch, Zugspitze, Arosa and Hohenpeissenberg where the linear trends end in 2000 (indicated by the dashed vertical line in a). Twelve of these 19 sites have significant positive ozone trends (i.e., a trend of zero lies outside the 90% confidence interval); the 7 sites with non-significant trends are: Japanese MBL (marine boundary layer), Summit (Greenland), Barrow (Alaska), Storfjofdi (Iceland), Samoa (tropical South Pacific Ocean), Cape Point (South Africa) and South Pole (Antarctica).

Figure 2.8: Relative changes in tropospheric NO₂ column amounts (logarithmic scale) in 7 selected world regions dominated by high NO_x emissions. Values are normalized for 1996 and derived from the GOME (Global Ozone Monitoring Experiment) instrument from 1996 to 2002 and SCIAMACHY (Scanning Imaging Spectrometer for Atmospheric Cartography) from 2003 to 2010 (Hilboll et al., 2013). The regions are indicated in the map inset.

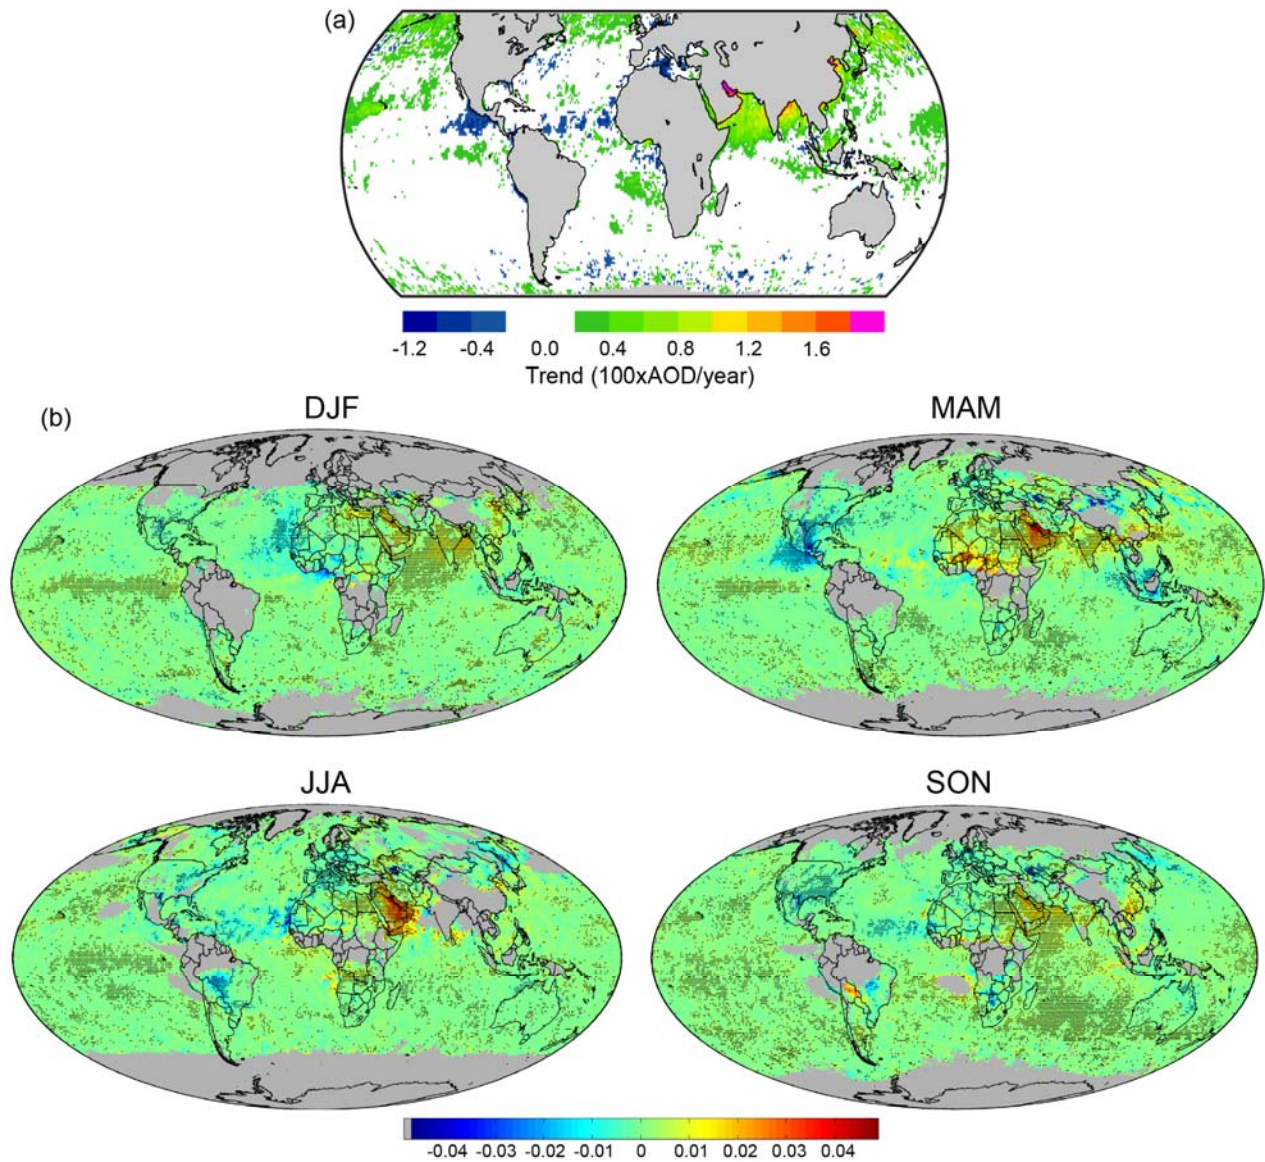

Figure 2.9: a) Annual average Aerosol Optical Depth (AOD) trends at 0.55 μm for 2000–2009, based on de-seasonalized, conservatively cloud-screened MODIS aerosol data over oceans (Zhang and Reid, 2010). Negative AOD trends off Mexico are due to enhanced volcanic activity at the beginning of the record. Most non-zero trends are significant (i.e., a trend of zero lies outside the 95% confidence interval). b) Seasonal average AOD trends at 0.55 μm for 1998 to 2010 using SeaWiFS data (Hsu et al., 2012). Grey areas indicate incomplete or missing data. Black dots indicate significant trends (i.e., a trend of zero lies outside the 95% confidence interval).

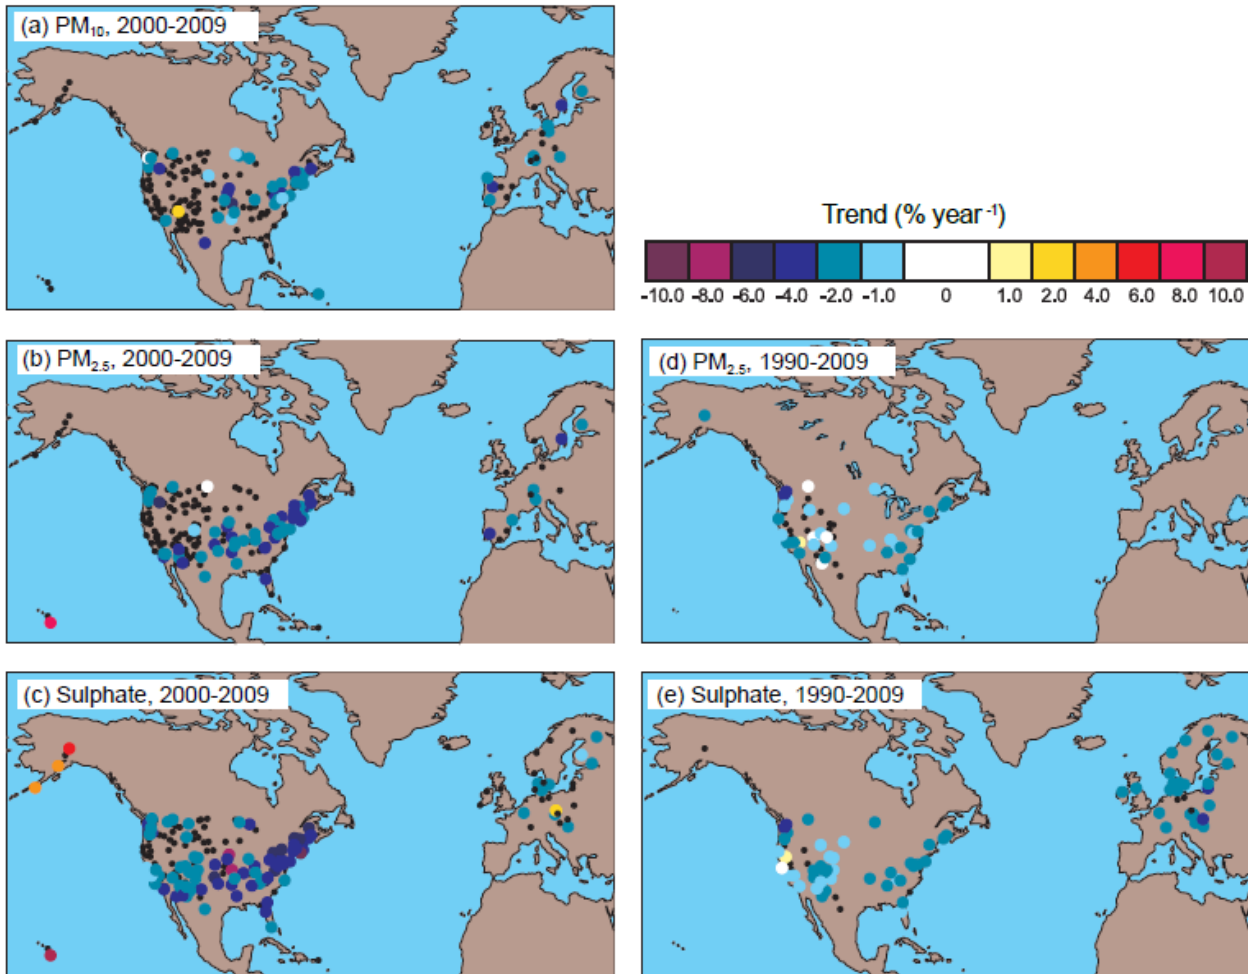

Figure 2.10: Trends in particulate matter (PM₁₀ and PM_{2.5} with aerodynamic diameters < 10 and 2.5 μm , respectively) and sulphate in Europe and USA for two overlapping periods 2000-2009 (a, b, c) and 1990-2009 (d, e). The trends are based on measurements from the EMEP (Torseth et al., 2012) and IMPROVE (Hand et al., 2011) networks in Europe and USA, respectively. Sites with significant trends (i.e., a trend of zero lies outside the 95% confidence interval) are shown in colour; black dots indicate sites with non-significant trends.

Box 2.2, Figure 1: a) Global Mean Surface Temperature (GMST) anomalies relative to a 1961–1990 climatology based on HadCRUT4 annual data. The straight black lines are Least Squares trends for 1901–2012, 1901–1950 and 1951–2012. b) Same data as in a), with Smoothing Spline (solid curve) and the 90% confidence interval on the smooth curve (dashed lines). Note that the (strongly overlapping) 90% confidence intervals for the least square lines in (a) are omitted for clarity. See Figure 2.20 for the other two GMST data products.

Figure 2.11: Global mean energy budget under present day climate conditions. Numbers state magnitudes of the individual energy fluxes in W/m^2 , adjusted within their uncertainty ranges to close the energy budgets. Numbers in parentheses attached to the energy fluxes cover the range of values in line with observational constraints. Figure adapted from Wild et al. (2013).

Figure 2.12: Comparison of net Top Of Atmosphere (TOA) flux and upper Ocean Heating Rates (OHR). Global annual average (July to June) net TOA flux from CERES observations (based upon the EBAF-TOA_Ed2.6r product)(black line) and 0-700 (blue) and 0-1,800 m (red) OHR from the Pacific Marine Environmental Laboratory/Jet Propulsion Laboratory/Joint Institute for Marine and Atmospheric Research (PMEL/JPL/JIMAR), 0-700 m OHR from the National Oceanic Data Center (NODC) (Levitus et al., 2009)(green), and 0-700 m OHR from the Hadley Center (Palmer et al., 2007)(brown). The length of the coloured bars corresponds to the magnitude of OHR. Thin vertical lines are error bars, corresponding to the magnitude of uncertainties. Uncertainties for all annual OHR are given at one standard error derived from ocean heat content anomaly uncertainties (Lyman et al., 2010). CERES net TOA flux uncertainties are given at the 90% confidence level determined following Loeb et al. (2012). Adapted from Loeb et al.(2012).

Figure 2.13: Annual mean Surface Solar Radiation (SSR) as observed at Stockholm, Sweden, from 1923 to 2010. Stockholm has the longest SSR record available worldwide. Updated from Wild (2009) and Ohmura (2009).

Figure 2.14: Global annual average Land-Surface Air Temperature (LSAT) anomalies relative to a 1961–1990 climatology from the latest versions of four different datasets (Berkeley, CRUTEM, GHCN and GISS).

Figure 2.15: Temporal changes in the prevalence of different measurement methods in the International Comprehensive Ocean-Atmosphere Dataset (ICOADS). a) fractional contributions of observations made by different measurement methods: bucket observations (blue), engine room intake (ERI) and hull contact sensor observations (green), moored and drifting buoys (red), and unknown (yellow). b) Global annual average Sea Surface Temperature (SST) anomalies based on different kinds of data: ERI and hull contact sensor (green), bucket (blue), buoy (red), and all (black). Averages are computed over all $5^\circ \times 5^\circ$ where both ERI/hull and bucket measurements, but not necessarily buoy data, were available. Adapted from Kennedy et al. (2011a).

Figure 2.16: Global annual average Sea Surface Temperature (SST) and Night Marine Air Temperature (NMAT) relative to a 1961–1990 climatology from gridded datasets of SST observations (HadSST2 and its successor HadSST3), the raw SST measurement archive (ICOADS, v2.5) and night marine air temperatures dataset HadNMAT2 (Kent et al., 2013). HadSST2 and HadSST3 both are based on SST observations from versions of the ICOADS dataset, but differ in degree of measurement bias correction.

Figure 2.17: Global monthly mean Sea Surface Temperature (SST) anomalies relative to a 1961–1990 climatology from satellites (ATSRs) and in situ records (HadSST3). Black lines: the 100-member HadSST3 ensemble. Red lines: ATSR-based night-time subsurface temperature at 0.2m depth ($SST_{0.2m}$) estimates from the ATSR Reprocessing for Climate (ARC) project. Retrievals based on three spectral channels (D3, solid line) are more accurate than retrievals based on only two (D2, dotted line). Contributions of the three different ATSR missions to the curve shown are indicated at the bottom. The in situ and satellite records were co-located within $5^{\circ} \times 5^{\circ}$ monthly grid boxes: only those where both datasets had data for the same month were used in the comparison. Adapted from Merchant et al. (2012).

Figure 2.18: Global annual average Sea Surface Temperature (SST) and Night Marine Air Temperature (NMAT) relative to a 1961–1990 climatology from state of the art datasets. Spatially interpolated products are shown by solid lines; non-interpolated products by dashed lines.

Figure 2.19: Decadal Global Mean Surface Temperature (GMST) anomalies (white vertical lines in grey blocks) and their uncertainties (90% confidence intervals as grey blocks) based upon the Land-Surface Air Temperature (LSAT) and Sea Surface Temperature (SST) combined HadCRUT4 (v4.1.1.0) ensemble (Morice et al., 2012). Anomalies are relative to a 1961–1990 climatology. 1850s indicates the period 1850–1859, and so on. NCDC MLOST and GISS dataset best-estimates are also shown.

Figure 2.20: Annual Global Mean Surface Temperature (GMST) anomalies relative to a 1961–1990 climatology from the latest version of the three combined Land-Surface Air Temperature (LSAT) and Sea Surface Temperature (SST) datasets (HadCRUT4, GISS and NCDC MLOST). Published dataset uncertainties are not included for reasons discussed in Box 2.1.

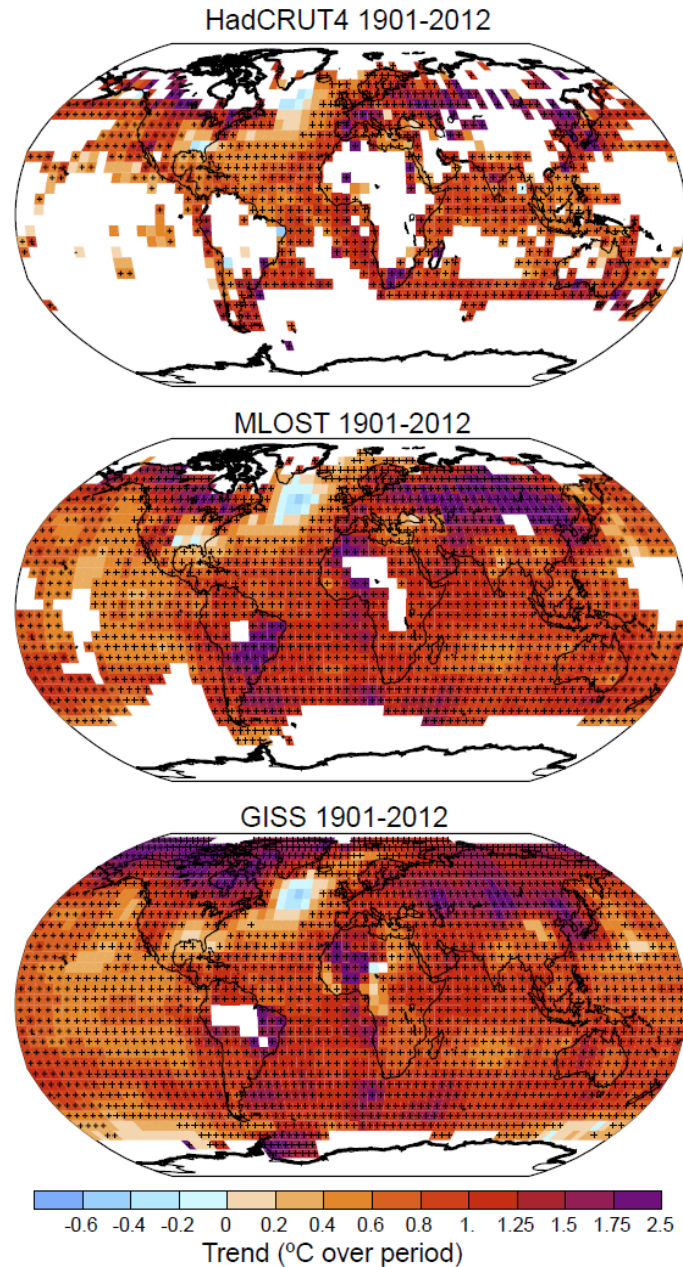

Figure 2.21: Trends in Global Mean Surface Temperature (GMST) from the three datasets of Figure 2.20 for 1901–2012. White areas indicate incomplete or missing data. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). Differences in coverage primarily reflect the degree of interpolation to account for data void regions undertaken by the dataset providers ranging from none beyond grid box averaging (HadCRUT4) to substantial (GISS).

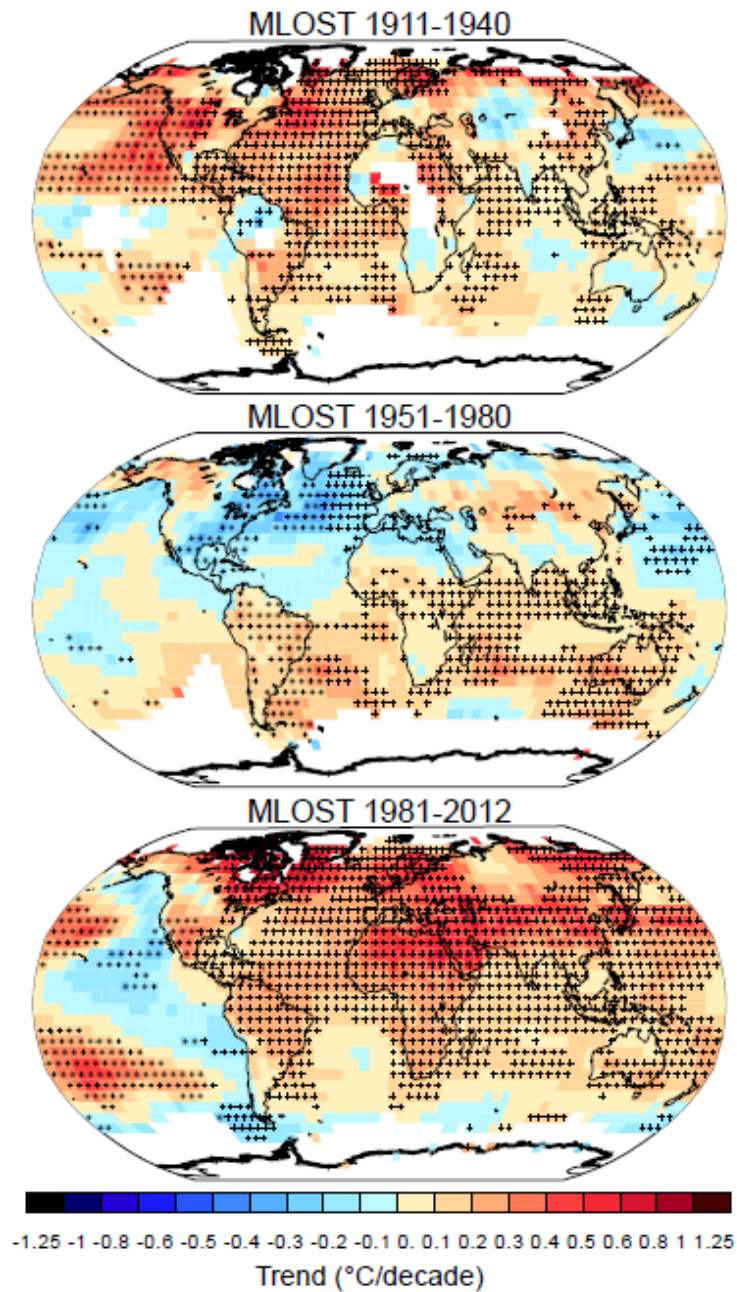

Figure 2.22: Trends in Global Mean Surface Temperature (GMST) from NCDC MLOST for three non-consecutive shorter periods (1911–1940; 1951–1980; 1981–2012). White areas indicate incomplete or missing data. Trends and significance have been calculated as in Figure 2.22.

Figure 2.23: Vertical weighting functions for those satellite temperature retrievals discussed in this chapter (modified from Seidel et al. (2011)). The dashed line indicates the typical maximum altitude achieved in the historical radiosonde record. The three SSU channels are denoted by the designated names 25, 26 and 27. LS (Lower Stratosphere) and MT (Mid Troposphere) are two direct MSU measures and LT (Lower Troposphere) and *G (Global Troposphere) are derived quantities from one or more of these that attempt to remove the stratospheric component from MT.

Figure 2.24: Global annual average lower stratospheric (top) and lower tropospheric (bottom) temperature anomalies relative to a 1981–2010 climatology from different datasets. STAR does not produce a lower tropospheric temperature product. Note that the y-axis resolution differs between the two panels.

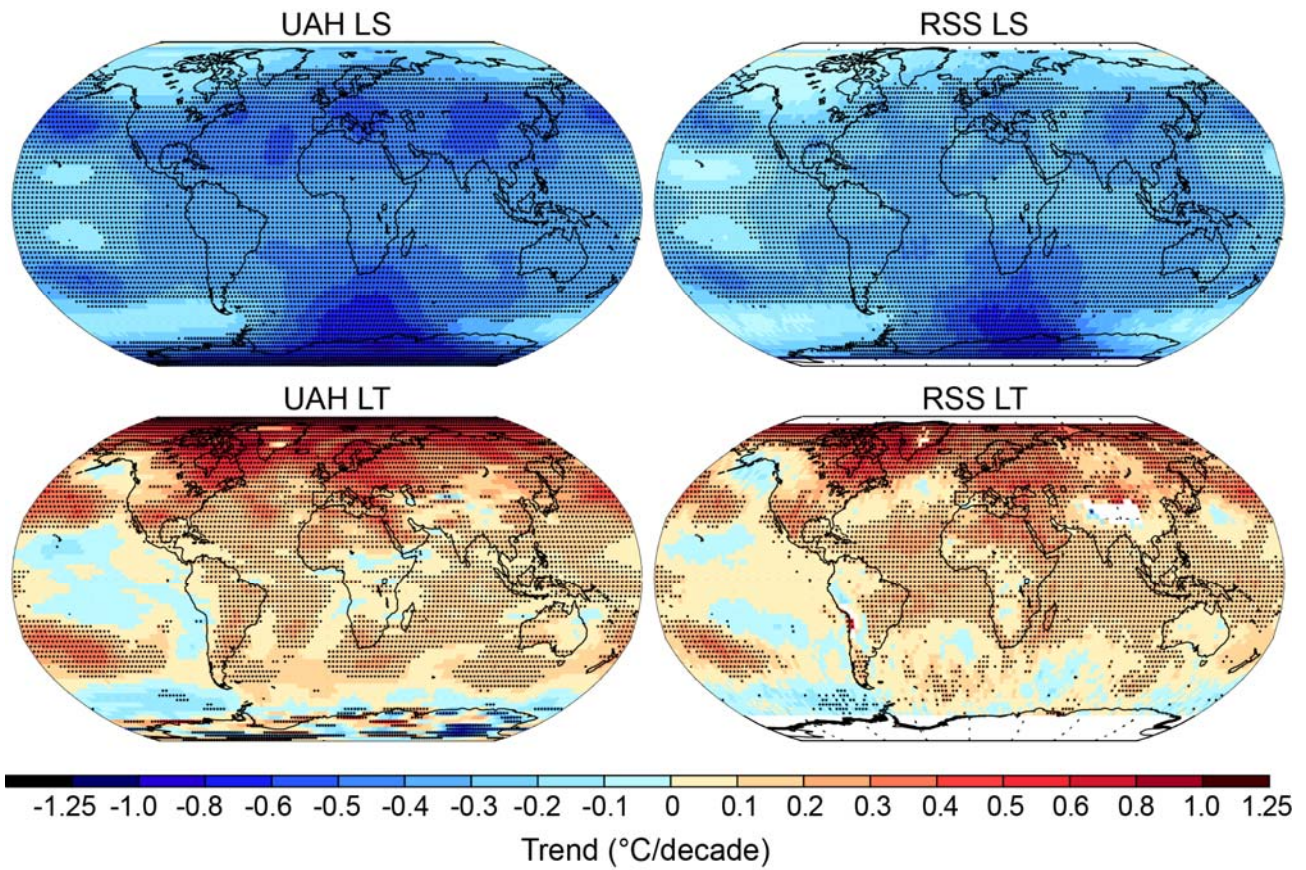

Figure 2.25: Trends in MSU upper air temperature over 1979–2012 from UAH (left hand panels) and RSS (right hand panels) and for LS (top row) and LT (bottom row). Data are temporally complete within the sampled domains for each dataset. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval).

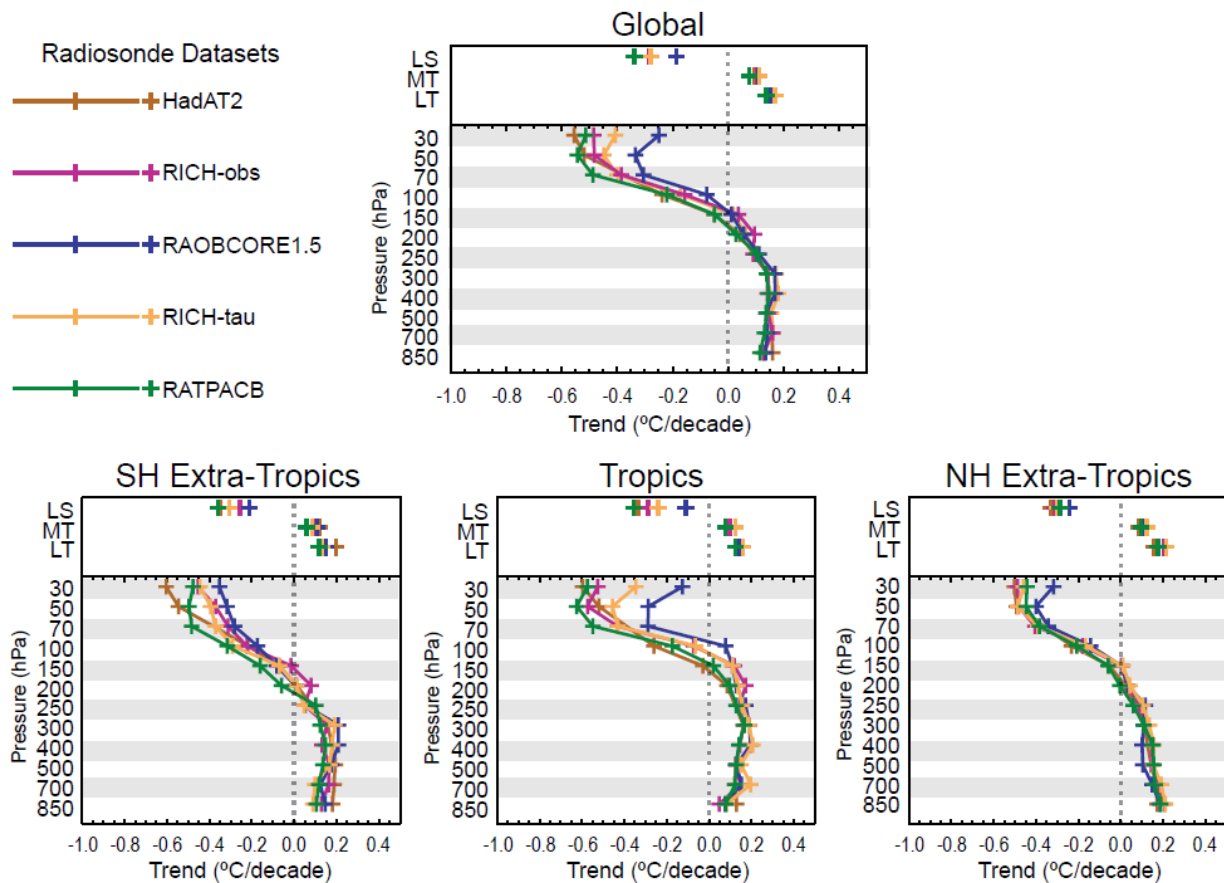

Figure 2.26: Trends in upper air temperature for all available radiosonde data products that contain records for 1958–2012 for the globe (top) and tropics (20°N–20°S) and extra-tropics (bottom). The bottom panel trace in each case is for trends on distinct pressure levels. Note that the pressure axis is not linear. The top panel points show MSU layer equivalent measure trends. MSU layer equivalents have been processed using the method of Thorne et al. (2005). No attempts have been made to sub-sample to a common data mask.

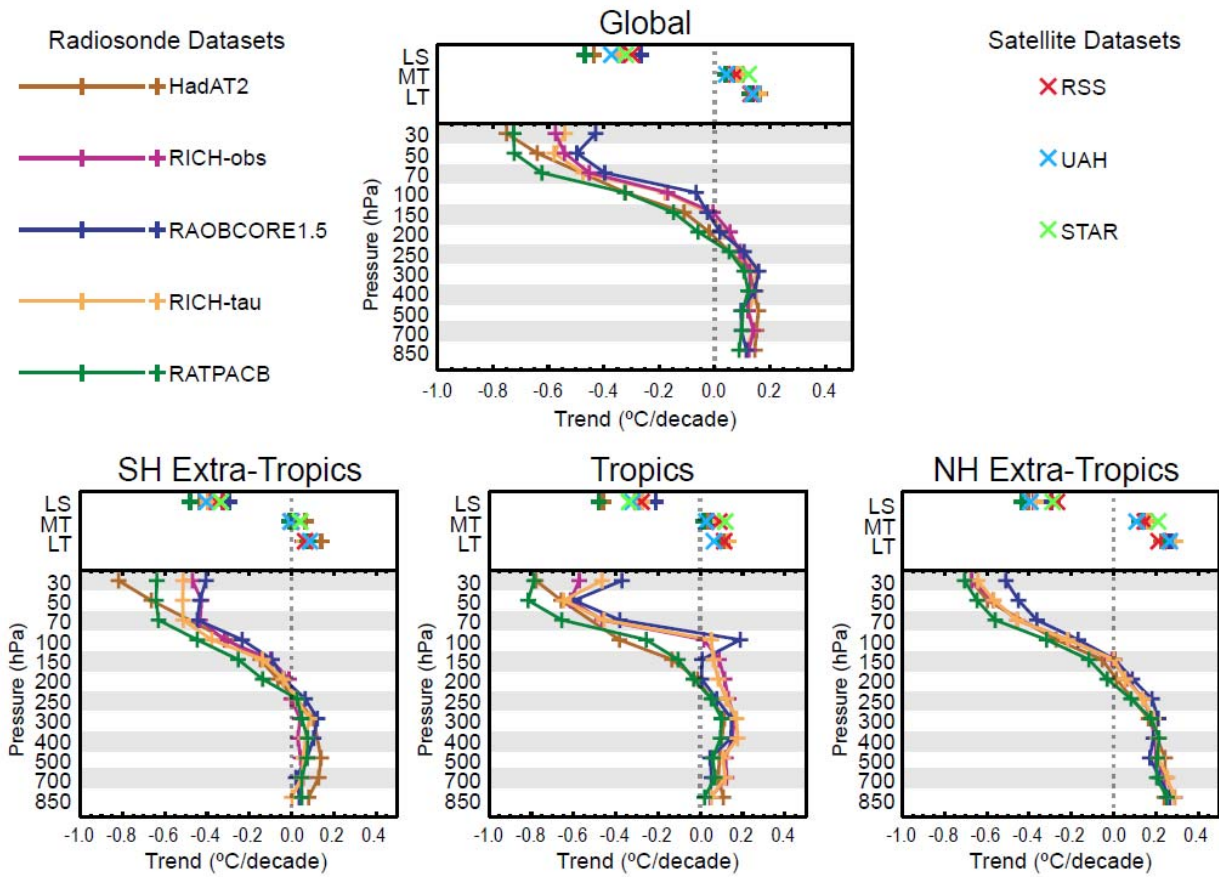

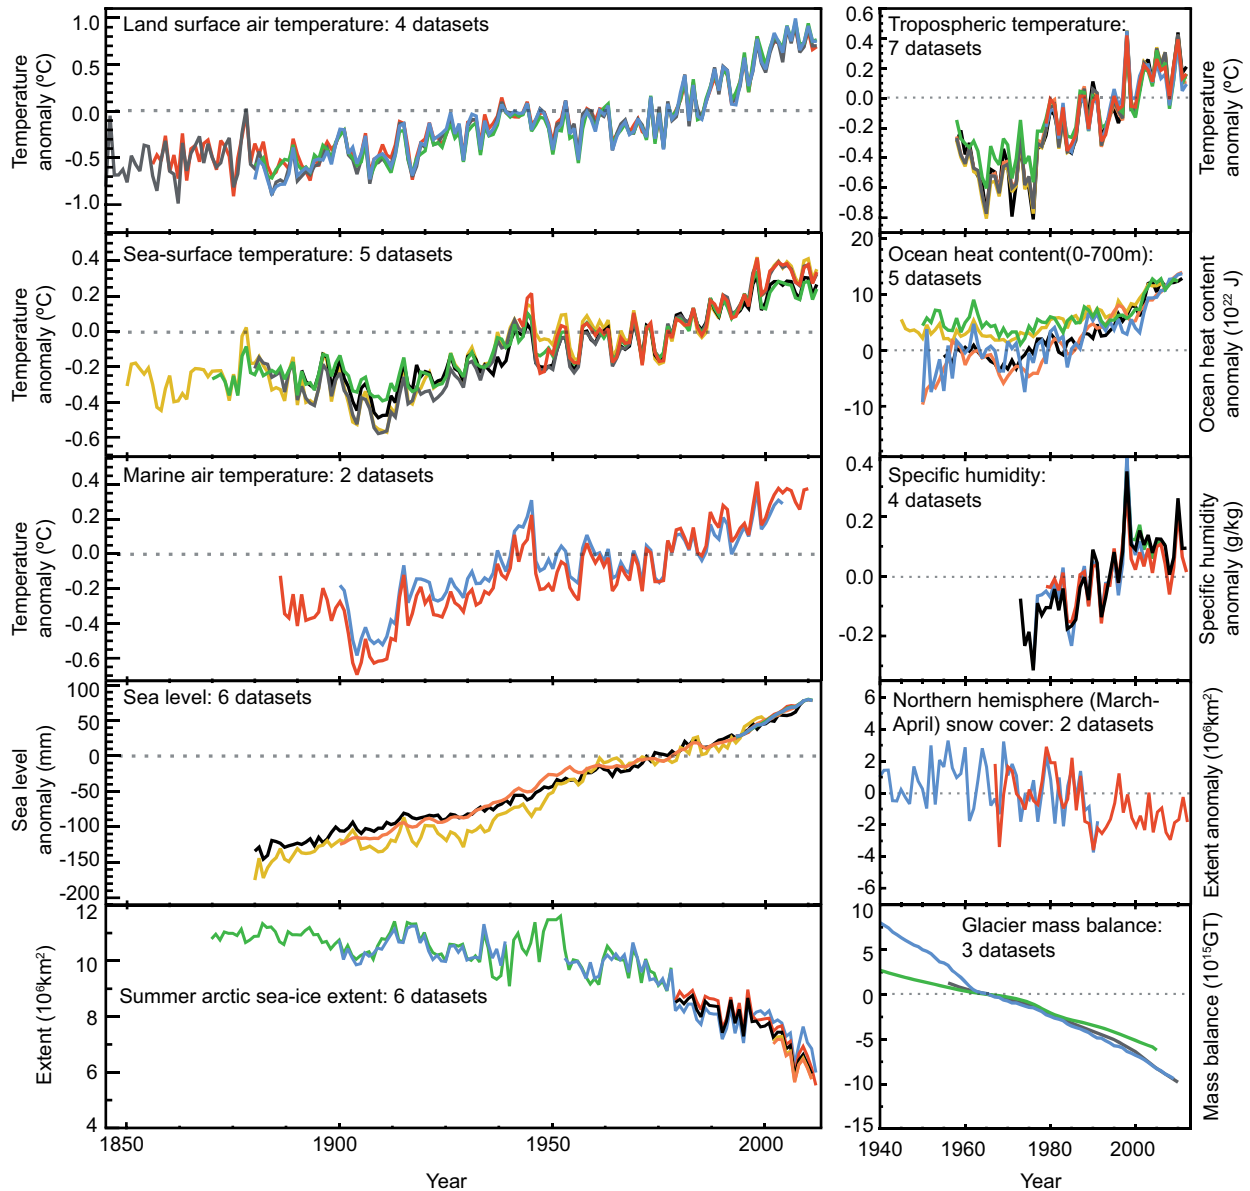

Figure 2.27: As Figure 2.26 except for the satellite era 1979–2012 period and including MSU products (RSS, STAR and UAH).

FAQ 2.1, Figure 1: Independent analyses of many components of the climate system that would be expected to change in a warming world exhibit trends consistent with warming (arrow direction denotes the sign of the change), as shown in FAQ 2.1, Figure 2.

FAQ 2.1, Figure 2: Multiple independent indicators of a changing global climate. Each line represents an independently-derived estimate of change in the climate element. In each panel all datasets have been normalized to a common period of record. A full detailing of which source datasets go into which panel is given in the Supplementary Material 2.SM.5.

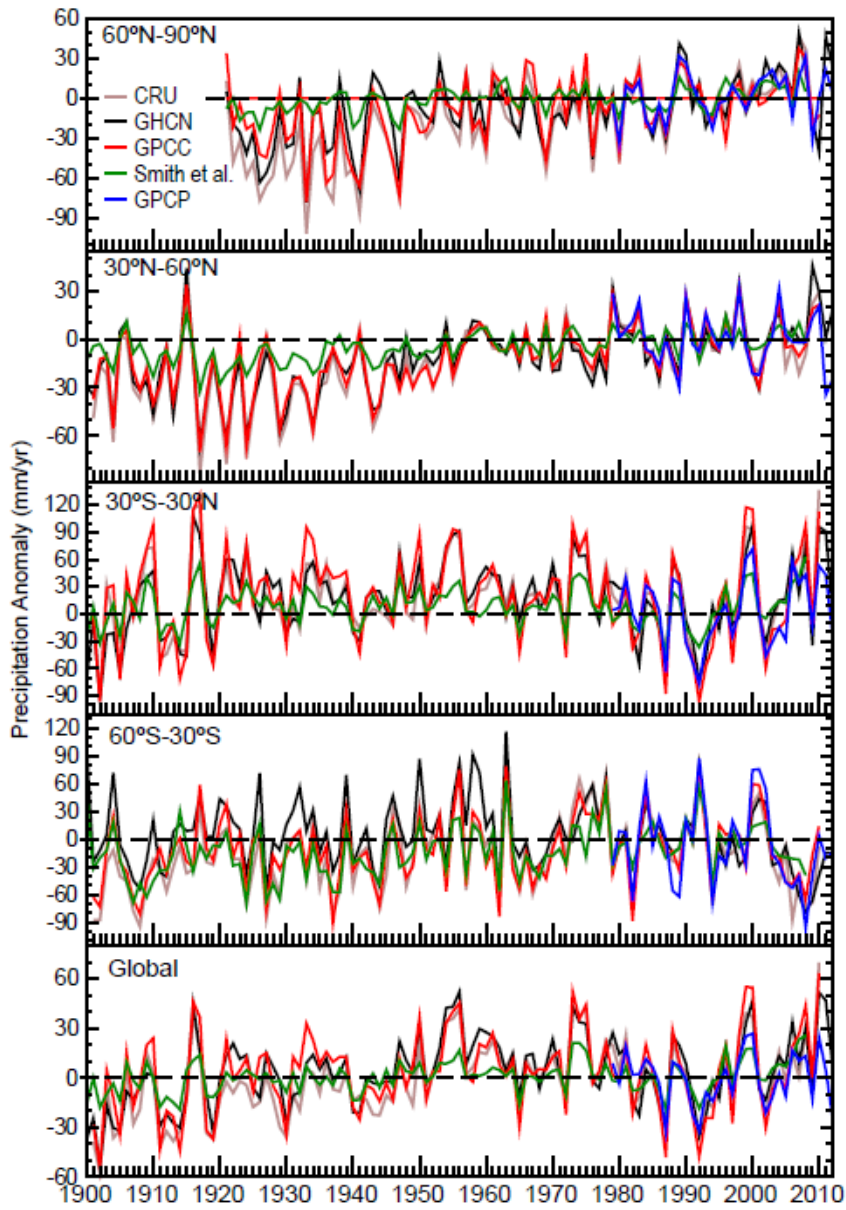

Figure 2.28: Annual precipitation anomalies averaged over land areas for four latitudinal bands and the globe from five global precipitation datasets relative to a 1981–2000 climatology.

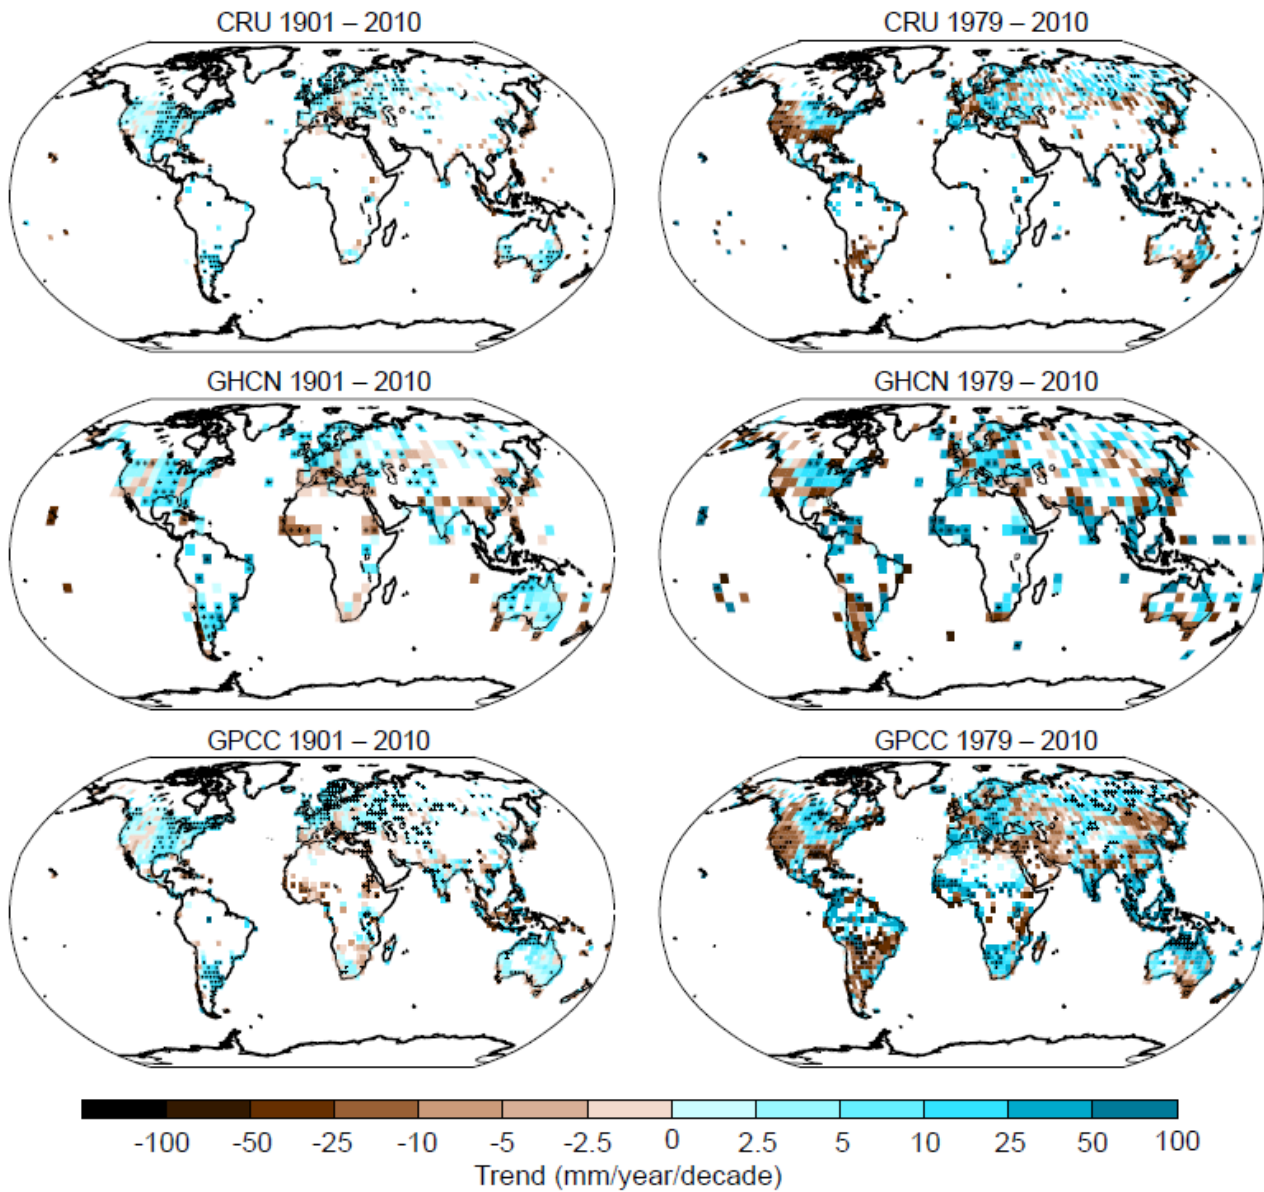

Figure 2.29: Trends in precipitation over land from the CRU, GHCN and GPCC datasets for 1901–2010 (left hand panels) and 1979–2010 (right hand panels). Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval).

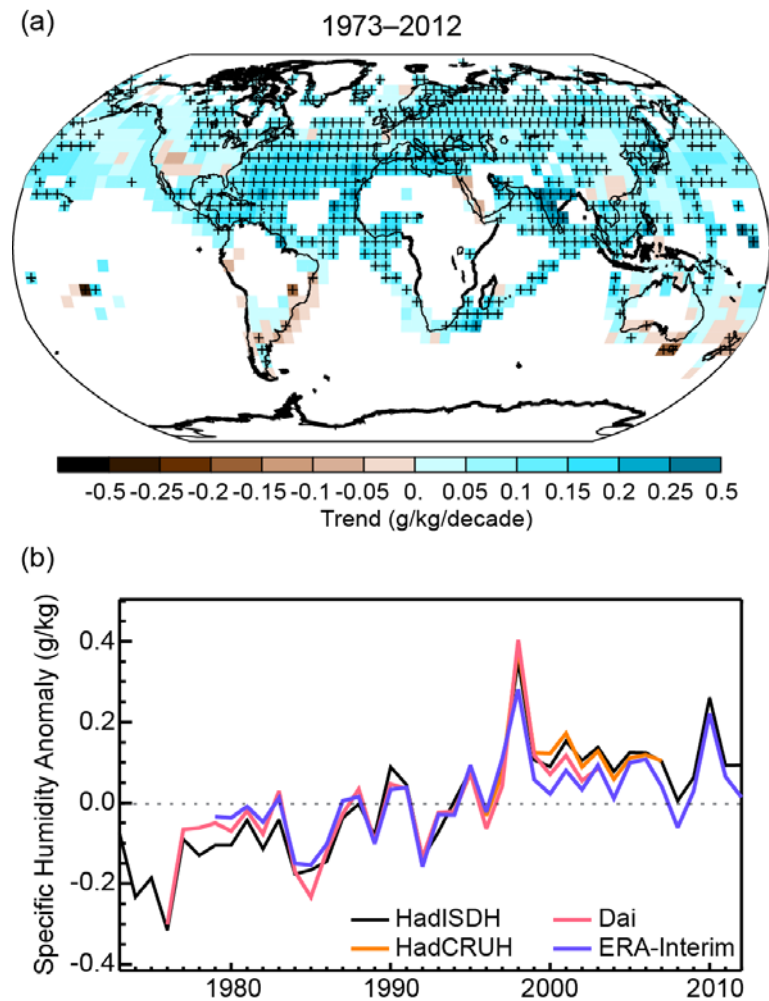

Figure 2.30: a) Trends in surface specific humidity from HadISDH and NOCS over 1973–2012. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). b) Global annual average anomalies in land surface specific humidity from Dai (2006; red), HadCRUH (Willett et al., 2013; orange), HadISDH (Willett et al., 2013; black), and ERA-Interim (Simmons et al., 2010; blue). Anomalies are relative to the 1979–2003 climatology.

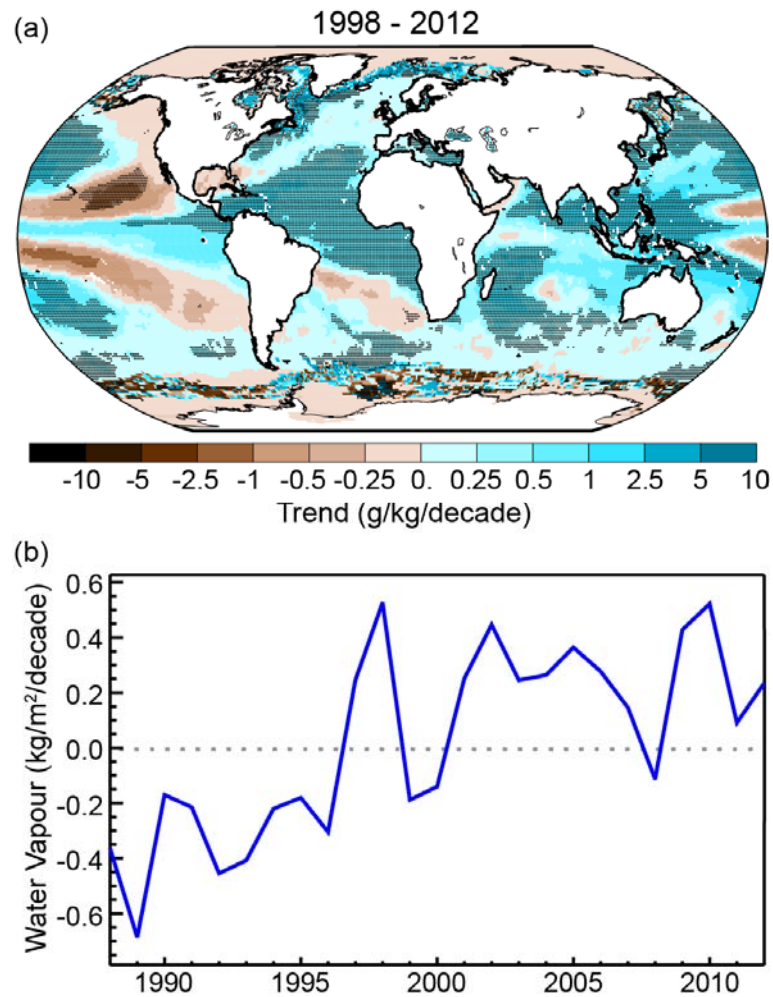

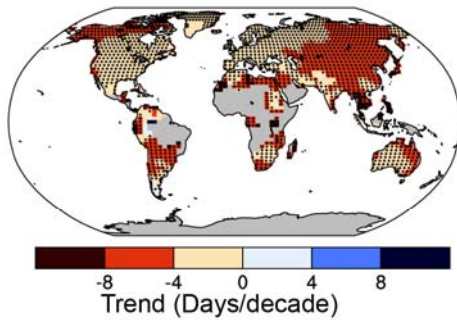

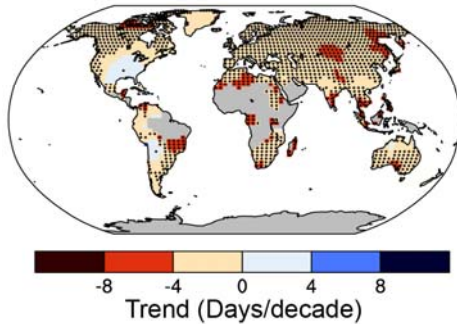

Figure 2.31: a) Trends in column integrated water vapour over ocean surfaces from Special Sensor Microwave Imager, (Wentz et al., 2007) for the period 1988–2010. Trends have been calculated only for those grid boxes with greater than 70% complete records and more than 20% data availability in first and last decile of the period. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). b) Global annual average anomalies in column integrated water vapour averaged over ocean surfaces. Anomalies are relative to the 1988–2007 average.

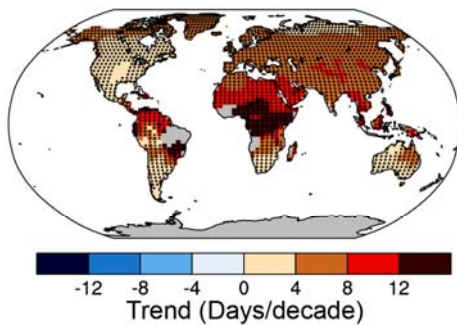

(a) Cold Nights

(b) Cold Days

(c) Warm Nights

(d) Warm Days

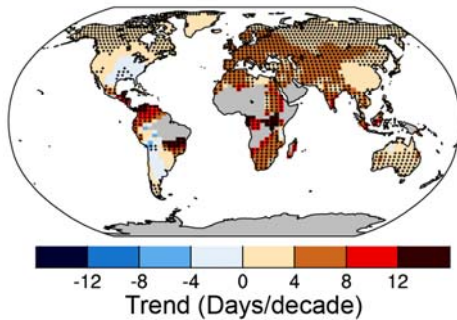

Figure 2.32: Trends in annual frequency of extreme temperatures over the period 1951–2010, for: (a) cold nights (TN10p), (b) cold days (TX10p), (c) warm nights (TN90p) and (d) warm days (TX90p) (Box 2.4, Table 1). Trends were calculated only for grid boxes that had at least 40 years of data during this period and where data ended no earlier than 2003. Grey areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). The data source for trend maps is HadEX2 (Donat et al., 2013c) updated to include the latest version of the European Climate Assessment dataset (Klok and Tank, 2009). Beside each map are the near-global time series of annual anomalies of these indices with respect to 1961–1990 for three global indices datasets: HadEX2 (red); HadGHCND (Caesar et al., 2006; blue) and updated to 2010 and GHCNDEX (Donat et al., 2013a; green). Global averages are only calculated using grid boxes where all three datasets have at least 90% of data over the time period. Trends are significant (i.e., a trend of zero lies outside the 90% confidence interval) for all the global indices shown.

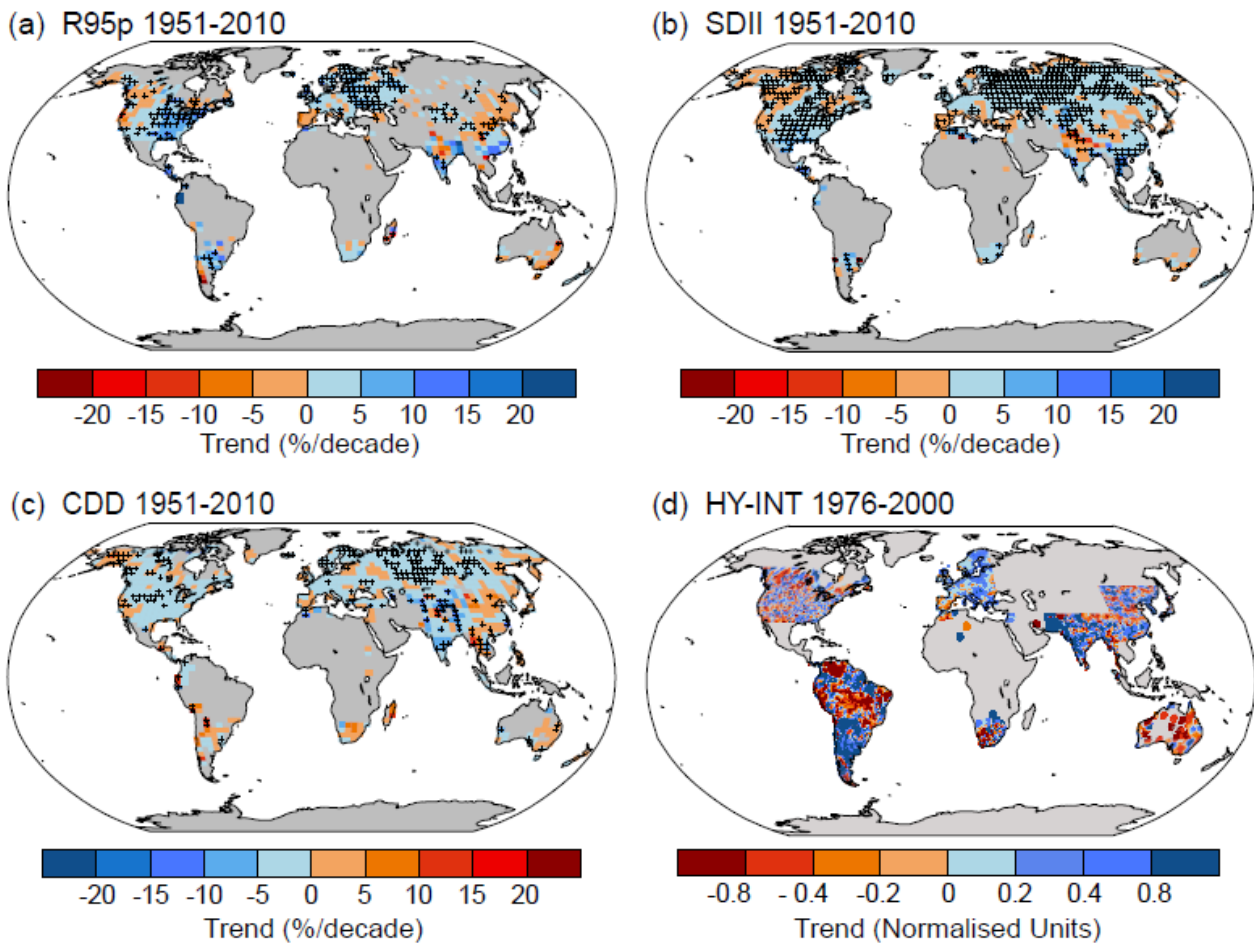

Figure 2.33: Trends in (a) annual amount of precipitation from days >95th percentile (R95p) (b) daily precipitation intensity (SDII) and (c) frequency of the annual maximum number of consecutive dry days (CDD) (Box 2.4, Table 1). Trends are shown as relative values for better comparison across different climatic regions. Trends were calculated only for grid boxes that had at least 40 years of data during this period and where data ended no earlier than 2003. Grey areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). The data source for trend maps is HadEX2 (Donat et al., 2013a) updated to include the latest version of the European Climate Assessment dataset (Klok and Tank, 2009). (d) Trends (normalized units) in hydroclimatic intensity (HY-INT: a multiplicative measure of length of dry spell and precipitation intensity) over the period 1976–2000 (adapted from Giorgi et al. (2011)). An increase (decrease) in HY-INT reflects an increase (decrease) in the length of drought and /or extreme precipitation events.

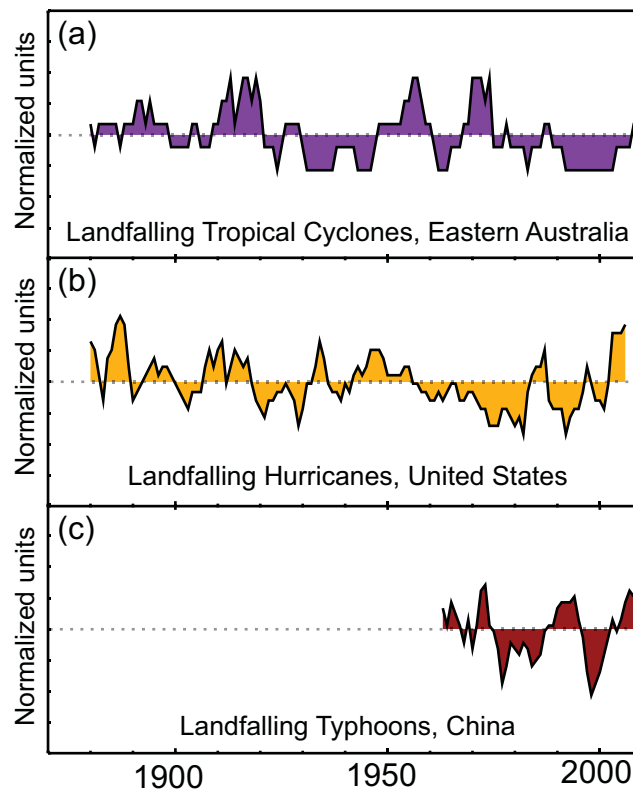

Figure 2.34: Normalized 5-year running means of the number of (a) adjusted land falling eastern Australian tropical cyclones (adapted from Callaghan and Power (2011) and updated to include 2010/2011 season) and (b) unadjusted land falling U.S. hurricanes (adapted from Vecchi and Knutson (2011) and (c) land-falling typhoons in China (adapted from CMA, 2011). Vertical axis ticks represent one standard deviation, with all series normalized to unit standard deviation after a 5-year running mean was applied.

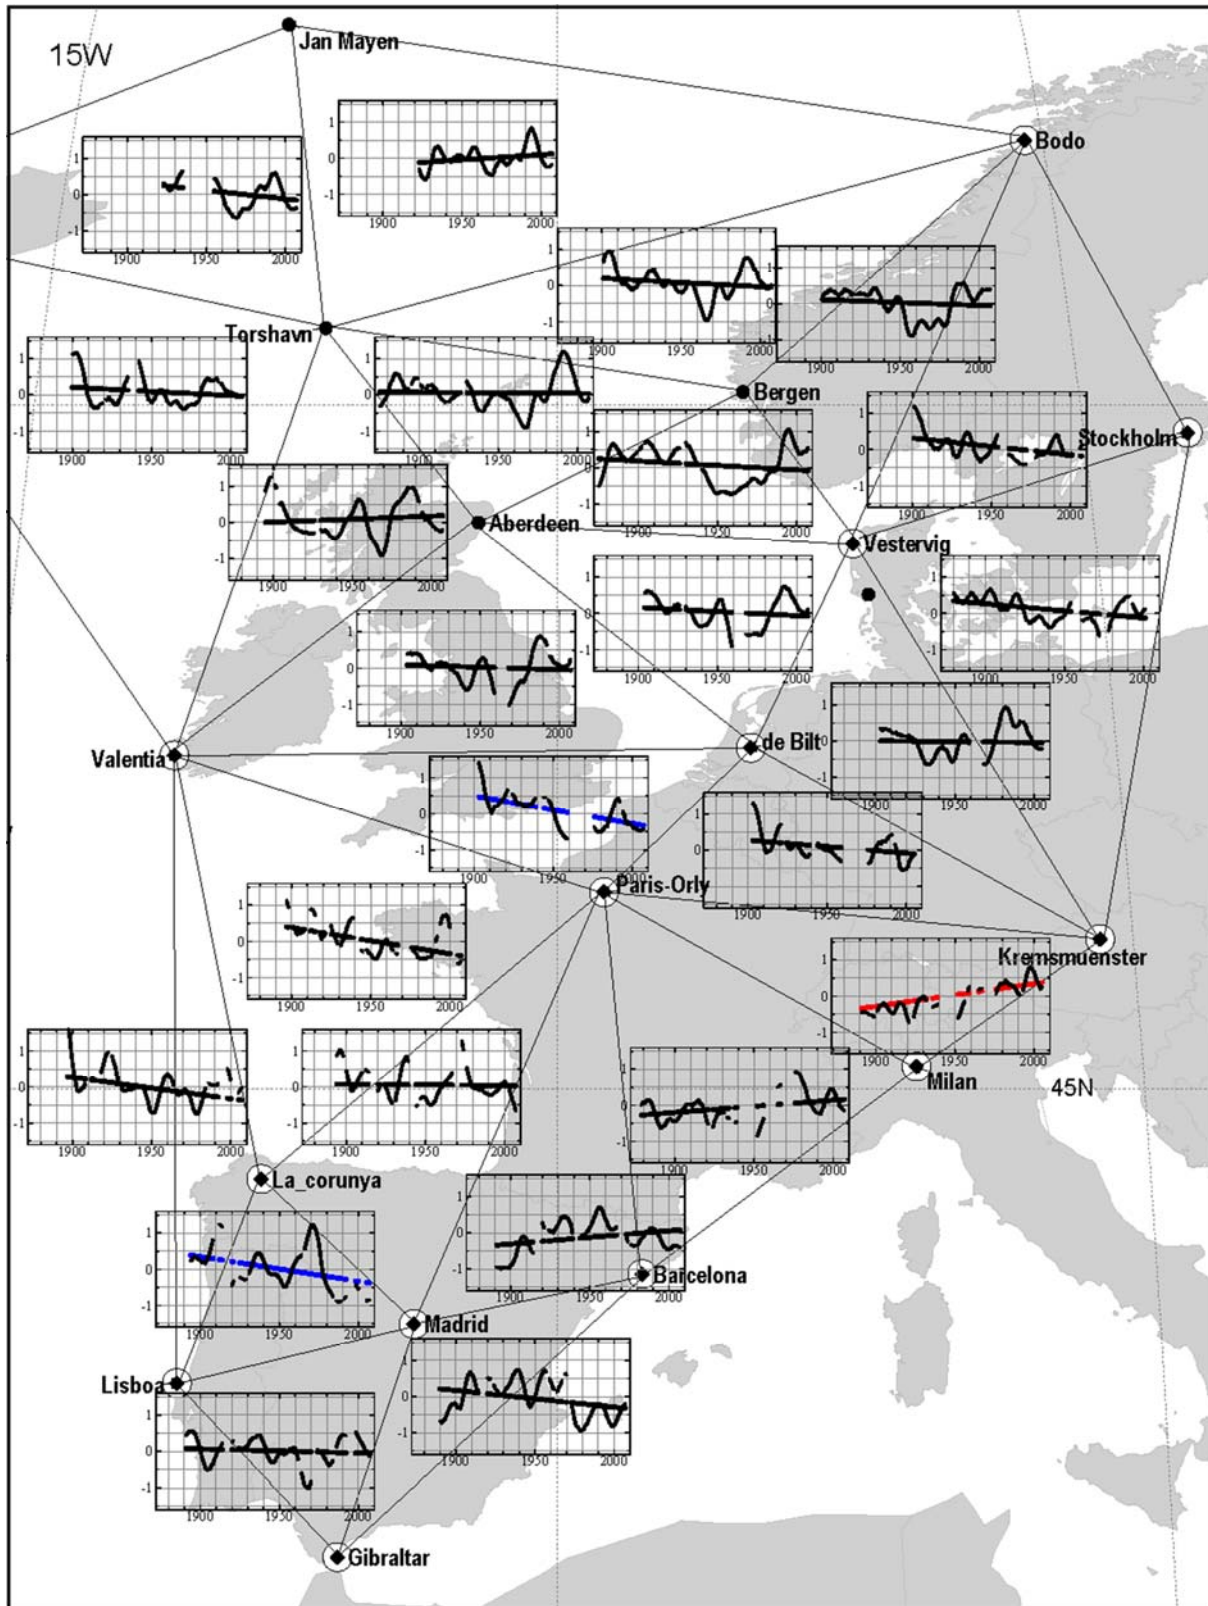

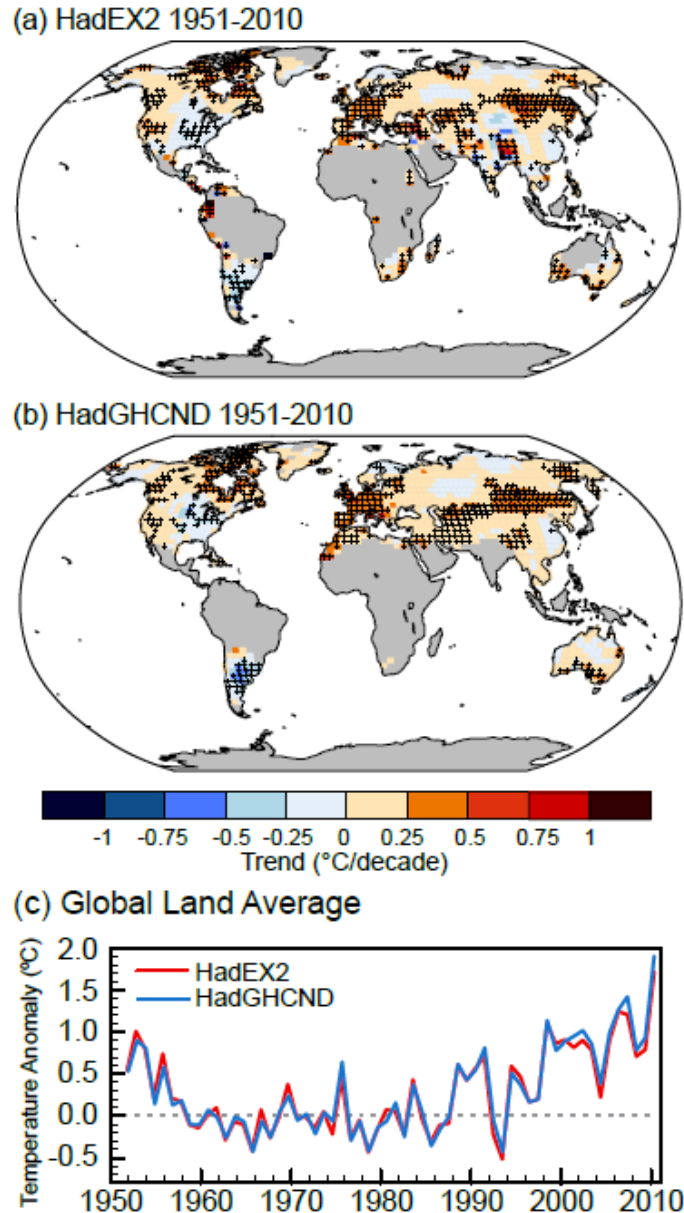

Figure 2.35: 99th percentiles of geostrophic wind speeds for winter (DJF). Triangles show regions where geostrophic wind speeds have been calculated from in situ surface pressure observations. Within each pressure triangle, Gaussian low-pass filtered curves and estimated linear trends of the 99th percentile of these geostrophic wind speeds for winter are shown. The ticks of the time (horizontal) axis range from 1875 to 2005, with an interval of 10 years. Disconnections in lines show periods of missing data. Red (blue) trend lines indicate upward (downward) significant trends (i.e., a trend of zero lies outside the 95% confidence interval). From Wang et al. (2011).

Box 2.4, Figure 1: Trends in the warmest day of the year using different datasets for the period 1951–2010. The datasets are (a) HadEX2 (Donat et al., 2013c) updated to include the latest version of the European Climate Assessment dataset (Klok and Tank, 2009), (b) HadGHCND (Caesar et al., 2006) using data updated to 2010 (Donat et al., 2013a), and (c) Globally averaged annual warmest day anomalies for each dataset. Trends were calculated only for grid boxes that had at least 40 years of data during this period and where data ended no earlier than 2003. Grey areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval). Anomalies are only calculated using grid boxes where both datasets have data and where 90% of data are available.

FAQ 2.2, Figure 1: Distribution of (a) daily minimum and (b) daily maximum temperature anomalies relative to a 1961–1990 climatology for two periods: 1951–1980 (blue) and 1981–2010 (red) using the HadGHCND dataset. The shaded blue and red areas represent the coldest 10% and warmest 10% respectively of (a) nights and (b) days during the 1951–1980 period. The darker shading indicates by how much the number of the coldest days and nights has reduced (dark blue) and by how much the number of the warmest days and nights has increased (dark red) during the 1981–2010 period compared to the 1951–1980 period.

FAQ 2.2, Figure 2: Trends in the frequency (or intensity) of various climate extremes (arrow direction denotes the sign of the change) since the middle of the 20th century (except for North Atlantic storms where the period covered is from the 1970s).

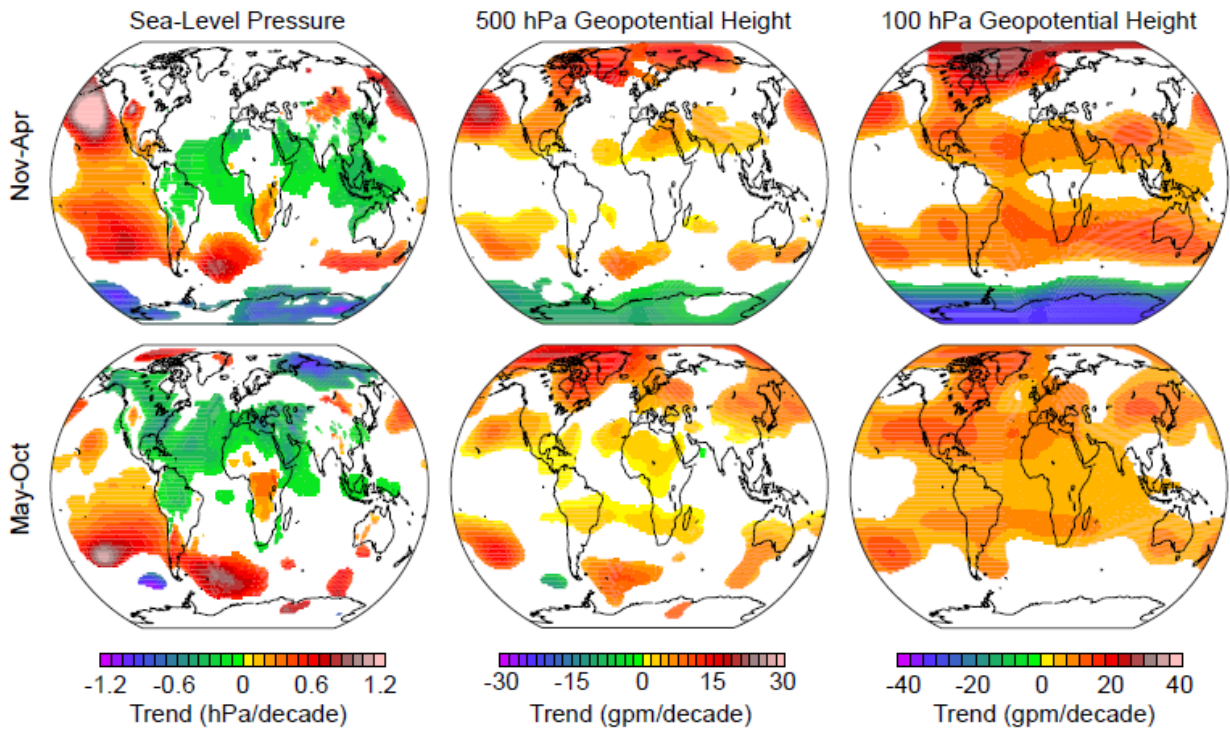

Figure 2.36: Trends in (left) Sea Level Pressure (SLP), (middle) 500 hPa geopotential height (GPH), and (right) 100 hPa GPH in (top) November to April 1979/1980 to 2011/2012 and (bottom) May to October 1979 to 2011 from ERA-Interim data. Trends are only shown if significant (i.e., a trend of zero lies outside the 90% confidence interval).

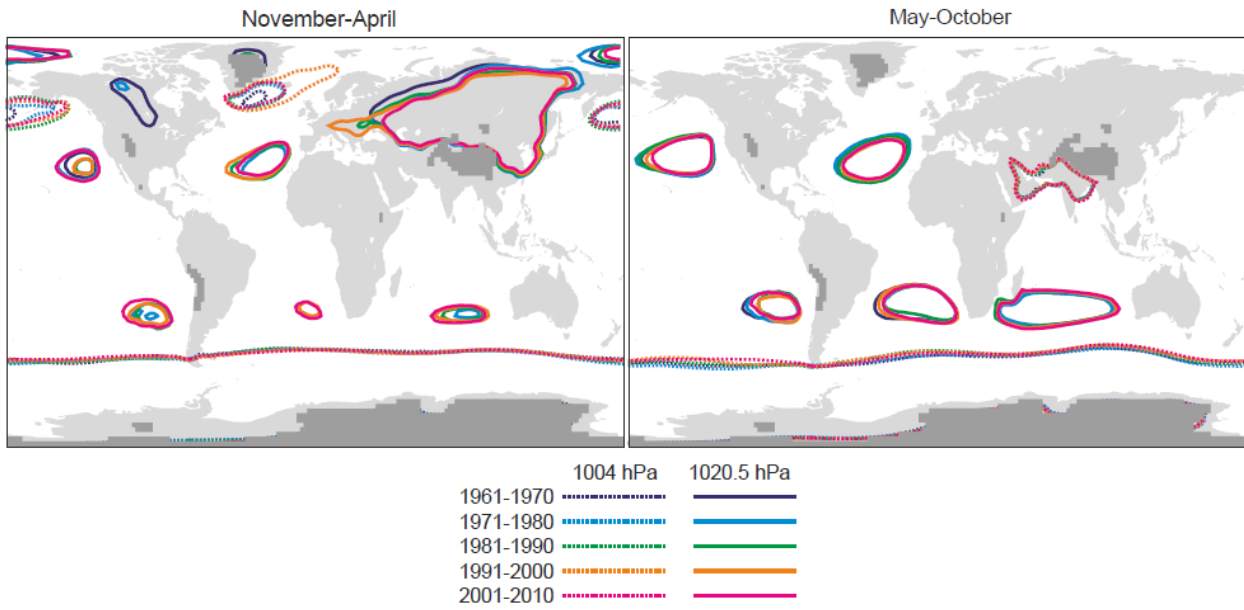

Figure 2.37: Decadal averages of Sea Level Pressure (SLP) from the 20th century Reanalysis (20CR) for (left) November of previous year to April and (right) May to October shown by two selected contours: 1004 hPa (dashed lines) and 1020.5 hPa (solid lines). Topography above 2 km above mean sea level in 20CR is shaded in dark grey.

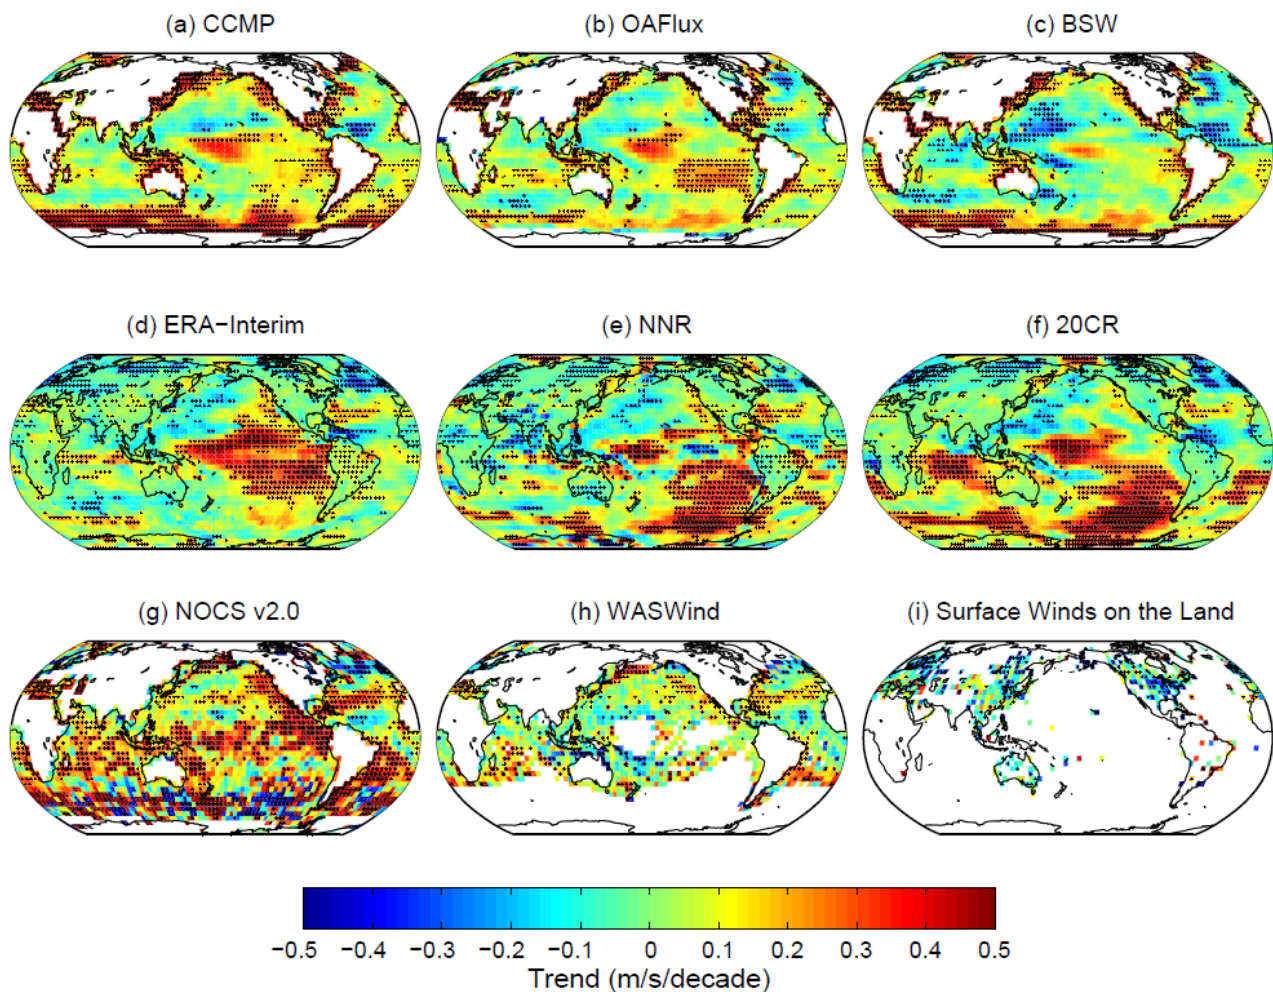

Figure 2.38: Trends in surface wind speed for 1988–2010. Shown in the top row are datasets based on the satellite wind observations: (a) Cross-Calibrated Multi-Platform wind product (CCMP, Atlas et al., 2011); (b) wind speed from the Objectively Analyzed Air-Sea Heat Fluxes dataset, release 3 (OAFlux); (c) Blended Sea Winds (BSW, Zhang et al., 2006); in the middle row are datasets based on surface observations: (d) wind speed from the Surface Flux Dataset, v.2, from NOC, Southampton, U.K. (Berry and Kent, 2009); (e) Wave- and Anemometer-based Sea Surface Wind (WASWind, (Tokinaga and Xie, 2011a)); (f) Surface Winds on the Land (Vautard et al., 2010); and in the bottom row are surface wind speeds from atmospheric reanalyses: (g) ERA-Interim; (h) NCEP-NCAR, v.1 (NNR); and (i) 20th century Reanalysis (20CR, Compo et al., 2011). Wind speeds correspond to 10 m heights in all products. Land station winds (panel f) are also for 10 m (but anemometer height is not always reported) except for the Australian data where they correspond to 2 m height. To improve readability of plots, all datasets (including land station data) were averaged to the $4^\circ \times 4^\circ$ uniform longitude-latitude grid. Trends were computed for the annually averaged timeseries of $4^\circ \times 4^\circ$ cells. For all datasets except land station data, an annual mean was considered available only if monthly means for no less than eight months were available in that calendar year. Trend values were computed only if no less than 17 years had values and at least one year was available among the first and last three years of the period. White areas indicate incomplete or missing data. Black plus signs (+) indicate grid boxes where trends are significant (i.e., a trend of zero lies outside the 90% confidence interval).

Figure 2.39: a) Indices of the strength of the northern Hadley circulation in December to March (Ψ_{\max} is the maximum of the meridional mass stream function at 500 hPa between the equator and 40°N. b) Indices of the strength of the Pacific Walker circulation in September to January ($\Delta\omega$ is the difference in the vertical velocity between [10°S to 10°N, 180°W to 100°W] and [10°S to 10°N, 100°E to 150°E] as in Oort and Yienger (1996), Δc is the difference in cloud cover between [6°N–12°S, 165°E–149°W] and [18°N–6°N, 165°E–149°W] as in Deser et al. (2010a), v_E is the effective wind index from SSM/I satellite data, updated from Sohn and Park (2010), u is the zonal wind at 10 m averaged in the region [10°S–10°N, 160°E–160°W], ΔSLP is the SLP difference between [5°S–5°N, 160°W–80°W] and [5°S–5°N, 80°E–160°E] as in Vecchi et al. (2006)). Reanalysis datasets include 20CR, NCEP/NCAR, ERA-Interim, JRA-25, MERRA, and CFSR, except for the zonal wind at 10 m (20CR, NCEP/NCAR, ERA-Interim), where available until January 2013. ERA-40 and NCEP2 are not shown as they are outliers with respect to the strength trend of the northern Hadley circulation (Mitas and Clement, 2005; Song and Zhang, 2007; Hu et al., 2011; Stachnik and Schumacher, 2011). Observation datasets include HadSLP2 (Section 2.7.1), ICOADS (Section 2.7.2, only 1957–2009 data are shown) and WASWIND (Section 2.7.2), reconstructions are from Broennimann et al. (2009). Where more than one time series was available, anomalies from the 1980/1981 to 2009/2010 mean values of each series are shown.

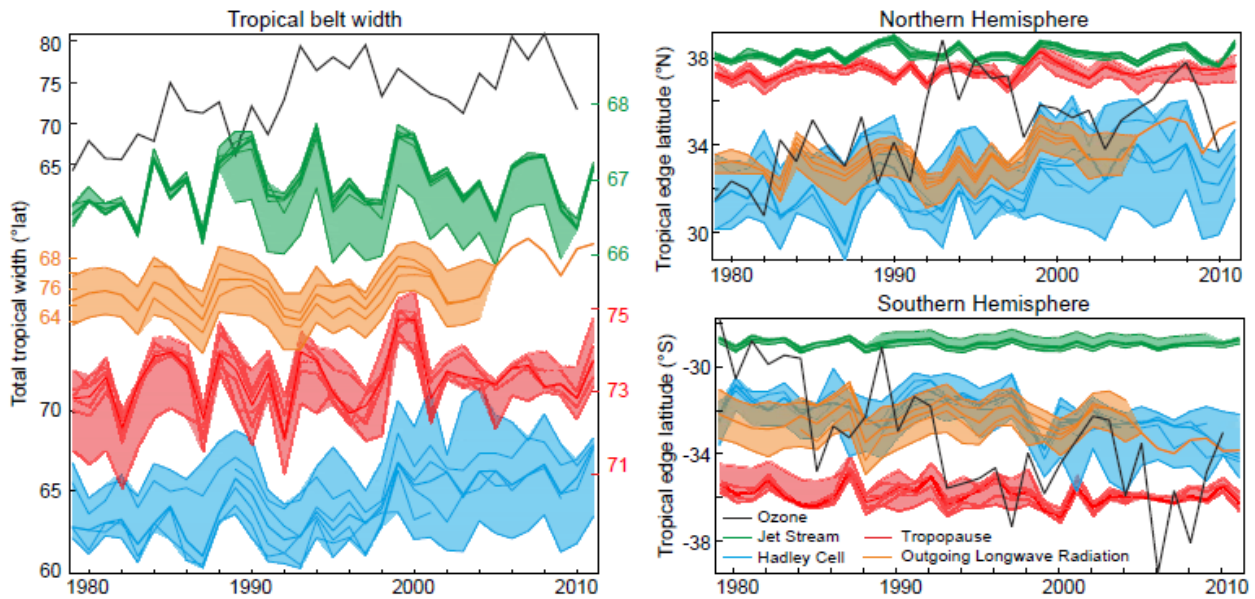

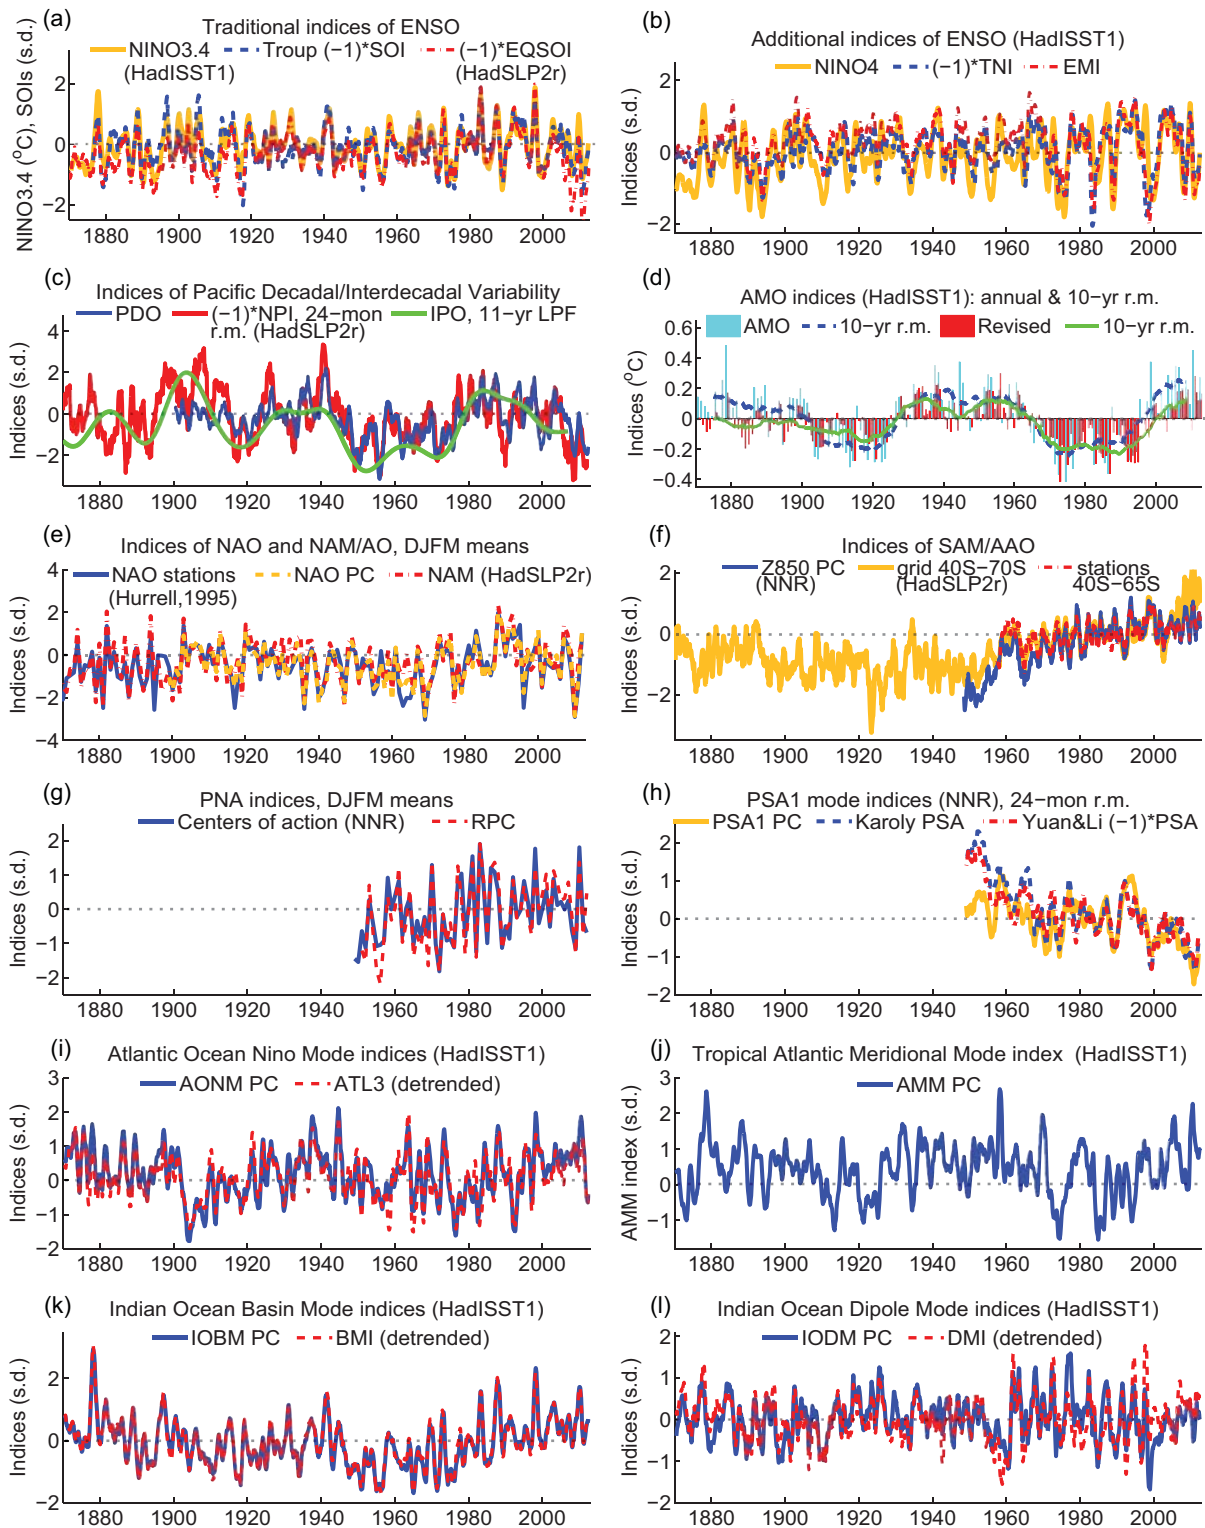

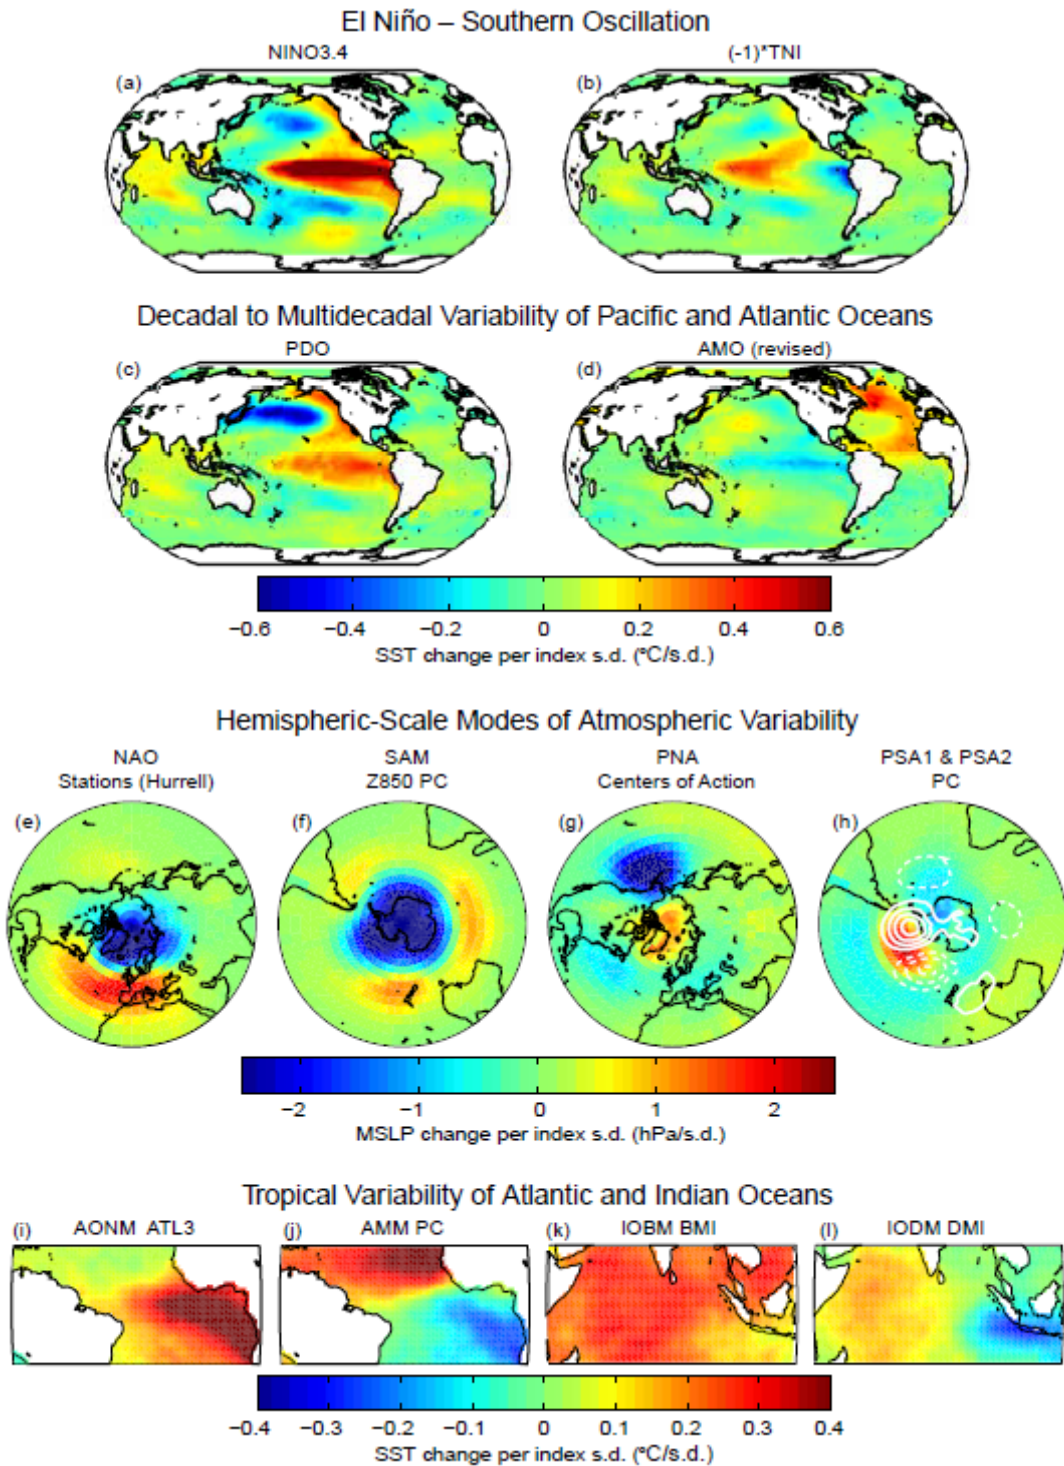

Figure 2.40: Annual average tropical belt width (left) and tropical edge latitudes in each hemisphere (right). The tropopause (red), Hadley cell (blue), and jet stream (green) metrics are based on reanalyses (NCEP/NCAR, ERA-40, JRA25, ERA-Interim, CFSR, and MERRA, see Box 2.3); outgoing longwave radiation (orange) and ozone (black) metrics are based on satellite measurements. The ozone metric refers to equivalent latitude (Hudson et al., 2006; Hudson, 2012). Adapted and updated from Seidel et al. (2008) using data presented in Davis and Rosenlof (2011) and Hudson (2012). Where multiple datasets are available for a particular metric, all are shown as light solid lines, with shading showing their range and a heavy solid line showing their median.

Box 2.5, Figure 1: Some indices of climate variability, as defined in Box 2.5, Table 1, plotted in the 1870–2012 interval. Where ‘HadISST1’, ‘HadSLP2r’, or ‘NNR’ are indicated, the indices were computed from the Sea Surface Temperature (SST) or Sea Level Pressure (SLP) values of the former two datasets or from 500 or 850 hPa geopotential height fields from the NNR. Dataset references given in the panel titles apply to all indices shown in that panel. Where no dataset is specified, a publicly available version of an index from the authors of a primary reference given in Box 2.5, Table 1 was used. All indices were standardized with regard to 1971–2000 period except for NINO3.4 (centralized for 1971–2000) and AMO indices (centralized for 1901–1970). Indices marked as “detrended” had their linear trend for 1870–2012 removed. All indices are shown as 12-month running means except when the temporal resolution is explicitly indicated (e.g., ‘DJFM’ for December-to-March averages) or smoothing level (e.g., 11-year LPF for a low-pass filter with half-power at 11 years).

Box 2.5, Figure 2: Spatial patterns of climate modes listed in Box 2.5, Table 1. All patterns shown here are obtained by regression of either Sea Surface Temperature (SST) or Sea Level Pressure (SLP) fields on the standardized index of a climate mode. For each climate mode one of the specific indices shown in Box 2.5, Figure 1 was used, as identified in the panel subtitles. SST and SLP fields are from HadISST1 and HadSLP2r datasets (interpolated gridded products based on datasets of historical observations). Regressions were done on monthly means for all patterns except for NAO and PNA, which were done with the DJFM means, and for PSA1 and PSA2, where seasonal means were used. Each regression was done for the longest period within the 1870-2012 interval when the index was available. For each pattern the time series was linearly de-trended over the entire regression interval. All patterns are shown by color plots, except for PSA2, which is shown by white contours over the PSA1 color plot (contour steps are 0.5 hPa, zero contour is skipped, negative values are indicated by dash).

Executive Summary

Temperature and Heat Content Changes

It is *virtually certain*¹ that the upper ocean (above 700 m) has warmed from 1971 to 2010, and *likely* that it has warmed from the 1870s to 1971. *Confidence* in the assessment for the time period since 1971 is *high*² based on increased data coverage after this date and on a high level of agreement among independent observations of subsurface temperature [3.2], sea surface temperature [2.2.2], and sea level rise, which is known to include a substantial component due to thermal expansion [3.7, Chapter 13]. There is less certainty in changes prior to 1971 because of relatively sparse sampling in earlier time periods. Strongest warming is found near the sea surface ($>0.1^{\circ}\text{C}$ per decade in the upper 75 m between 1971–2010), decreasing to about 0.015°C per decade at 700 m. It is *very likely* that the surface intensification of this warming signal increased the thermal stratification of the upper ocean by about 4% between 0 and 200 m depth. Instrumental biases in historical upper ocean temperature measurements have been identified and mitigated since AR4, reducing artificial decadal variation in temperature and upper ocean heat content, most prominent during the 1970s and 1980s. [3.2.1–3.2.3, Figures 3.1–3.2, Figure 3.9]

It is *likely* that the ocean warmed between 700–2000 m from 1957 to 2010, based on five-year averages. It is *likely* that the ocean warmed from 3000 m to the bottom from 1992 to 2005, while no significant trends in global average temperature were observed between 2000 and 3000 m depth from circa 1992 to 2005. The largest changes in deep ocean temperature have been observed close to the sources of deep and bottom water in the northern North Atlantic and especially in the Southern Ocean, with amplitudes lessening along the routes through which these waters spread. [3.2.4, 3.5.1, Figure 3.2b, Figure 3.3, FAQ 3.1]

It is *virtually certain* that upper ocean (0–700 m) heat content increased during the relatively well-sampled 40-year period from 1971 to 2010. The rate of increase was *likely* 137 [120–154] TW (1 TW = 10^{12} Watts), calculated using a statistical analysis of ocean variability to estimate change in sparsely sampled areas and to estimate uncertainties. Published rates for that time period range from 74 TW to 137 TW, with generally smaller trends for estimates that assume zero anomalies in regions with sparse data. While not all trends agree within their statistical uncertainties, all are positive, and all are statistically different from zero. [3.2.3, Figure 3.2]

Warming of the ocean between 700 and 2000 m *likely* contributed about 30% of the total increase in global ocean heat content (0–2000 m) between 1957 and 2009. While globally integrated ocean heat content in some of the 0–700 m estimates increased more slowly from 2003–2010 than over the previous decade, ocean heat uptake from 700–2000 m *likely* continued unabated during this period. [3.2.4, Figure 3.2, Box 9.2]

Ocean warming dominates the global energy change inventory. Warming of the ocean accounts for about 93% of the increase in Earth's energy inventory between 1971 and 2010 with warming of the upper (0–700 m) ocean accounting for about 64% of the total. Melting ice (including Arctic sea ice, ice sheets, and glaciers) and warming of the continents and atmosphere account for the remainder of the change in energy. The estimated net increase in Earth's energy storage between 1971 and 2010 is 274 [196 to 351] ZJ (1 ZJ = 1021 Joules), with a heating rate of 213 TW from a linear fit to annual inventories over that time period, equivalent to 0.42 W m^{-2} heating applied continuously over Earth's entire surface, and 0.55 W m^{-2} for the portion owing to ocean warming applied over the ocean's entire surface area. [Section 3.2.3, Figure 3.2, Box 3.1]

¹ In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50 –100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details)."

² In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

Salinity and Freshwater Content Changes

It is very likely that regional trends have enhanced the mean geographical contrasts in sea surface salinity since the 1950s: saline surface waters in the evaporation-dominated mid-latitudes have become more saline, while relatively fresh surface waters in rainfall-dominated tropical and polar regions have become fresher. The mean contrast between high and low salinity regions increased by 0.13 [0.08–0.17] from 1950 to 2008. It is *very likely* that the interbasin contrast in freshwater content has increased: the Atlantic has become saltier and the Pacific and Southern oceans have freshened. While similar conclusions were reached in AR4, recent studies based on expanded data sets and new analysis approaches provide *high confidence* in the assessment of trends in ocean salinity. [3.3.2, 3.3.3, Figures 3.4, 3.5 and 3.21d, FAQ3.3]

It is very likely that large-scale trends in salinity have also occurred in the ocean interior. It is *likely* that both the subduction of surface water anomalies formed by changes in evaporation-precipitation and the movement of density surfaces due to warming have contributed to the observed changes in subsurface salinity. [3.3.2–3.3.4, Figures 3.5 and 3.9]

The spatial patterns of the salinity trends, mean salinity and the mean distribution of evaporation-precipitation are all similar. This provides, with *medium confidence*, indirect evidence that the pattern of evaporation-precipitation over the oceans has been enhanced since the 1950s. [3.3.2–3.3.4, Figures 3.4, 3.5 and 3.20d, FAQ 3.3].

Air-Sea Flux and Wave Height Changes

Uncertainties in air-sea heat flux datasets are too large to allow detection of the change in global mean net air-sea heat flux, of the order of 0.5 W m^{-2} since 1971, required for consistency with the observed ocean heat content increase. The products cannot yet be reliably used to directly identify trends in the regional or global distribution of evaporation or precipitation over the oceans on the timescale of the observed salinity changes since 1950. [3.4.2, 3.4.3, Figures 3.6–3.7]

Basin-scale wind stress trends at decadal to centennial timescales have been observed in the North Atlantic, Tropical Pacific and Southern Ocean with *low to medium confidence*. These results are based largely on atmospheric reanalyses, in some cases a single product, and the confidence level is dependent on region and timescale considered. The evidence is strongest for the Southern Ocean for which there is *medium confidence* that zonal mean wind stress has increased in strength since the early 1980s. [3.4.4, Figure 3.8]

There is *medium confidence* based on ship observations and reanalysis forced wave model hindcasts that mean significant wave height has increased since the 1950s over much of the North Atlantic north of 45°N , with typical winter season trends of up to 20 cm per decade. [3.4.5].

Changes in Water Masses and Circulation

Observed changes in water mass properties *likely* reflect the combined effect of long-term trends in surface forcing (e.g., warming of the surface ocean and changes in evaporation-precipitation) and interannual-to-multidecadal variability related to climate modes. Most of the observed temperature and salinity changes in the ocean interior can be explained by subduction and spreading of water masses with properties that have been modified at the sea surface. From 1950–2000, it is *likely* that subtropical salinity maximum waters became more saline, while fresh intermediate waters formed at higher latitude have generally become fresher. For Upper North Atlantic Deep Water changes in properties and formation rates are *very likely* dominated by decadal variability. The Lower North Atlantic Deep Water has *likely* cooled from 1955–2005, and the freshening trend highlighted in AR4 reversed in the mid-1990s. It is *likely* that the Antarctic Bottom Water warmed and contracted globally since the 1980s and freshened in the Indian/Pacific sectors from 1970 to 2008. [3.5, FAQ 3.1].

Recent observations have strengthened evidence for variability in major ocean circulation systems on time scales from years to decades. It is *very likely* that the subtropical gyres in the North Pacific and South Pacific have expanded and strengthened since 1993. It is about *as likely as not* that this is linked to decadal

variability in wind forcing rather than being part of a longer-term trend. Based on measurements of the full Atlantic Meridional Overturning Circulation and its individual components at various latitudes and different time periods, there is no evidence of a long-term trend. There is also no evidence for trends in the transports of the Indonesian Throughflow, the Antarctic Circumpolar Current (ACC), or between the Atlantic Ocean and Nordic Seas. However, a southward shift of the ACC by about 1° of latitude in 40 years is observed in data spanning the time period 1950–2010 with *medium confidence*. [3.6, Figures 3.10, 3.11]

Sea Level Change

Global mean sea level (GMSL) has risen by 0.19 [0.17–0.21] m over the period 1901–2010, calculated using the mean rate over these 110 years, based on tide gauge records and since 1993 additionally on satellite data. It is very likely that the mean rate was 1.7 [1.5 to 1.9] mm yr⁻¹ between 1901 and 2010 and increased to 3.2 [2.8 to 3.6] mm yr⁻¹ between 1993 and 2010. This assessment is based on high agreement among multiple studies using different methods, long tide gauge records corrected for vertical land motion, and independent observing systems (tide gauges and altimetry) since 1993 (see also TFE.2, Figure 1). It is *likely* that GMSL rose between 1920 and 1950 at a rate comparable to that observed between 1993 and 2010, as individual tide gauges around the world and reconstructions of GMSL show increased rates of sea level rise during this period. Rates of sea level rise over broad regions can be several times larger or smaller than that of GMSL for periods of several decades due to fluctuations in ocean circulation. High agreement between studies with and without corrections for vertical land motion suggests that it is *very unlikely* that estimates of the global average rate of sea level change are significantly biased due to vertical land motion that has been unaccounted for. [3.7.2, 3.7.3, Table 3.1, Figures 3.12, 3.13, 3.14]

It is very likely that warming of the upper 700 m has been contributing an average of 0.6 [0.4 to 0.8] mm yr⁻¹ of sea level rise since 1971. It is *likely* that warming between 700 m and 2000 m has been contributing an additional 0.1 mm yr⁻¹ [0 to 0.2] of sea level rise since 1971, and that warming below 2000 m has been contributing another 0.1 [0.0 to 0.2] mm yr⁻¹ of sea level rise since the early 1990s. It is *very likely* that the ocean mass has increased at a rate between 1 and 2 mm yr⁻¹ (equivalent sea level rate) since 2002, based on high agreement between different studies using satellite gravity measurements and altimeter measurements after removing steric variations. [3.7.2, Figure 3.13]

It is likely that the rate of sea level rise increased from the early 19th century to the early 20th century, and further increased over the 20th century. The inference of 19th century change is based on a small number of very long tide gauge records from northern Europe and North America. Multiple long tide gauge records and reconstructions of global mean sea level confirm a higher rate of rise from the late 19th century. It is *likely* that the average acceleration over the 20th century is between [-0.002 to 0.019] mm yr⁻², as two of three reconstructions extending back to at least 1900 show an acceleration during the 20th century. [3.7.4]

It is likely that the magnitude of extreme high sea level events has increased since 1970. A rise in mean sea level can explain most of the increase in extreme sea levels: changes in extreme high sea levels are reduced to less than 5 mm yr⁻¹ at 94% of tide gauges once the rise in mean sea level is accounted for. [3.7.5, Figure 3.15]

Changes in Ocean Biogeochemistry

Based on high agreement between independent estimates using different methods and data sets (e.g., oceanic carbon, oxygen, and transient tracer data), it is very likely that the global ocean inventory of anthropogenic carbon (C_{ant}) increased from 1994 to 2010. The oceanic C_{ant} inventory in 2010 is estimated to be 155 PgC with an uncertainty of ±20%. The annual global oceanic uptake rates calculated from independent data sets (from oceanic C_{ant} inventory changes, from atmospheric O₂/N₂ measurements or from pCO₂ data) and for different time periods agree with each other within their uncertainties and *very likely* are in the range of 1.0–3.2 PgC yr⁻¹ [3.8.1, Figure 3.16]

It is very likely that oceanic uptake of anthropogenic CO₂ results in gradual acidification of the ocean. The pH of seawater has decreased by 0.1 since the beginning of the industrial era, corresponding to a 26% increase in hydrogen ion concentration. The observed pH trends range between -0.0014 and -0.0024 yr⁻¹ in surface waters. In the ocean interior, natural physical and biological processes, as well as uptake of

anthropogenic CO₂ can cause changes in pH over decadal and longer time scales. [3.8.2, Table 3.2, Box 3.2, Figures 3.18, 3.19, FAQ 3.2]

High agreement among analyses provides *medium confidence* that oxygen concentrations have decreased in the open ocean thermocline in many ocean regions since the 1960s. The general decline is consistent with the expectation that warming-induced stratification leads to a decrease in the supply of oxygen to the thermocline from near surface waters, that warmer waters can hold less oxygen, and that changes in wind-driven circulation affect oxygen concentrations. It is *likely* that the tropical oxygen minimum zones have expanded in recent decades. [3.8.3, Figure 3.20]

Synthesis

The observations summarized in this chapter provide strong evidence that ocean properties of relevance to climate have changed during the past forty years, including temperature, salinity, sea level, carbon, pH, and oxygen. The observed patterns of change in the subsurface ocean are consistent with changes in the surface ocean in response to climate change and natural variability and with known physical and biogeochemical processes in the ocean, providing *high confidence* in this assessment. [3.9, Figures 3.21, 3.22]

3.1 Introduction

The ocean influences climate by storing and transporting large amounts of heat, freshwater, and carbon, and exchanging these properties with the atmosphere. About 93% of the excess heat energy stored by the earth over the last 50 years is found in the ocean (Church et al., 2011; Levitus et al., 2012). The ability of the ocean to store vast amounts of heat reflects the large mass and heat capacity of seawater relative to air and the fact that ocean circulation connects the surface and interior ocean. More than three quarters of the total exchange of water between the atmosphere and the earth's surface through evaporation and precipitation takes place over the oceans (Schmitt, 2008). The ocean contains 50 times more carbon than the atmosphere (Sabine et al., 2004) and is at present acting to slow the rate of climate change by absorbing one quarter of human emissions of carbon dioxide from fossil fuel burning, cement production, deforestation and other land use change (Mikaloff-Fletcher et al., 2006; Le Quéré et al., 2010). Changes in the ocean may result in climate feedbacks that either increase or reduce the rate of climate change. Climate variability and change on time-scales from seasons to millennia is therefore closely linked to the ocean and its interactions with the atmosphere and cryosphere. The large inertia of the oceans means that they naturally integrate over short-term variability and often provide a clearer signal of longer-term change than other components of the climate system. Observations of ocean change therefore provide a means to track the evolution of climate change, and a relevant benchmark for climate models.

The lack of long-term measurements of the global ocean and changes in the observing system over time makes documenting and understanding change in the oceans a difficult challenge (Appendix 3.A). Many of the issues raised in Box 2.1 regarding uncertainty in atmospheric climate records are common to oceanographic data. Despite the limitations of historical records, AR4 identified significant trends in a number of ocean variables relevant to climate change, including ocean heat content, sea level, regional patterns of salinity, and biogeochemical parameters (Bindoff et al., 2007). Since AR4, substantial progress has been made in improving the quality and coverage of ocean observations. Biases in historical measurements have been identified and reduced, providing a clearer record of past change. The Argo array of profiling floats has provided near-global, year-round measurements of temperature and salinity in the upper 2000 m since 2005. The satellite altimetry record is now over twenty years in length. Longer continuous time series of important components of the meridional overturning circulation and tropical oceans have been obtained. The spatial and temporal coverage of biogeochemical measurements in the ocean has expanded. As a result of these advances, there is now stronger evidence of change in the ocean and our understanding of the causes of ocean change is improved.

This chapter summarizes the observational evidence of change in the ocean, with an emphasis on basin- and global-scale changes relevant to climate, with a focus on studies published since the AR4. As in Chapter 2, the robustness of observed changes is assessed relative to sources of observational uncertainty. The attribution of ocean change, including the degree to which observed changes are consistent with anthropogenic climate change, is addressed in Chapter 10. The evidence for changes in subsurface ocean temperature and heat content is assessed in Section 3.2; changes in sea surface temperature are covered in Chapter 2. Changes in ocean heat content dominate changes in the global energy inventory (Box 3.1). Recent studies have strengthened the evidence for regional changes in ocean salinity and their link to changes in evaporation and precipitation over the oceans (Section 3.3), a connection already identified in AR4. Evidence for changes in the fluxes of heat, water, and momentum (wind stress) across the air-sea interface is assessed in Section 3.4. Considering ocean changes from a water-mass perspective adds additional insight into the nature and causes of ocean change (Section 3.5). While direct observations of ocean circulation are more limited than those of temperature and salinity, there is growing evidence of variability and change of ocean current patterns relevant to climate (Section 3.6). Observations of sea level change are summarized in Section 3.7; Chapter 13 builds on the evidence presented in this and other chapters to provide an overall synthesis of past and future sea level change. Biogeochemical changes in the ocean, including ocean acidification, are covered in Section 3.8. Chapter 6 combines observations with models to discuss past and present changes in the carbon cycle. Section 3.9 provides an overall synthesis of changes observed in the ocean during the instrumental period and highlights key uncertainties. Unless otherwise noted, uncertainties (in square brackets) represent 5–95% confidence intervals.

3.2 Changes in Ocean Temperature and Heat Content

3.2.1 *Effects of Sampling on Ocean Heat Content Estimates*

Temperature is the most often-measured subsurface ocean variable. Historically, a variety of instruments have been used to measure temperature, with differing accuracies, precisions, and sampling depths. Both the mix of instruments and the overall sampling patterns have changed in time and space (Boyer et al., 2009), complicating efforts to determine and interpret long-term change. The evolution of the observing system for ocean temperature is summarized in Appendix 3.A. Upper ocean temperature (hence heat content) varies over multiple time-scales including seasonal (e.g. Roemmich and Gilson, 2009), interannual—especially with El Niño, which has a strong influence on ocean heat uptake (Roemmich and Gilson, 2011), decadal (e.g. Carson and Harrison, 2010), and centennial (Gouretski et al., 2012; Roemmich et al., 2012). Ocean data assimilation products using these data exhibit similar significant variations (e.g. Xue et al., 2012). Sparse historical sampling coupled with large amplitude variations on shorter time and spatial scales raise challenges for estimating globally averaged upper ocean temperature changes. Uncertainty analyses indicate that the historical data set begins to be reasonably well suited for this purpose starting around 1970 (e.g. Domingues et al., 2008; Lyman and Johnson, 2008; Palmer and Brohan, 2011). UOHC uncertainty estimates shrink after 1970 with improved sampling, so this assessment focuses on changes since 1971. Estimates of UOHC have been extended back to 1950 by averaging over longer time intervals, such as five-year running means, to compensate for sparse data distributions in earlier time periods (e.g. Levitus et al., 2012). These estimates may be most appropriate in the deeper ocean, where strong interannual variability in upper ocean temperature distributions such as that associated with El Niño (Roemmich and Gilson, 2011) is less likely to be aliased.

Since AR4 the significant impact of measurement biases in some of the widely-used instruments (the expendable (XBT) and mechanical bathythermograph (MBT) as well as a subset of Argo floats) on estimates of ocean temperature and upper (0–700 m) ocean heat content (hereafter UOHC) changes has been recognized (Gouretski and Koltermann, 2007; Barker et al., 2011). Careful comparison of measurements from the less accurate instruments with those from the more accurate ones has allowed some of the biases to be identified and mitigated (Wijffels et al., 2008; Ishii and Kimoto, 2009; Levitus et al., 2009; Gouretski and Reseghetti, 2010; Hamon et al., 2012). One major consequence of this bias mitigation has been the reduction of an artificial decadal variation in upper ocean heat content that was apparent in the observational assessment for AR4, in notable contrast to climate model output (Domingues et al., 2008). Substantial time-dependent XBT and MBT biases introduced spurious warming in the 1970s and cooling in the early 1980s in the analyses assessed in AR4. Most ocean state estimates that assimilate biased data (Carton and Santorelli, 2008) also showed this artificial decadal variability while one (Stammer et al., 2010) apparently rejected these data on dynamical grounds. More recent estimates assimilating better-corrected data sets (Giese et al., 2011) also result in reduced artificial decadal variability during this time period.

Recent estimates of upper ocean temperature change also differ in their treatment of unsampled regions. Some studies (e.g. Ishii and Kimoto, 2009; Levitus et al., 2012) effectively assume a temperature anomaly of zero in these regions, while other studies (Palmer et al., 2007; Lyman and Johnson, 2008) assume that the averages of sampled regions are representative of the global mean in any given year, and yet others (Smith and Murphy, 2007; Domingues et al., 2008) use ocean statistics (from numerical model output and satellite altimeter data, respectively) to extrapolate temperature anomalies in sparsely sampled areas and estimate uncertainties. These differences in approach, coupled with choice of background climatology, can lead to significant divergence in basin-scale averages (Gleckler et al., 2012) especially in sparsely sampled regions (e.g., the extra-tropical Southern Hemisphere prior to Argo), and as a result can produce different global averages (Lyman et al., 2010). However, for well-sampled regions and times, the various analyses of temperature changes yield results in closer agreement, as do reanalyses (Xue et al., 2012).

3.2.2 *Upper Ocean Temperature*

Depth-averaged 0–700 m ocean temperature trends from 1971–2010 are positive over most of the globe (Levitus et al., 2009; Figure 3.1a). The warming is more prominent in the northern hemisphere, especially the North Atlantic. This result holds in different analyses, using different time periods, bias corrections and data sources (e.g., with or without XBT or MBT data) (e.g. Palmer et al., 2007; Durack and Wijffels, 2010; Gleckler et al., 2012; Figures 3.1 and 3.9). However, the greater volume of the Southern Hemisphere oceans increases the contribution of their warming to global heat content. Zonally averaged upper ocean temperature

trends show warming at nearly all latitudes and depths (Levitus et al., 2009, Figure 3.1b). A maximum in warming south of 30°S is present in Figure 3.1b, but is not as strong as in other analyses (e.g. Gille, 2008), likely because the data are relatively sparse in this location so anomalies are attenuated by the objectively analyzed fields used for Figure 3.1 and because warming in the upper 1000 m of the Southern Ocean was stronger between the 1930s and the 1970s than between the 1970s and 1990s (Gille, 2008). Another warming maximum is present at 25°N–65°N. Both warming signals extend to 700 m (Levitus et al., 2009, Figure 3.1b), and are consistent with poleward displacement of the mean temperature field. Other zonally averaged temperature changes are also consistent with poleward displacement of the mean temperatures. For example, cooling at depth between 30°S and the equator (Figure 3.1b) is consistent with a southward shift of cooler water near the equator. Poleward displacements of some subtropical and subpolar zonal currents and associated wind changes are discussed in Section 3.6.

Globally averaged ocean temperature anomalies as a function of depth and time (Figure 3.1c) relative to a 1971–2010 mean reveal warming at all depths in the upper 700 m over the relatively well-sampled 40-year period considered. Strongest warming is found closest to the sea surface, and the near-surface trends are consistent with independently measured sea surface temperature (Chapter 2). The global average warming over this period exceeds 0.1°C per decade in the upper 75 m, decreasing to 0.015°C per decade by 700 m (Figure 3.1c). Comparison of Argo data to Challenger expedition data from the 1870s suggests that warming started earlier than 1971, and was also larger in the Atlantic than in the Pacific over that longer time interval (Roemmich et al., 2012). An observational analysis of temperature in the upper 400 m of the global ocean starting in the year 1900 (Gouretski et al., 2012) finds warming between circa 1900 and 1945, as well as after 1970, with some evidence of slight cooling between 1945 and 1970.

The globally averaged temperature difference between the ocean surface and 200 m (Figure 3.1d) has increased by about 0.25°C from 1971–2010 (Levitus et al., 2009). This change, which corresponds to a 4% increase in density stratification, is widespread in all the oceans north of about 40°S.

[INSERT FIGURE 3.1 HERE]

Figure 3.1: **a)** Depth-averaged 0–700 m temperature trend for 1971–2010 (longitude vs. latitude, colors and grey contours in °C per decade). **b)** Zonally-averaged temperature trends (latitude versus depth, colors and grey contours in °C per decade) for 1971–2010, with zonally averaged mean temperature over-plotted (black contours in °C). **c)** Globally-averaged temperature anomaly (time versus depth, colors and grey contours in °C) relative to the 1971–2010 mean. **d)** Globally-averaged temperature difference between the ocean surface and 200 m depth (black: annual values, red: 5-year running mean). All panels are constructed from an update of the annual analysis of Levitus et al. (2009).

A potentially important impact of ocean warming is the effect on sea ice, floating glacial ice, and ice sheet dynamics (see Chapter 4 for a discussion of these topics). While some of the global integrals of UOHC neglect changes poleward of ±60° (Ishii and Kimoto, 2009) or ±65° (Domingues et al., 2008) latitude, at least some parts of the Arctic have warmed: In the Arctic Ocean, subsurface pulses of relatively warm water of Atlantic origin can be traced around the Eurasian Basin, and analyses of data from 1950–2010 show a decadal warming of this water mass since the late 1970s (Polyakov et al., 2012), as well as a shoaling, by 75–90 m (Polyakov et al., 2010). Arctic surface waters have also warmed, at least in the Canada Basin, from 1993–2007 (Jackson et al., 2010).

3.2.3 Upper Ocean Heat Content

Global integrals of 0–700 m UOHC (Figure 3.2a) estimated from ocean temperature measurements all show a gain from 1971–2010 (Palmer et al., 2007; Smith and Murphy, 2007; e.g. Domingues et al., 2008; Ishii and Kimoto, 2009; Levitus et al., 2012). These estimates usually start around 1950, although as noted above and discussed in the Appendix, historical data coverage is sparse, so global integrals are increasingly uncertain for earlier years, especially prior to 1970. There is some convergence towards agreement in instrument bias correction algorithms since AR4 (Section 3.2.1), but other sources of uncertainty include the different assumptions regarding mapping and integrating UOHCs in sparsely sampled regions, differences in quality control of temperature data, and differences among baseline climatologies used for estimating changes in heat content (Lyman et al., 2010). Although there are still apparent interannual variations about the upward trend of global UOHC since 1970, different global estimates have variations at different times and for different periods, suggesting that sub-decadal variability in the time rate of change is still quite uncertain in

the historical record. Most of the estimates in Figure 3.2a do exhibit decreases for a few years immediately following major volcanic eruptions in 1963, 1982, and 1991 (Domingues et al., 2008).

Again, all of the global integrals of UOHC in Figure 3.2a have increased between 1971 and 2010. Linear trends fit to the UOHC estimates for the relatively well-sampled 40-year period from 1971–2010 estimate the heating rate required to account for this warming: 118 [82 to 154] TW (1 TW = 10^{12} Watts) for Levitus et al. (2012), 98 [67 to 130] TW for Ishii and Kimoto (2009), 137 [120 to 154] TW for Domingues et al. (2008), 108 [80 to 136] TW for Palmer et al. (2007), and 74 [43 to 105] TW for Smith and Murphy (2007). Uncertainties are calculated as 90% confidence intervals for an ordinary least squares fit, taking into account the reduction in the degrees of freedom implied by the temporal correlation of the residuals. While these rates of energy gain do not all agree within their statistical uncertainties, all are positive, and all are statistically different from zero. Generally the smaller trends are for estimates that assume zero anomalies in areas of sparse data, as expected for that choice, which will tend to reduce trends and variability. Hence the assessment of the Earth's energy uptake (Box 3.1) employs a global UOHC estimate (Domingues et al., 2008) chosen because it fills in sparsely sampled areas and estimates uncertainties using a statistical analysis of ocean variability patterns.

Globally integrated ocean heat content in three of the five 0–700 m estimates appear to be increasing more slowly from 2003–2010 than over the previous decade (Figure 3.2a). While this apparent change is concurrent with a slowing of the increase global mean surface temperature, as discussed in Box 9.2, this is also a time period when the ocean observing system transitioned from predominantly XBT to predominantly Argo temperature measurements (Johnson and Wijffels, 2011). Shifts in observing systems can sometimes introduce spurious signals, so this apparent recent change should be viewed with caution.

[INSERT FIGURE 3.2 HERE]

Figure 3.2: **a)** Observation-based estimates of annual global mean upper (0–700 m) ocean heat content in ZJ (1 ZJ = 10^{21} Joules) updated from (see legend): (Levitus et al., 2012), (Ishii and Kimoto, 2009), (Domingues et al., 2008), (Palmer et al., 2007), and (Smith and Murphy, 2007). Uncertainties are shaded, and plotted as published (at the one standard error level, except one standard deviation for Levitus, with no uncertainties provided for Smith). Estimates are shifted to align for 2006–2010, five years that are well measured by Argo, and then plotted relative to the resulting mean of all curves for 1971, the starting year for trend calculations. **b)** Observation-based estimates of annual five-year running mean global mean mid-depth (700–2000 m) ocean heat content in ZJ (Levitus et al., 2012) and the deep (2000–6000 m) global ocean heat content trend from 1992–2005 (Purkey and Johnson, 2010), both with one standard error uncertainties shaded (see legend).

3.2.4 Deep Ocean Temperature and Heat Content

Below 700 m data coverage is too sparse to produce annual global ocean heat content estimates prior to about 2005, but from 2005–2010 and 0–1500 m the global ocean is warming (von Schuckmann and Le Traon, 2011). Five-year running mean estimates yield a 700–2000 m global ocean heat content trend from 1957 to 2009 (Figure 3.2b) that is about 30% of that for 0–2000 m over the length of the record (Levitus et al., 2012). Ocean heat uptake from 700–2000 m continues unabated since 2003 (Figure 3.2b); as a result, ocean heat content from 0–2000 m shows less slowing after 2003 than does 0–700 m heat content (Levitus et al., 2012).

Global sampling of the ocean below 2000 m is limited to a number of repeat oceanographic transects, many occupied only in the last few decades (Figure 3.3b), and several time-series stations, some of which extend over decades. This sparse sampling in space and time makes assessment of global deep ocean heat content variability less certain than that for the upper ocean (Ponte, 2012), especially at mid-depths, where vertical gradients are still sufficiently large for transient variations (ocean eddies, internal waves, and internal tides) to alias estimates made from sparse data sets. However, the deep North Atlantic Ocean is better sampled than the rest of the globe, making estimates of full-depth deep ocean heat content changes there feasible north of 20°N since the mid 1950s (Mauritzen et al., 2012).

Based on the limited information available, it is *likely* that the global ocean did not show a significant trend between 2000 and 3000 m depth from circa 1992–2005 (Figures 3.2b and 3.3a; Kouketsu et al., 2011). At these depths it has been around a millennium on average since waters in the Indian and Pacific oceans were last exposed to air-sea interaction (Gebbie and Huybers, 2012).

Warming from 1992–2005 is *likely* greater than zero from 3000 m to the ocean floor (Figures 3.2b and 3.3a; Kouketsu et al., 2011), especially in recently formed Antarctic Bottom Water. South of the Sub-Antarctic Front (Figure 3.3b), much of the water column warmed between 1992 and 2005 (Purkey and Johnson, 2010). Globally, deep warming rates are highest near 4500 m (Figure 3.3a), usually near the sea floor where the AABW influence is strongest, and attenuate towards the north (Figure 3.3b), where the AABW influence weakens. Global scale abyssal warming on relatively short multi-decadal time-scales is possible because of communication of signals by planetary waves originating within the Southern Ocean, reaching even such remote regions as the North Pacific (Kawano et al., 2010; Masuda et al., 2010). This AABW warming may partly reflect a recovery from cool conditions induced by the 1970s Weddell Sea Polynya (Robertson et al., 2002), but further north, in the Vema Channel of the South Atlantic, observations since 1970 suggest strong bottom water warming did not commence there until circa 1991 (Zenk and Morozov, 2007).

[INSERT FIGURE 3.3 HERE]

Figure 3.3: **a)** Areal mean warming rates (°C per decade) versus depth (thick lines) with 5 to 95% confidence limits (shading), both global (orange) and south of the Sub-Antarctic Front (purple), centred on 1992–2005. **b)** Mean warming rates (°C per decade) below 4000 m (colorbar) estimated for deep ocean basins (thin black outlines), centred on 1992–2005. Stippled basin warming rates are not significantly different from zero at 95% confidence. The positions of the Sub-Antarctic Front (purple line) and the repeat oceanographic transects from which these warming rates are estimated (thick black lines) also shown. Data from Purkey and Johnson (2010).

In the North Atlantic, strong decadal variability in North Atlantic Deep Water (NADW) temperature and salinity (Wang et al., 2010), largely associated with the North Atlantic Oscillation (NAO, Box 2.5) (e.g. Yashayaev, 2007; Sarafanov et al., 2008), complicates efforts to determine long-term trends from the historical record. Heat content in the North Atlantic north of 20°N from 2000 m to the ocean floor increased slightly from 1955–1975, and then decreased more strongly from 1975–2005 (Mauritzen et al., 2012), with a net cooling trend of -4 TW from 1955–2005 estimated from a linear fit. The global trend estimate below 2000 m is +35 TW from 1992–2005 (Purkey and Johnson, 2010), with strong warming in the Southern Ocean.

3.2.5 Conclusion

It is *virtually certain* that the upper ocean (0–700 m) warmed from 1971–2010. This result is supported by three independent and consistent methods of observation including (i) multiple analyses of subsurface temperature measurements described here, (ii) sea surface temperature data (Section 2.4.2) from satellites and in situ measurements from surface drifters and ships, and (iii) the record of sea level rise, which is known to include a substantial component owing to thermosteric expansion (Section 3.7 and Chapter 13). The warming rate is about 0.1°C per decade in the upper 75 m, decreasing to about 0.015°C per decade by 700 m. It is *very likely* that surface intensification of the warming signal increases the thermal stratification of the upper ocean by about 4% (between 0 and 200 m depth) from 1971–2010. It is also *likely* that the upper ocean warmed over the first half of the twentieth century, based again on these same three independent and consistent, although much sparser, observations. Deeper in the ocean, it is *likely* that the waters from 700–2000 m have warmed on average between 1957 and 2009 and *likely* that no significant trend was observed between 2000–3000 m from 1992–2005. It is *very likely* that the deep (2000 m–bottom) North Atlantic Ocean north of 20°N warmed from 1955–1975, and then cooled from 1975–2005, with an overall cooling trend. It is *likely* that most of the water column south of the Subantarctic Front warmed at a rate of about 0.03°C per decade from 1992–2005, and waters of Antarctic origin warmed below 3000 m at a global average rate approaching 0.01°C per decade at 4500 m over the same time period. For the deep ocean, sparse sampling, currently below 2000 m, is the greatest source of uncertainty.

[START BOX 3.1 HERE]

Box 3.1: Change in Global Energy Inventory

Earth has been in radiative imbalance, with less energy exiting the top of the atmosphere than entering, since at least circa 1970 (Murphy et al., 2009; Church et al., 2011; Levitus et al., 2012). Quantifying this energy gain is essential for understanding the response of the climate system to radiative forcing. Small amounts of this excess energy warm the atmosphere and continents, evaporate water, and melt ice, but the bulk of it

warms the ocean (Box 3.1, Figure 1). The ocean dominates the change in energy because of its large mass and high heat capacity compared to the atmosphere. In addition, the ocean has a very low albedo and absorbs solar radiation much more readily than ice.

[INSERT BOX 3.1, FIGURE 1 HERE]

Box 3.1, Figure 1: Plot of energy accumulation in ZJ (1 ZJ = 10^{21} J) within distinct components of Earth's climate system relative to 1971 and from 1971–2010 unless otherwise indicated. See text for data sources. Ocean warming (heat content change) dominates, with the upper ocean (light blue, above 700 m) contributing more than the deep ocean (dark blue, below 700 m; including below 2000 m estimates starting from 1992). Ice melt (light grey; for glaciers and ice caps, Greenland and Antarctic ice sheet estimates starting from 1992, and Arctic sea ice estimate from 1979–2008); continental (land) warming (orange); and atmospheric warming (purple; estimate starting from 1979) make smaller contributions. Uncertainty in the ocean estimate also dominates the total uncertainty (dot-dashed lines about the error from all five components at 90% confidence intervals).

The global atmospheric energy change inventory accounting for specific heating and water evaporation is estimated by combining satellite estimates for temperature anomalies in the lower troposphere (Mears and Wentz, 2009a; updated to version 3.3) from 70°S to 82.5°N and the lower stratosphere (Mears and Wentz, 2009b; updated to version 3.3) from 82.5°S to 82.5°N weighted by the ratio of the portions of atmospheric mass they sample (0.87 and 0.13, respectively). These temperature anomalies are converted to energy changes using a total atmospheric mass of 5.14×10^{18} kg, a mean total water vapor mass of 12.7×10^{15} kg (Trenberth and Smith, 2005), a heat capacity of $1 \text{ J g}^{-1} \text{ }^\circ\text{C}^{-1}$, a latent heat of vaporization of 2.464 J kg^{-1} , and a fractional increase of integrated water vapor content of $0.075 \text{ }^\circ\text{C}^{-1}$ (Held and Soden, 2006). Smaller changes in potential and kinetic energy are considered negligible. Standard deviations for each year of data are used for uncertainties, and the time-series starts in 1979. The warming trend from a linear fit from 1979 to 2010 amounts to 2 TW (1 TW = 10^{12} Watts).

The global average rate of continental warming and its uncertainty has been estimated from borehole temperature profiles from 1500–2000 at 50-year intervals (Beltrami et al., 2002). The 1950–2000 estimate of land warming, 6 TW, is extended into the first decade of the 21st century, although that extrapolation is almost certainly an underestimate of the energy absorbed as land surface air temperatures for years since 2000 are some of the warmest on record (Section 2.4.1).

All annual ice melt rates (for glaciers and ice-caps, ice sheets, and sea ice from Chapter 4) are converted into energy change using a heat of fusion ($334 \times 10^3 \text{ J kg}^{-1}$) and density (920 kg m^{-3}) for freshwater ice. The heat of fusion and density of ice may vary, but only slightly among the different ice types, and warming the ice from sub-freezing temperatures requires much less energy than that to melt it, so these second order contributions are neglected here. The linear trend of energy storage from 1971 to 2010 is 7 TW.

For the oceans, an estimate of global upper (0–700 m depth) ocean heat content change using ocean statistics to extrapolate to sparsely sampled regions and estimate uncertainties (Domingues et al., 2008) is used (see Section 3.2), with a linear trend from 1971–2010 of 137 TW. For the ocean from 700–2000 m, annual five-year running mean estimates are used from 1970–2009 and annual estimates for 2010–2011 (Levitus et al., 2012). For the ocean from 2000 m–bottom, a uniform rate of energy gain of 35 [6 to 61] TW from warming rates centred on 1992–2005 (Purkey and Johnson, 2010), is applied from 1992–2011, with no warming below 2000 m assumed prior to 1992. Their 5 to 95% uncertainty estimate may be too small, since it assumes the usually sparse sampling in each deep ocean basin analysed is representative of the mean trend in that basin. The linear trend for heating the ocean below 700 m is 62 TW for 1971–2010.

It is *virtually certain* that Earth has gained substantial energy from 1971–2010 — the estimated increase in energy inventory between 1971 and 2010 is 274 [196 to 351] ZJ (1 ZJ = 10^{21} J), with a rate of 213 TW from a linear fit to the annual values over that time period (Box 3.1, Figure 1). Ocean warming dominates the total energy change inventory, accounting for roughly 93% on average from 1971–2010. Melting ice (including Arctic sea ice, ice sheets, and glaciers) accounts for 3% of the total, and warming of the continents 3%. Warming of the atmosphere makes up the remaining 1%. The 1971–2010 estimated rate of oceanic energy gain is 199 TW from a linear fit to data over that time period, implying a mean heat flux of 0.55 W m^{-2} across the global ocean surface area. Earth's net estimated energy increase from 1993–2010 is 163 [127 to 201] ZJ with a trend estimate of 275 TW. The ocean portion of the trend for 1993–2010 is 257 TW, equivalent to a mean heat flux into the ocean of 0.71 W m^{-2} .

[END BOX 3.1 HERE]

3.3 Changes in Salinity and Freshwater Content

3.3.1 Introduction

The ocean plays a pivotal role in the global water cycle: about 85% of the evaporation and 77% of the precipitation occurs over the ocean (Schmitt, 2008). The horizontal salinity distribution of the upper ocean largely reflects this exchange of freshwater, with high surface salinity generally found in regions where evaporation exceeds precipitation, and low salinity found in regions of excess precipitation and runoff (Figure 3.4a,b). Ocean circulation also affects the regional distribution of surface salinity. The subduction (Section 3.5) of surface waters transfers the surface salinity signal into the ocean interior, so that subsurface salinity distributions are also linked to patterns of evaporation, precipitation, and continental run-off at the sea surface. Melting and freezing of ice (both sea ice and glacial ice) also influence ocean salinity.

Regional patterns and amplitudes of atmospheric moisture transport could change in a warmer climate, because warm air can contain more moisture (FAQ 3.3). The water vapour content of the troposphere *likely* has increased since the 1970s, at a rate consistent with the observed warming (Section 2.4.4, 2.5.5, 2.5.6). It has not been possible to detect robust trends in regional precipitation and evaporation over the ocean because observations over the ocean are sparse and uncertain (Section 3.4.2). Ocean salinity, on the other hand, naturally integrates the small difference between these two terms and has the potential to act as a rain gauge for precipitation minus evaporation over the ocean (e.g. Lewis and Fofonoff, 1979; Schmitt, 2008; Yu, 2011; Pierce et al., 2012; Terray et al., 2012; Section 10.4). Diagnosis and understanding of ocean salinity trends is also important because salinity changes, like temperature changes, affect circulation and stratification, and therefore the ocean's capacity to store heat and carbon as well as to change biological productivity. Salinity changes also contribute to regional sea level change (Steele and Ermold, 2007).

In AR4, surface and subsurface salinity changes consistent with a warmer climate were highlighted, based on linear trends for the period between 1955 and 1998 in the historical global salinity data set (Boyer et al., 2005) as well as on more regional studies. In the early few decades the salinity data distribution was good in the northern hemisphere, especially the North Atlantic, but the coverage was poor in some regions such as the central South Pacific, central Indian, and polar oceans (Appendix 3.A). However, Argo provides much more even spatial and temporal coverage in the 2000s. These additional observations, improvements in the availability and quality of historical data, and new analysis approaches now allow a more complete assessment of changes in salinity.

'Salinity' refers to the weight of dissolved salts in a kilogram of seawater. Because the total amount of salt in the ocean does not change, the salinity of seawater can only be changed by addition or removal of fresh water. All salinity values quoted in the chapter are expressed on the Practical Salinity Scale 1978 (PSS78) (Lewis and Fofonoff, 1979).

3.3.2 Global to Basin-Scale Trends

The salinity of near-surface waters is changing on global and basin scales, with increase in the more evaporative regions and decrease in the precipitation-dominant regions in almost all ocean basins.

3.3.2.1 Sea Surface Salinity

Multidecadal trends in sea surface salinity have been documented in studies published since AR4 (Boyer et al., 2007; Hosoda et al., 2009; Roemmich and Gilson, 2009; Durack and Wijffels, 2010), confirming the trends reported in AR4 based mainly on Boyer et al. (2005). The spatial pattern of surface salinity change is similar to the distribution of surface salinity itself: salinity tends to increase in regions of high mean salinity, where evaporation exceeds precipitation, and tends to decrease in regions of low mean salinity, where precipitation dominates (Figure 3.4). For example, salinity generally increased in the surface salinity maxima formed in the evaporation-dominated subtropical gyres. The surface salinity minima at subpolar latitudes and the intertropical convergence zones have generally freshened. Interbasin salinity differences are also

enhanced: the relatively salty Atlantic has become more saline on average, while the relatively fresh Pacific has become fresher (Figures 3.5 and 3.9). No well-defined trend is found in the subpolar North Atlantic, which is dominated by decadal variability from atmospheric modes like the North Atlantic Oscillation (NAO, Box 2.5). The fifty-year salinity trends in Figure 3.4c, both positive and negative, are statistically significant at the 99% level over 43.8% of the global ocean surface (Durack and Wijffels, 2010); trends were less significant over the remainder of the surface. The patterns of salinity change in the complementary Hosoda et al. (2009) study of differences between the periods 1960–1989 and 2003–2007 (Figure 3.4d), using a different methodology, have a point-to-point correlation of 0.64 with the Durack and Wijffels (2010) results, with significant differences only in limited locations such as adjacent to the West Indies, Labrador Sea, and some coastlines (Figure 3.4c and d).

It is *very likely* that the globally averaged contrast between regions of high and low salinity relative to the global mean salinity has increased. The contrast between high and low salinity regions, averaged over the ocean area south of 70°N, increased by 0.13 [0.08 to 0.17] PSS78 from 1950 to 2008 using the data set of Durack and Wijffels (2010), and by 0.12 [0.10 to 0.15] PSS78 using the data set of Boyer et al. (2009) with the range reported in brackets signifying a 99% confidence interval (Figure 3.21d).

[INSERT FIGURE 3.4 HERE]

Figure 3.4: **a)** The 1955–2005 climatological-mean sea surface salinity (World Ocean Atlas 2009 of Antonov et al., 2010) color contoured at 0.5 PSS78 intervals (black lines). **b)** Annual mean evaporation-precipitation averaged over the period 1950–2000 (NCEP) color contoured at 0.5 m yr⁻¹ intervals (black lines). **c)** The 58-year (2008 minus 1950) sea surface salinity change derived from the linear trend (PSS78), with seasonal and ENSO signals removed (Durack and Wijffels, 2010) color contoured at 0.116 PSS78 intervals (black lines). **d)** The 30-year (2003–2007 average centered at 2005, minus the 1960–1989 average, centered at 1975) sea surface salinity difference (PSS78) (Hosoda et al., 2009) color contoured at 0.06 PSS78 intervals (black lines). Contour intervals in (c) and (d) are chosen so that the trends can be easily compared, given the different time intervals in the two analyses. White areas in (c) – (d) are marginal seas where the calculations are not carried out. Regions where the change is not significant at the 99% confidence level are stippled in grey.

3.3.2.2 Upper Ocean Subsurface Salinity

Compatible with observed changes in surface salinity, robust multi-decadal trends in subsurface salinity have been detected (Boyer et al., 2005; Boyer et al., 2007; Steele and Ermold, 2007; Böning et al., 2008; Durack and Wijffels, 2010; Helm et al., 2010; Wang et al., 2010). Global, zonally averaged multi-decadal salinity trends (1950–2008) in the upper 500 m (Figures 3.4, 3.5, 3.9 and Section 3.5) show salinity increases at the salinity maxima of the subtropical gyres, freshening of the low-salinity intermediate waters sinking in the Southern Ocean (Subantarctic Mode Water and Antarctic Intermediate Water) and North Pacific (North Pacific Intermediate Water). On average, the Pacific freshened, and the Atlantic became more saline. These trends, shown in Figures 3.5 and 3.9, are significant at a 95% confidence interval.

Freshwater content in the upper 500 m *very likely* changed, based on the World Ocean Database 2009 (Boyer et al., 2009), analyzed by Durack and Wijffels (2010) and independently as an update to Boyer et al. (2005) for 1955 – 2010 (Figure 3.5a,b,e,f). Both show freshening in the North Pacific, salinification in the North Atlantic south of 50°N, and salinification in the northern Indian Ocean (trends significant at 90% confidence). A significant freshening in the Southern Ocean south of 50°S is observed globally.

Density layers that are ventilated (connected to the sea surface) in precipitation-dominated regions have freshened, while those ventilated in evaporation-dominated regions have increased in salinity, compatible with an enhancement of the mean surface freshwater flux pattern (Helm et al., 2010). In addition, where warming has caused surface outcrops of density layers to move (poleward) into higher salinity surface waters, the subducted salinity in the density layers has increased; where outcrops have moved into fresher surface waters, the subducted salinity decreased (Durack and Wijffels, 2010). Vertical and lateral shifts of density surfaces, owing to both changes in water mass renewal rates and wind-driven circulation, have also contributed to the observed subsurface salinity changes (Levitus, 1989; Bindoff and McDougall, 1994).

A change in total, globally integrated freshwater content and salinity requires an addition or removal of freshwater; the only significant source is land ice (ice sheets and glaciers). The estimate of change in globally averaged salinity and freshwater content remains smaller than its uncertainty, as was true in the

AR4 assessment. For instance, globally averaged sea surface salinity change from 1950 to 2008 is small (+0.003 [-0.056 to 0.062]) compared to its error estimate (Durack and Wijffels, 2010). Thus a global freshening due to land ice loss has not yet been discerned in global surface salinity change even if it were assumed that all added freshwater were in the ocean's surface layer.

[INSERT FIGURE 3.5 HERE]

Figure 3.5: Zonally integrated freshwater content changes (FWCC; km^3 per degree of latitude) in the upper 500 m over one-degree zonal bands and linear trends (1955-2010) of zonally averaged salinity (PSS78; lower panels) in the upper 500 m of the **a) c) Atlantic, b) d) Pacific, e) g) Indian, and f) h) World Oceans.** The FWCC time period is from 1955 to 2010 (Boyer et al., 2005; blue lines) and 1950 to 2008 (Durack and Wijffels, 2010; red lines). Data are updated from Boyer et al. (2005) and calculations of FWCC are done according to the method of Boyer et al. (2007), using five-year averages of salinity observations and fitting a linear trend to these averages. Error estimates are 95% confidence intervals. The contour interval of salinity trend in the lower panels is 0.01 PSS78 per decade and dashed contours are 0.005 PSS78 per decade. Red shading indicates values equal to or greater than 0.05 PSS78 per decade and blue shading indicates values equal to or less than -0.005 PSS78 per decade.

3.3.3 Regional Changes in Upper Ocean Salinity

Regional changes in ocean salinity are broadly consistent with the conclusion that regions of net precipitation (precipitation greater than evaporation) have *very likely* become fresher, while regions of net evaporation have become more saline. This pattern is seen in salinity trend maps (Figure 3.4); zonally-averaged salinity trends and freshwater inventories for each ocean (Figure 3.5); and the globally-averaged contrast between regions of high and low salinity (Figure 3.21d). In the high-latitude regions, higher runoff, increased melting of ice, and changes in freshwater transport by ocean currents have *likely* also contributed to observed salinity changes (Bersch et al., 2007; Polyakov et al., 2008; Jacobs and Giulivi, 2010).

3.3.3.1 Pacific and Indian Oceans

In the tropical Pacific, surface salinity has declined by 0.1 to 0.3 over 50 years in the precipitation-dominated western equatorial regions and by up to 0.6 to 0.75 in the Intertropical Convergence Zone and the South Pacific Convergence Zone (Cravatte et al., 2009), while surface salinity has increased by up to 0.1 over the same period in the evaporation-dominated zones in the southeastern and north-central tropical Pacific (Figure 3.9). The fresh, low density waters in the warm pool of the western equatorial Pacific expanded in area as the surface salinity front migrated eastward by 1500–2500 km over the period 1955–2003 (Delcroix et al., 2007; Cravatte et al., 2009). Similarly, in the Indian Ocean, the net precipitation regions in the Bay of Bengal and the warm pool contiguous with the tropical Pacific warm pool have been freshening by up to 0.1 to 0.2, while the saline Arabian Sea and south Indian Ocean have been getting saltier by up to 0.2 (Durack and Wijffels, 2010).

In the North Pacific, the subtropical thermocline has freshened by 0.1 since the early 1990s, following surface freshening that began around 1984 (Ren and Riser, 2010); the freshening extends down through the intermediate water that is formed in the northwest Pacific (Nakano et al., 2007), continuing the freshening documented by Wong et al. (1999). Warming of the surface water that subducts to supply the intermediate water is one reason for this signal, as the fresh water from the subpolar North Pacific is now entering the subtropical thermocline at lower density.

Salinity changes, together with temperature changes (Section 3.2.2), affect stratification; salinity has more impact than temperature in some regions. In the western tropical Pacific, for example, the density changes from 1970 to 2003 at a trend of $-0.013 \text{ kg m}^{-3} \text{ yr}^{-1}$, about 60% of that due to salinity (Delcroix et al., 2007). The decreasing density trend mainly occurs near the surface only, which should affect stratification across the base of the mixed layer. In the Oyashio region of the western North Pacific, salinity decrease near the surface accounts for about 60% of the density decrease of $-0.004 \text{ kg m}^{-3} \text{ yr}^{-1}$ from 1968 to 1998 (Ono et al., 2001).

3.3.3.2 Atlantic Ocean

The net evaporative North Atlantic has become saltier as a whole over the past 50 years (Figure 3.9; Boyer et al., 2007). The largest increase in the upper 700 m occurred in the Gulf Stream region (0.006 per decade

between 1955–1959 and 2002–2006) (Wang et al., 2010). Salinity increase is also evident following the circulation pathway of Mediterranean Outflow Water (Figure 3.9; Fusco et al., 2008). This increase can be traced back to the western basin of the Mediterranean, where salinity of the deep water increased during the period from 1943 to the mid-2000s (Smith et al., 2008; Vargas-Yáñez et al., 2010).

During the time period between 1955–1959 and 2002–2006 (using salinities averaged over the indicated 5-year ranges), the upper 700 m of the subpolar North Atlantic freshened by up to 0.002 per decade (Wang et al., 2010), while an increase in surface salinity was found between the average taken over 1960–1989 and the 5-year average over 2003–2007 (Hosoda et al., 2009). Decadal and multi-decadal variability in the subpolar gyre and Nordic Seas is vigorous and has been related to various climate modes such as the NAO, the Atlantic multidecadal oscillation (AMO, Box 2.5), and even ENSO (Polyakov et al., 2005; Yashayaev and Loder, 2009), obscuring long-term trends. The 1970s to 1990s freshening of the northern North Atlantic and Nordic Seas (Dickson et al., 2002; Curry et al., 2003; Curry and Mauritzen, 2005) reversed to salinification (0–2000 m depth) starting in the late 1990s (Boyer et al., 2007; Holliday et al., 2008), and the propagation of this signal could be followed along the eastern boundary from south of 60°N in the Northeast Atlantic to Fram Strait at 79°N (Holliday et al., 2008). Advection has also played a role in moving higher salinity subtropical waters to the subpolar gyre (Hatun et al., 2005; Bersch et al., 2007; Lozier and Stewart, 2008; Valdimarsson et al., 2012). The variability of the cross equatorial transport contribution to this budget is highly uncertain. Reversals of North Atlantic surface salinity of similar amplitude and duration to those observed in the last 50 years are apparent in the early 20th century (Reverdin et al., 2002; Reverdin, 2010). The evaporation-dominated subtropical South Atlantic has become saltier by 0.1 to 0.3 during the period from 1950 to 2008 (Hosoda et al., 2009; Durack and Wijffels, 2010; Figure 3.4).

3.3.3.3 Arctic Ocean

Sea ice in the Arctic has declined significantly in recent decades (Chapter 4.2), which might be expected to reduce the surface salinity and increase freshwater content as freshwater locked in multi-year sea ice is released. Generally, strong multidecadal variability, regional variability, and the lack of historical observations have made it difficult to assess long-term trends in ocean salinity and freshwater content for the Arctic as a whole (Rawlins et al., 2010). The signal that is now emerging, including salinity observations from 2005 to 2010, indicates increased freshwater content, with *medium confidence*.

Over the 20th century (1920 to 2003) the central Arctic Ocean in the upper 150m became fresher in the 1950s and then more saline by the early 2000s, with a net small salinification over the whole record (Polyakov et al., 2008), while at the Siberian Shelf the river discharge increased (Shiklomanov and Lammers, 2009) and the shelf waters became fresher (Polyakov et al., 2008).

Upper ocean freshening has also been observed regionally in the southern Canada basin from the period 1950–1980 to the period 1990–2000s (Proshutinsky et al., 2009; Yamamoto-Kawai et al., 2009). These are the signals reflected in the freshwater content trend from 1955 to 2010 shown in Figure 3.5a, f: salinification at the highest latitudes and a band of freshening at about 70°N to 80°N. Ice production and sustained export of freshwater from the Arctic Ocean in response to winds are suggested as key contributors to the high latitude salinification (Polyakov et al., 2008; McPhee et al., 2009). The contrasting changes in different regions of the Arctic have been attributed to the effects of Ekman transport, sea ice formation (and melt), and a shift in the pathway of Eurasian river runoff (McPhee et al., 2009; Yamamoto-Kawai et al., 2009; Morison et al., 2012).

Between the periods 1992–1999 and 2006–2008, not only the central Arctic Ocean freshened (Rabe et al., 2011; Giles et al., 2012), but freshening is now observed in all regions including those that were becoming more saline through the early 2000s (updated from Polyakov et al., 2008). Moreover, freshwater transport out of the Arctic has increased in that time period (McPhee et al., 2009).

3.3.3.4 Southern Ocean

Widespread freshening (trend of –0.01 per decade, significant at 95% confidence, from the 1980s to 2000s) of the upper 1000 m of the Southern Ocean was inferred by taking differences between modern data (mostly Argo) and a long-term climatology along mean streamlines (Böning et al., 2008). Decadal variability, while

notable, does not overwhelm this trend (Böning et al., 2008). Both a southward shift of the Antarctic Circumpolar Current and water-mass changes contribute to the observed trends during the period 1992–2009 (Meijers et al., 2011). The zonally-averaged freshwater content for each ocean and the world (Figure 3.5) shows this significant Southern Ocean freshening, which exceeds other regional trends and is present in each basin (Indian, Atlantic and Pacific, Figure 3.9).

3.3.4 Evidence for Change of the Hydrological Cycle from Salinity Changes

The similarity between the geographic distribution of significant salinity and freshwater content trends (Figures 3.4, 3.5, and 3.21) and both the mean salinity pattern and the distribution of mean evaporation – precipitation (Figure 3.4) indicates, *with medium confidence*, that the large-scale pattern of net evaporation minus precipitation over the oceans has been enhanced. While the surface salinity pattern could be enhanced by increased stratification owing to surface warming, the large-scale changes in column-integrated freshwater content are *very unlikely* to result from changes in stratification in the thin surface layer. Furthermore, the large spatial scale of the observed changes in freshwater content cannot be explained by changes in ocean circulation such as shifts of gyre boundaries. The observed changes in surface and subsurface salinity require additional horizontal atmospheric water transport from regions of net evaporation to regions of net precipitation. A similar conclusion was reached in AR4 (Bindoff et al., 2007). The water vapour in the troposphere has *likely* increased since the 1970s, owing to warming (2.4.4, 2.5.5, 2.5.6; FAQ 3.3). The inferred enhanced pattern of net evaporation – precipitation can be related to water vapor increase, although the linkage is complex (Emori and Brown, 2005; Held and Soden, 2006). From 1950 to 2000, the large-scale pattern of surface salinity has amplified at a rate that is larger than model simulations for the historical 20th century and 21st century projections. The observed rate of surface salinity amplification is comparable to the rate expected from a water cycle response following the Clausius-Clapeyron relationship (Durack et al., 2012).

Studies published since AR4, based on expanded data sets and new analysis approaches, have substantially decreased the level of uncertainty in the salinity and freshwater content trends (e.g. Stott et al., 2008; Hosoda et al., 2009; Roemmich and Gilson, 2009; Durack and Wijffels, 2010; Helm et al., 2010), and thus increased confidence in the inferred changes of evaporation and precipitation over the ocean.

3.3.5 Conclusion

Both positive and negative trends in ocean salinity and freshwater content have been observed throughout much of the ocean, both at the sea surface and in the ocean interior. It is *virtually certain* that the salinity contrast between regions of high and low surface salinity has increased since the 1950s. It is *very likely* that since the 1950s, the mean regional pattern of upper ocean salinity has been enhanced: saline surface waters in the evaporation-dominated mid-latitudes have become more saline, while the relatively fresh surface waters in rainfall-dominated tropical and polar regions have become fresher. Similarly, it is *very likely* that the interbasin contrast between saline Atlantic and fresh Pacific surface waters has increased, and it is *very likely* that freshwater content in the Southern Ocean has increased. There is *medium* confidence that these patterns in salinity trends are caused by increased horizontal moisture transport in the atmosphere, suggesting changes in evaporation and precipitation over the ocean as the lower atmosphere has warmed.

Trends in salinity have been observed in the ocean interior as well. It is *likely* that the subduction of surface water mass anomalies and the movement of density surfaces have contributed to the observed salinity changes on depth levels. Changes in freshwater flux and the migration of surface density outcrops caused by surface warming (e.g., to regions of lower or higher surface salinity) have *likely* both contributed to the formation of salinity anomalies on density surfaces.

3.4 Changes in Ocean Surface Fluxes

3.4.1 Introduction

Exchanges of heat, water and momentum (wind stress) at the sea surface are important factors for driving the ocean circulation. Changes in these air-sea fluxes may result from variations in the driving surface meteorological state variables (air temperature and humidity, sea surface temperature, wind speed, cloud

cover, precipitation) and can impact both water-mass formation rates and ocean circulation. Air-sea fluxes also influence temperature and humidity in the atmosphere and, therefore, the hydrological cycle and atmospheric circulation. AR4 concluded that, at the global scale, the accuracy of the observations is insufficient to permit a direct assessment of changes in heat flux (AR4 Section 5.2.4). As described below, while substantial progress has been made since AR4, that conclusion still holds for this assessment.

The net air-sea heat flux is the sum of two turbulent (latent and sensible) and two radiative (shortwave and longwave) components. Ocean heat gain from the atmosphere is defined to be positive according to the sign convention employed here. The latent and sensible heat fluxes are computed from the state variables using bulk parameterizations; they primarily depend on the products of wind speed and the vertical near-sea-surface gradients of humidity and temperature respectively. The air-sea freshwater flux is the difference of precipitation (P) and evaporation (E). It is linked to heat flux through the relationship between evaporation and latent heat flux. Thus, when considering potential trends in the global hydrological cycle, consistency between observed heat budget and evaporation changes is required in areas where evaporation is the dominant term in hydrological cycle changes. Ocean surface shortwave and longwave radiative fluxes can be inferred from satellite measurements using radiative transfer models, or computed using empirical formulae, involving astronomical parameters, atmospheric humidity, cloud cover and SST. The wind stress is given by the product of the wind speed squared and the drag coefficient. For detailed discussion of all terms see for example Gulev et al. (2010).

Atmospheric reanalyses, discussed earlier Box 2.3, are referred to frequently in the following sections and for clarity the products cited are summarised here: ECMWF 40 year Reanalysis (referred to as ERA40 hereafter, Uppala et al., 2005), ECMWF Interim Reanalysis (ERA-Interim, Dee et al., 2011), NCEP/NCAR Reanalysis 1 (NCEP1, Kalnay et al., 1996), NCEP/DOE Reanalysis 2 (NCEP2, Kanamitsu et al., 2002), NCEP Climate Forecast System Reanalysis (CFRSR, Saha et al., 2010), NASA Modern Era Reanalysis for Research and Applications (MERRA, Rienecker et al., 2011) and NOAA-CIRES Twentieth Century Reanalysis, version 2 (20CRv2, Compo et al., 2011).

3.4.2 Air-Sea Heat Flux

3.4.2.1 Turbulent Heat Fluxes and Evaporation

The latent and sensible heat fluxes have a strong regional dependence with typical values varying in the annual mean from close to zero to -220 W m^{-2} and -70 W m^{-2} respectively over strong heat loss sites (Yu and Weller, 2007). Estimates of these terms have many potential sources of error (e.g., sampling issues, instrument biases, changing data sources, uncertainty in the flux computation algorithms). These sources may be spatially and temporally dependent, and are difficult to quantify (Gulev et al., 2007), consequently flux error estimates have a high degree of uncertainty. Spurious temporal trends may arise as a result of variations in measurement method for the driving meteorological state variables, in particular wind speed (Tokinaga and Xie, 2011). The overall uncertainty of the annually averaged global ocean mean for each term is expected to be in the range 10–20%. In the case of the latent heat flux term, this corresponds to an uncertainty of up to 20 W m^{-2} . In comparison, changes in global mean values of individual heat flux components expected as a result of anthropogenic climate change since 1900 are at the level of $<2 \text{ W m}^{-2}$ (Pierce et al., 2006).

Many new turbulent heat flux datasets have become available since AR4 including products based on atmospheric reanalyses, satellite and in situ observations, and hybrid or synthesized datasets that combine information from these three different sources. It is not possible to identify a single best product as each has its own strengths and weaknesses (Gulev et al., 2010); several datasets are summarised here to illustrate the key issues. The Hamburg Ocean-Atmosphere Parameters and Fluxes from Satellite (HOAPS) data product provides global turbulent heat fluxes (and precipitation) developed from observations at microwave and infrared wavelengths (Andersson et al., 2011). In common with other satellite datasets it provides globally complete fields, however, it spans a relatively short period (1987–onwards) and is thus of limited utility for identifying long-term changes. A significant advance in flux dataset development methodology is the 1×1 degree grid Objectively Analysed Air-Sea heat flux (OAFflux) dataset that covers 1958 onwards and for the first time synthesizes state variables (sea surface temperature, air temperature and humidity, wind speed) from reanalyses and satellite observations, prior to flux calculation (Yu and Weller, 2007). OAFflux has the

potential to minimize severe spatial sampling errors that limit the usefulness of datasets based on ship observations alone and provides a new resource for temporal variability studies. However, the data sources for OAFlux changed in the 1980s, with the advent of satellite data, and the consequences of this change need to be assessed. In an alternative approach, Large and Yeager (2009) modified NCEP1 reanalysis state variables prior to flux calculation using various adjustment techniques, to produce the hybrid Coordinated Ocean-ice Reference Experiments (CORE) turbulent fluxes for 1948–2007 (Griffies et al., 2009). However, as the adjustments employed to produce the CORE fluxes were based on limited periods (e.g., 2000–2004 for wind speed) it is not clear to what extent CORE can be reliably used for studies of interdecadal variability over the 60 year period that it spans.

Analysis of OAFlux suggests that global mean evaporation may vary at interdecadal timescales, with the variability being relatively small compared to the mean (Yu, 2007; Li et al., 2011; Figure 3.6a). Changing data sources, particularly as satellite observations became available in the 1980s, may contribute to this variability (Schanze et al., 2010) and it is not yet possible to identify how much of the variability is due to changes in the observing system. The latent heat flux variations (Figure 3.6b) closely follow those in evaporation (with allowance for the sign definition which results in negative values of latent heat flux corresponding to positive values of evaporation) but do not scale exactly as there is an additional minor dependence on sea surface temperature through the latent heat of evaporation. The large uncertainty ranges that are evident in each of the time series highlight the difficulty in establishing whether there is a trend in global ocean mean evaporation or latent heat flux. The uncertainty range for latent heat flux is much larger than the 0.5 W m^{-2} level of net heat flux change expected from the ocean heat content increase (Box 3.1). Thus, it is not yet possible to use such datasets to establish global ocean multidecadal trends in evaporation or latent heat flux at this level. The globally averaged sensible heat flux is smaller in magnitude than the latent heat flux and has a smaller absolute range of uncertainty (Figure 3.6b).

[INSERT FIGURE 3.6 HERE]

Figure 3.6: Time series of annual mean global ocean average evaporation (red line panel a), sensible heat flux (green line panel b) and latent heat flux (blue line panel b) from 1958 to 2012 determined by Yu from a revised and updated version of the original OAFlux dataset Yu and Weller (2007). Shaded bands show uncertainty estimates and the black horizontal bars in panel (b) show the time periods for which reanalysis output and satellite observations were employed in the OAFlux analysis; they apply to both panels.

3.4.2.2 Surface Fluxes of Shortwave and Longwave Radiation

The surface shortwave flux has a strong latitudinal dependence with typical annual mean values of 250 W m^{-2} in the tropics. The annual mean surface net longwave flux ranges from -30 to -70 W m^{-2} . Estimates of these terms are available from in situ climatologies, from atmospheric reanalyses, and, since the 1980s, from satellite observations. These datasets have many potential sources of error that include: uncertainty in the satellite retrieval algorithms and in situ formulae, cloud representation in reanalyses, sampling issues and changing satellite sensors (Gulev et al., 2010). As for the turbulent fluxes, the uncertainty of the annually averaged global ocean mean shortwave or longwave flux is difficult to determine and in the range 10–20%.

High accuracy in-situ radiometer measurements are available at land sites since the 1960s (see Wild, 2009 Figure 1), allowing analysis of decadal variations in the surface shortwave flux. However, this is not the case over the oceans, where there are very few in-situ measurements (the exception being moored buoy observations in the tropical band 15°S – 15°N since the 1990s, (the exception being moored buoy observations in the tropical band 15°S – 15°N since the 1990s, Pinker et al., 2009). Consequently, for global ocean shortwave analyses it is necessary to rely on satellite observations, which are less accurate (compared to in-situ determination of radiative fluxes), restrict the period that can be considered to the mid-1980s onwards, but do provide homogeneous sampling. Detailed discussion of variations in global (land and ocean) averaged surface solar radiation is given in Section 2.3.3; *confidence* in variability of radiation averaged over the global ocean is *low* due to the lack of direct observations.

3.4.2.3 Net Heat Flux and Ocean Heat Storage Constraints

The most reliable source of information for changes in the global mean net air-sea heat flux comes from the constraints provided by analyses of changes in ocean heat storage. The estimate of increase in global ocean heat content for 1971–2010 quantified in Box 3.1 corresponds to an increase in mean net heat flux from the

atmosphere to the ocean of 0.55 W m^{-2} . In contrast, closure of the global ocean mean net surface heat flux budget to within 20 W m^{-2} from observation based surface flux datasets has still not been reliably achieved (e.g., Trenberth et al., 2009). The increase in mean net air-sea heat flux is thus small compared to the uncertainties of the global mean. Large and Yeager (2012) examined global ocean average net heat flux variability using the CORE dataset over 1984–2006 and concluded that natural variability, rather than long-term climate change, dominates heat flux changes over this relatively short, recent period. Since AR4, some studies have shown consistency in regional net heat flux variability at sub-basin scale since the 1980s; notably in the Tropical Indian Ocean (Yu et al., 2007) and North Pacific (Kawai et al., 2008). However, detection of a change in air-sea fluxes responsible for the long-term ocean warming remains beyond the ability of currently available surface flux datasets.

3.4.3 Ocean Precipitation and Freshwater Flux

Assessment of changes in ocean precipitation at multidecadal timescales is very difficult due to the lack of reliable observation based datasets prior to the satellite era. The few studies available rely on reconstruction techniques. Remote sensing based precipitation observations from the Global Precipitation Climatology Project (GPCP) for 1979–2003 have been used by Smith et al. (2009; 2012) to reconstruct precipitation for 1900–2008 (over 75°S – 75°N) by employing statistical techniques that make use of the correlation between precipitation and both SST and Sea Level Pressure (SLP). Each of the reconstructions shows both centennial and decadal variability in global ocean mean precipitation (Figure 3.7). The trend from 1900 to 2008 is 1.5 mm per month per century for Smith et al. (2012). For the period of overlap, the reconstructed global ocean mean precipitation time series show consistent variability with GPCP as is to be expected (Figure 3.7). Focusing on the Tropical Ocean (25°S – 25°N) for the recent period 1979–2005, Gu et al. (2007) have identified a precipitation trend of 0.06 mm day^{-1} per decade using GPCP. Concerns have been expressed in the cited studies over the need for further work both to determine the most reliable approach to precipitation reconstruction and to evaluate the remotely sensed precipitation datasets. Given these concerns, *confidence* in ocean precipitation trend results is *low*.

[INSERT FIGURE 3.7 HERE]

Figure 3.7: Long term reconstruction of ocean precipitation anomaly averaged over 75°S – 75°N from Smith et al. (2012) annual values – thin blue line, low-pass filtered (15 year running mean) values – bold blue line with uncertainty estimates (shading); Smith et al. (2009) low-pass filtered values – dotted grey line. Also shown is the corresponding GPCPv2.2 derived ocean precipitation anomaly time series averaged over the same latitudinal range (annual values – thin magenta line, low-pass filtered values – bold magenta line); note Smith et al. (2012) employed an earlier version of the GPCP dataset leading to minor differences relative to the published time series in their paper. Precipitation anomalies were taken relative to the 1979–2008 period.

Evaporation and precipitation fields from atmospheric reanalyses can be tested for internal consistency of different components of the hydrological cycle. Specifically, the climatological mean value for E–P averaged over the global ocean should equal both the corresponding mean for P–E averaged over land and the moisture transport from ocean to land. Trenberth et al. (2011) find in an assessment of eight atmospheric reanalyses that this is not the case for each product considered, and they also report spurious trends due to variations in the observing system with time. Schanze et al. (2010) examine inter-annual variability within the OAF flux evaporation and GPCP precipitation datasets, and find that use of satellite data prior to 1987 is limited by discontinuities attributable to variations in data type. Thus, it is not yet possible to use such datasets to establish whether there are significant multi-decadal trends in mean E–P. However, regional trends in surface salinity since the 1950s do suggest trends in E–P over the same time (see Section 3.3.4).

3.4.4 Wind Stress

Wind stress fields are available from reanalyses, satellite-based datasets, and in situ observations. Basin scale wind stress trends at decadal to centennial timescales have been reported for the Southern Ocean, the North Atlantic and the Tropical Pacific as detailed below. However, these results are based largely on atmospheric reanalyses, in some cases a single product, and consequently the confidence level is *low* to *medium* depending on region and timescale considered.

In the Southern Ocean, the majority of reanalyses in the most comprehensive study available show an increase in the annual mean zonal wind stress (Swart and Fyfe, 2012; Figure 3.8). They find an increase in

annual mean wind stress strength in four (NCEP1, NCEP2, ERAI and 20CRv2) of the six reanalyses considered (Figure 3.8). The mean of all reanalyses available at a given time (Figure 3.8, black line) also shows an upward trend from about 0.15 N m^{-2} in the early 1950s to 0.20 N m^{-2} in the early 2010s. An earlier study, covering 1979–2009, found a wind stress increase in two of four reanalyses considered (Xue et al., 2010). A positive trend of zonal wind stress from 1980 to 2000 was also reported by Yang et al. (2007) using a single reanalysis (ERA40) and found to be consistent with increases in wind speed observations made on Macquarie Island (54.5°S , 158.9°E) and by the SSM/I satellite (data from 1987 onwards). The wind stress strengthening is found by Yang et al. (2007) to have a seasonal dependence, with strongest trends in January, and has been linked by them to changes in the Southern Annular Mode (SAM, Box 2.5), which has continued to show an upward trend since AR4 (Section 2.6.8). Taken as a whole, these studies provide *medium confidence* that Southern Ocean wind stress has strengthened since the early 1980s. A strengthening of the related wind speed field in the Southern Ocean, consistent with the increasing trend in the SAM, has also been noted in Section 2.7.2 from satellite-based analyses and atmospheric reanalyses.

[INSERT FIGURE 3.8 HERE]

Figure 3.8: Time series of annual average maximum zonal-mean zonal wind stress (N m^{-2}) over the Southern Ocean for various atmospheric reanalyses: CFSR (orange), NCEP1 (cyan), NCEP2 (red), ERAI (dark blue), MERRA (green), 20CR (gray), and mean of all reanalyses at a given time (thick black), see Box 2.3 for details of reanalyses. Updated version of Figure 1a in Swart and Fyfe (2012), with CFSR, MERRA and the mean of all reanalyses added.

In the Tropical Pacific, a reanalysis based study found a strengthening of the trade wind associated wind stress for 1990–2009, but for the earlier period 1959–1989 there is no clear trend (Merrifield, 2011). Strengthening of the related Tropical Pacific Ocean wind speed field in recent decades is evident in reanalysis and satellite based datasets. Taken together with evidence for rates of sea level rise in the western Pacific larger than the global mean (Section 3.7.3) these studies provide *medium confidence* that Tropical Pacific wind stress has increased since 1990. This increase may be related to the Pacific Decadal Oscillation (Merrifield et al., 2012). At centennial timescales, attempts have been made to reconstruct the wind stress field in the Tropical Pacific by making use of the relationship between wind stress and sea level pressure (SLP) in combination with historic SLP data. Vecchi et al. (2006), using this approach, found a reduction of 7% in zonal mean wind stress across the Equatorial Pacific from the 1860s to the 1990s and related it to a possible weakening of the tropical Walker circulation. Observations discussed in Section 2.7.5 indicate that this weakening has largely been offset by strengthening of the circulation since the 1990s.

Changes in winter season wind stress curl over the North Atlantic from 1950 to early 2000s from NCEP1 and ERA40 have leading modes that are highly correlated with the NAO and East Atlantic circulation patterns; each of these patterns demonstrates a trend towards more positive index values superimposed on pronounced decadal variability over the period from the early 1960s to the late 1990s (Sugimoto and Hanawa, 2010). Wu et al. (2012) find a poleward shift over the past century of the zero wind stress curl line by 2.5° [1.5° to 3.5°] in the North Atlantic and 3.0° [1.6° to 4.4°] in the North Pacific from 20CRv2. *Confidence* in these results is *low* as they are based on a single product, 20CRv2 (the only century timescale reanalysis), which may be affected by temporal inhomogeneity in the number of observations assimilated (Krueger et al., 2013).

3.4.5 Changes in Surface Waves

Surface wind waves are generated by wind forcing and are partitioned into two components, namely wind-sea (wind-forced waves propagating slower than surface wind) and swell (resulting from the wind-sea development and propagating typically faster than surface wind). Significant wave height (SWH) represents the measure of the wind wave field consisting of wind-sea and swell and is approximately equal to the highest one-third of wave heights. Local wind changes influence wind-sea properties, while changes in remote storms affect swell. Thus, patterns of wind wave and surface wind variability may differ since wind waves integrate wind properties over a larger domain. As wind waves integrate characteristics of atmospheric dynamics over a range of scales they potentially serve as an indicator of climate variability and change. Global and regional time series of wind waves characteristics are available from buoy data, Voluntary Observing Ship (VOS) reports, satellite measurements, and model wave hindcasts. No source is superior, as all have their strengths and weaknesses (Sterl and Caires, 2005; Gulev and Grigorieva, 2006; Wentz and Ricciardulli, 2011).

3.4.5.1 *Changes in Surface Waves from VOS and Wave Model Hindcasts Forced by Reanalyses*

AR4 reported statistically significant positive SWH trends during 1900–2002 in the North Pacific (up to 8–10 cm per decade) and stronger trends (up to 14 cm per decade) from 1950 to 2002 for most of the mid-latitude North Atlantic and North Pacific, with insignificant trends, or small negative trends, in most other regions (Trenberth et al., 2007). Studies since AR4 have provided further evidence for SWH trends with more detailed quantification and regionalization.

Model hindcasts based on 20CRv2 (spanning 1871–2010) and ERA40 (spanning 1958–2001) show increases in annual and winter mean SWH in the north-east Atlantic, although the trend magnitudes depend on the reanalysis products used (Wang et al., 2009; Semedo et al., 2011; Wang et al., 2012). Analysis of VOS observations for 1958–2002 reveals increases in winter mean SWH over much of the North Atlantic, north of 45°N, and the central to eastern midlatitude North Pacific with typical trends of up to 20 cm per decade (Sterl and Caires, 2005; Gulev and Grigorjeva, 2006; Wang and Swail, 2006; Wang et al., 2009; Wang et al., 2012).

3.4.5.2 *Changes in Surface Waves from Buoy Data*

Positive regional trends in extreme wave heights have been reported at several buoy locations since the late 1970s, with some evidence for seasonal dependence, including at sites on the U.S. east and west coasts (Komar and Allan, 2008; Ruggiero et al., 2010) and the North-East Pacific coast (Menéndez et al., 2008). However, Gemmrich et al. (2011) found for the Pacific buoys that some trends may be artefacts due to step-type historical changes in the instrument types, observational practices and post-processing procedures. Analysis of data from a single buoy deployed west of Tasmania showed no significant trend in the frequency of extreme waves contrary to a significant positive trend seen in the ERA40 reanalysis (Hemer, 2010).

3.4.5.3 *Changes in Surface Waves from Satellite Data*

Satellite altimeter observations provide a further data source for wave height variability since the mid-1980s. Altimetry is of particular value in the Southern Hemisphere, and in some poorly sampled regions of the Northern Hemisphere, where analysis of SWH trends remains a challenge due to limited in-situ data and temporal inhomogeneity in the data used for reanalysis products. In the Southern Ocean, altimeter-derived SWH and model output both show regions with increasing wave height although these regions cover narrower areas in the altimeter analysis than in the models and have smaller trends (Hemer et al., 2010). Young et al. (2011a) compiled global maps of mean and extreme (90th and 99th percentile) surface wind speed and SWH trends for 1985–2008 using altimeter measurements. As the length of the dataset is short, it is not possible to determine whether their results reflect long-term SWH and wind speed trends, or are part of a multidecadal oscillation. For mean SWH, their analysis shows positive linear trends of up to 10–15 cm per decade in some parts of the Southern Ocean (with strongest changes between 80°E–160°W) that may reflect the increase in strength of the wind stress since the early 1980s (see 3.4.4). Young et al. (2011a) note, however, that globally the level of statistical significance is generally low in the mean and 90th percentile SWH trends but increases for the 99th percentile. Small negative mean SWH trends are found in many Northern Hemisphere ocean regions and these are of opposite sign to, and thus inconsistent with, trends in wind speed — the latter being primarily positive. Nevertheless, for the 99th SWH percentile, strong positive trends up to 50–60 cm per decade were identified in the Southern Ocean, North Atlantic, and North Pacific and these are consistent in sign with the extreme wind speed trends. Subsequent analysis has shown that the Young et al. (2011a) wind speed trends tend to be biased high when compared with microwave radiometer data (Wentz and Ricciardulli, 2011; Young et al., 2011b).

3.4.6 *Conclusions*

Uncertainties in air-sea heat flux datasets are too large to allow detection of the change in global mean net air-sea heat flux, on the order of 0.5 W m^{-2} since 1971, required for consistency with the observed ocean heat content increase. The accuracy of reanalysis and satellite observation based freshwater flux products is limited by changing data sources. Consequently, the products cannot yet be reliably used to directly identify

trends in the regional or global distribution of evaporation or precipitation over the oceans on the timescale of the observed salinity changes since 1950.

Basin scale wind stress trends at decadal to centennial timescales have been observed in the North Atlantic, Tropical Pacific, and Southern Ocean with *low to medium confidence*. These results are based largely on atmospheric reanalyses, in some cases a single product, and the confidence level is dependent on region and timescale considered. The evidence is strongest for the Southern Ocean for which there is *medium confidence* that zonal mean wind stress has increased in strength since the early 1980s.

There is *medium confidence* based on ship observations and reanalysis forced wave model hindcasts that mean significant wave height has increased since the 1950s over much of the North Atlantic north of 45°N, with typical winter season trends of up to 20 cm per decade.

3.5 Changes in Water-Mass Properties

3.5.1 Introduction

To a large degree, water properties are set at the sea surface through interaction between the ocean and the overlying atmosphere (and ice, in polar regions). The water characteristics resulting from these interactions (e.g., temperature, salinity, and concentrations of dissolved gases and nutrients) are transferred to various depths in the world ocean, depending on the density of the water. Warm, light water masses supply (or “ventilate”) the upper ocean at low-to-mid latitudes, while the colder, denser water masses formed at higher latitudes supply the intermediate and deep layers of the ocean (see schematic in FAQ 3.1, Figure 1). The formation and subduction of water masses are important for the ocean’s capacity to store heat, freshwater, carbon, oxygen, and other properties relevant to climate. In this section, the evidence for change in some of the major water masses of the world ocean is assessed.

The zonal-mean distributions of salinity, density, and temperature in each ocean basin (black contours in Figure 3.9) reflect the formation of water masses at the sea surface and their subsequent spreading into the ocean interior. For example, warm, salty waters formed in the regions of net evaporation between 10° and 30° latitude (Figure 3.4b) supply the subtropical salinity maximum waters found in the upper few hundred meters in each basin (Figure 3.9). Relatively fresh water masses produced at higher latitude, where precipitation exceeds evaporation, sink and spread equatorward to form salinity minimum layers at intermediate depths. Outflow of saline water from the Mediterranean Sea and Red Sea, where evaporation is very strong, accounts for the relatively high salinity observed in the upper 1000 m in the subtropical North Atlantic and North Indian basins, respectively.

Many of the observed changes in zonally averaged salinity, density and temperature are aligned with the spreading paths of the major water masses (Figure 3.9, trends from 1950 to 2000 shown in colors and white contours), illustrating how the formation and spreading of water masses transfer anomalies in surface climate to the ocean interior. The strongest anomalies in a water mass are found near its source region. For instance bottom and deep water anomalies are strongest in the Southern Ocean and the northern North Atlantic, with lessening amplitudes along the spreading paths of these water masses. In each basin, the subtropical salinity maximum waters have become more saline, while the low salinity intermediate waters have become fresher (Figure 3.9 a,d,g,j; see also Section 3.3). Strongest warming is observed in the upper 100 m, which has warmed almost everywhere, with reduced warming (Atlantic) or regions of cooling (Indian and Pacific) observed between 100 and 500 m depth.

Warming is observed throughout the upper 2000 m south of 40°S in each basin. Shifts in the location of ocean circulation features can also contribute to the observed trends in temperature and salinity, as discussed in Section 3.2. Density decreased throughout most of the upper 2000 m of the global ocean (middle column of Figure 3.9). The decrease in near-surface density (hence increase in stratification) is largest in the Pacific, where warming and freshening both act to reduce density, and smallest in the Atlantic where the salinity and temperature trends have opposite effects on density.

The remainder of this section focuses on evidence of change in globally relevant intermediate, deep, and bottom water masses.

3.5.2 *Intermediate Waters*

3.5.2.1 *North Pacific Intermediate Water (NPIW)*

The North Pacific Intermediate Water has freshened over the last two decades (Wong et al., 1999; Nakano et al., 2007; Figure 3.9g) and has warmed since the 1950s, as reported in AR4, Chapter 5. NPIW in the northwestern North Pacific warmed by 0.5°C from 1955 to 2004 and is now entering the subtropics at lower density; oxygen concentrations in the NPIW have declined, indicating weaker ventilation (Nakanowatari et al., 2007; Kouketsu et al., 2010). The strongest trends are in the Sea of Okhotsk, where NPIW is formed, and have been tentatively linked to increased air temperature and decreased sea-ice extent in winter (Nakanowatari et al., 2007; Figure 3.9i).

3.5.2.2 *Antarctic Intermediate Water (AAIW)*

In AR4, Chapter 5, AAIW was reported to have warmed and freshened since the 1960s (Figure 3.9). In most recent studies, usually—but not always—a dipole pattern was found: on isopycnals denser than the AAIW salinity minimum, a warming and salinification was observed and on isopycnals lighter than the AAIW salinity minimum, a cooling and freshening trend (Böning et al., 2008; Durack and Wijffels, 2010; Helm et al., 2010; McCarthy et al., 2011). The salinity minimum core of the AAIW also underwent changes consistent with these patterns on isopycnals: In 1970–2009, south of 30°S, the AAIW salinity minimum core showed a strong, large scale shoaling (30–50 dbar per decade) and warming (0.05°C–0.15°C per decade), leading to lighter densities (up to 0.03 kg m⁻³ per decade), while the salinity trends varied regionally. A long-term freshening of the AAIW core is found in the southwest Atlantic, southeast Pacific, and south-central Indian oceans, with salinification south of Africa and Australia. All trends were strongest close to the AAIW formation latitude just north of the Antarctic Circumpolar Current (Schmidtke and Johnson, 2012).

Both an increase in precipitation—evaporation and poleward migration of density surfaces caused by warming have *likely* contributed to the observed trends (Section 3.3; Böning et al., 2008; Durack and Wijffels, 2010; Helm et al., 2010; McCarthy et al., 2011). Changes in AAIW properties in particular locations have also been linked to other processes, including exchange between the Indian and Atlantic basins (McCarthy et al., 2011) and changes in surface forcing related to modes of climate variability like ENSO and the SAM (Garabato et al., 2009). Whether these changes in properties also affected the formation rates of AAIW cannot be assessed from the available observations.

3.5.3 *Deep and Bottom Waters*

Deep and bottom layers of the ocean are supplied by roughly equal volumes of dense water sinking in the northern North Atlantic (Lower North Atlantic Deep Water, LNADW) and around Antarctica (Antarctic Bottom Water, AABW) (FAQ 3.1, Figure 1).

3.5.3.1 *Upper North Atlantic Deep Water (UNADW)*

UNADW is formed by deep convection in the Labrador Sea between Canada and Greenland, so is also known as Labrador Sea Water (LSW). It is the shallowest component of the NADW, located above the overflow water masses that supply the Lower North Atlantic Deep Water (LNADW). AR4 Chapter 5 assessed the variability in water mass properties of LSW from the 1950s. Recent studies have confirmed the large interannual-to-multidecadal variability of LSW properties and provided new information on variability in formation rates and the impact on heat and carbon (Section 3.8.1) uptake by the deep ocean.

During the 1970s and 1980s and especially the 1990s the UNADW has been cold and fresh. In Figure 3.9A it is the strong freshening signal from the 1960s to the 1990s that dominates the trend. This freshening trend reversed in the late 1990s (Boyer et al., 2007; Holliday et al., 2008; see Section 3.3.3.2). Estimates of

the LSW formation rate³ decreased from about 7.6–8.9 Sv in 1997–1999 (Kieke et al., 2006) to roughly 0.5 Sv in 2003–2005 (Rhein et al., 2011), and since 1997, only less dense LSW was formed compared to the high NAO years before. There is, however, evidence that formation of denser LSW occurred in 2008 (Våge et al., 2009; Yashayaev and Loder, 2009), but not in the following years (Yashayaev and Loder, 2009; Rhein et al., 2011).

The strong variability in the formation of UNADW affected significantly the heat transfer into the deep North Atlantic (Mauritzen et al., 2012). Substantial heat entered the deep North Atlantic during the low NAO years of the 1960s, when salinity was large enough to compensate for the high temperatures, and dense LSW was still formed and exported to the subtropics.

3.5.3.2 Lower North Atlantic Deep Water (LNADW)

Dense waters overflowing the sills between Greenland and Scotland supply the LNADW. Both overflows freshened from the mid-1960s to the mid-1990s (Dickson et al., 2008). The salinity of the Faroe Bank overflow increased by 0.015–0.02 from 1997 to 2004, implying a density increase on the order of 0.01 kg m^{-3} (Hansen and Osterhus, 2007). The other main overflow, through Denmark Strait, shows large interannual variability in temperature and salinity, but no trends for the time period 1996–2011 (Jochumsen et al., 2012). Observations of the transport of the dense overflows are dominated by short-term variability and there is no evidence of a trend in the short time series available (see Section 3.6). As both overflow components descend into the North Atlantic, they entrain substantial amounts of ambient subpolar waters to create LNADW. As a whole, the LNADW in the North Atlantic cooled from the 1950s to 2005 (Mauritzen et al., 2012), a signal thus stemming primarily from the entrained waters, possibly an adjustment from an unusually warm period observed in the 1920s and 1930s (Drinkwater, 2006).

3.5.3.3 Antarctic Bottom Water (AABW)

The AABW has warmed since the 1980s or 1990s, most noticeably near Antarctica (Aoki et al., 2005; Rintoul, 2007; Johnson et al., 2008a; Purkey and Johnson, 2010; Kouketsu et al., 2011), but with warming detectable into the North Pacific and North Atlantic Oceans (Johnson et al., 2008b; Kawano et al., 2010). The warming of AABW between the 1990s and 2000s contributed to global ocean heat uptake (Section 3.2). The global volume of the AABW layer reduced by 8.2 [5.6 to 10.8] Sv during the last two decades (Johnson et al., 2008b; Mauritzen et al., 2012; Purkey and Johnson, 2012), making it *more likely than not* that at least the export rate of AABW from the Southern Ocean declined during this period.

The sources of AABW in the Indian and Pacific sectors of the Southern Ocean have freshened in recent decades. The strongest signal (0.03 per decade, between 1970 and 2008) is observed in the Ross Sea and has been linked to inflow of glacial melt water from the Amundsen and Bellingshausen Seas (Shepherd et al., 2004; Rignot et al., 2008; Jacobs and Giulivi, 2010). Freshening has been observed in AABW since the 1970s in the Indian sector (Rintoul, 2007) and between the 1990s and 2000s in the Pacific sector (Swift and Orsi, 2012; Purkey and Johnson, 2013).

In the Weddell Sea (the primary source of AABW in the Atlantic), a contraction of the bottom water mass was observed between 1984 and 2008 at the Prime Meridian, accompanied by warming of about 0.015°C , and by salinity variability on a multi-annual time scale. Transient tracer observations between 1984 and 2011 confirmed that the AABW there has become less well ventilated over that time period. The changes in the AABW, however, seem to be caused by the much stronger trends observed in the Warm Deep Water, as WDW is entrained into the AABW while sinking to the bottom, and not by changes in the AABW formation rate (Huhn et al., 2008; Huhn et al., 2013).

[INSERT FIGURE 3.9 HERE]

Figure 3.9: Upper 2000 m zonally averaged mean trend distribution, (year 2000 minus 1950; colours with white contours) of salinity (column 1), neutral density (column 2), and potential temperature (column 3), for the Atlantic

³ The formation rate of a water mass is the volume of water per year which is transformed into the density range of this water mass by surface processes (for instance cooling), eventually modified through ocean interior processes (for instance mixing). Formation rates are reported in Sverdrups (Sv). 1 Sv equals $10^6 \text{ m}^3 \text{ s}^{-1}$

Ocean (ATL) in row 1, Indian Ocean (IND), row 2, Pacific Ocean (PAC), row 3, and global ocean (GLO) in row 4. Mean fields are shown as black lines. Regions where the resolved linear trend is not significant at the 90% confidence level are stippled in gray. Salinity results are republished from Durack and Wijffels (2010) with the unpublished temperature and density results from this study also presented.

3.5.4 Conclusions

AR4 Chapter 5 concluded that observed changes in upper ocean water masses reflect the combination of long-term trends and interannual to decadal variability related to climate modes like ENSO, NAO, and SAM. The time series are still generally too short and incomplete to distinguish decadal variability from long-term trends, but understanding of the nature and causes of variability has improved in this assessment. The observed patterns of change in subsurface temperature and salinity (Sections 3.2, 3.3) are consistent with understanding of how and where water masses form, enhancing the level of confidence in the assessment of the observed changes.

Recent studies showed that the warming of the upper ocean (Section 3.2.2) *very likely* affects properties of water masses in the interior, in direct and indirect ways. Transport of SST and SSS anomalies caused by changes in surface heat and freshwater fluxes are brought into the ocean's interior by contact with the surface ocean (Sections 3.2, 3.3). Vertical and horizontal displacements of isopycnals due to surface warming could change salinity and temperature (Section 3.3). Circulation changes (Section 3.6) could also change salinity by shifting the outcrop area of this isopycnal in regions with higher (or lower) E-P. Properties of several deep and bottom water masses are the product of near surface processes and significant mixing or entrainment of other ambient water masses (Section 3.5). Changes in the properties of the entrained or admixed water mass could dominate the observed deep and bottom water mass changes, for instance in the LNADW and the AABW in the Weddell Sea.

From 1950–2000, it is *likely* that subtropical salinity maximum waters have become more saline, while fresh intermediate waters formed at higher latitudes have generally become fresher. In the extratropical North Atlantic, it is *very likely* that the temperature, salinity, and formation rate of the Upper North Atlantic Deep Water is dominated by strong decadal variability related to NAO. It is *likely* that Lower North Atlantic Deep Water has cooled from 1955–2005. It is *likely* that the abyssal layer ventilated by Antarctic Bottom Water (AABW) warmed over much of the globe since the 1980s or 1990s respectively, and the volume of cold AABW has been reduced over this time period.

3.6 Changes in Ocean Circulation

3.6.1 Global Observations of Ocean Circulation Variability

The present-day ocean observing system includes global observations of velocity made at the sea surface by the Global Drifter Program (Dohan et al., 2010), and at 1000 m depth by the Argo Program (Freeland et al., 2010). In addition, Argo observes the geostrophic shear between 2000 m and the sea surface. These two recently implemented observing systems, if sustained, will continue to document the large-spatial scale, long-timescale variability of circulation in the upper ocean. The drifter program achieved its target of 1250 drifters in 2005, and Argo its target of 3000 floats in 2007.

Historically, global measurements of ocean circulation are much sparser, so estimates of decadal and longer-term changes in circulation are very limited. Since 1992, high-precision satellite altimetry has measured the time variations in sea surface height (SSH), whose horizontal gradients are proportional to the surface geostrophic velocity. In addition, a single global top-to-bottom hydrographic survey was carried out by the World Ocean Circulation Experiment (WOCE), mostly during 1991–1997, measuring geostrophic shear as well as velocity from mid-depth floats and from lowered acoustic Doppler current profilers. A subset of WOCE and pre-WOCE transects is being repeated at 5–10 year intervals (Hood et al., 2010).

Ocean circulation studies in relation to climate have focused on variability in the wind-driven gyres (Section 3.6.2) and changes in the meridional overturning circulations (MOCs, Section 3.6.3 and 3.6.4) influenced by buoyancy loss and water-mass formation as well as wind forcing. The MOCs are responsible for much of the ocean's capacity to carry excess heat from the tropics to middle latitudes, and also are important in the

ocean's sequestration of carbon. The connections between ocean basins (Section 3.6.5) have also been subject to study because of the significance of inter-basin exchanges in wind-driven and thermohaline variability, and also because these can be logistically advantageous regions for measurement ("chokepoints"). An assessment is now possible of the recent mean and the changes in global geostrophic circulation over the previous decade (Figure 3.10, and discussion in Section 3.6.2). In general, changes in the slope of SSH across ocean basins indicate changes in the major gyres and the interior component of MOCs. Changes occurring in high gradient regions such as the Antarctic Circumpolar Current (ACC) may indicate shifts in the location of those currents. In the following, the best-studied and most significant aspects of circulation variability and change are assessed including wind-driven circulation in the Pacific, the Atlantic, and Antarctic MOCs, and selected interbasin exchanges.

[INSERT FIGURE 3.10 HERE]

Figure 3.10: Mean steric height of the sea surface relative to 2000 decibars (black contours at 10 cm intervals) shows the pattern of geostrophic flow for the Argo era (2004–2012) based on Argo profile data, updated from Roemmich and Gilson (2009). The sea surface height (SSH) trend (cm per decade, color shading) for the period 1993–2011 is based on the AVISO altimetry "reference" product (Ducet et al., 2000). Spatial gradients in the SSH trend, divided by the (latitude-dependant) Coriolis parameter, are proportional to changes in surface geostrophic velocity. For display, the mean steric height contours and SSH trends are spatially smoothed over 5° longitude and 3° latitude.

3.6.2 Wind-Driven Circulation Variability in the Pacific Ocean

The Pacific covers over half of the global ocean area and its wind-driven variability is of interest both for its consistency with wind stress observations and for potential air-sea feedbacks that could influence climate. Changes in Pacific Ocean circulation since the early 1990s to the present, from the subarctic gyre to the southern ocean, observed with satellite ocean data and in-situ ocean measurements, are in good agreement and consistent with the expected dynamical response to observed changes in wind stress forcing.

The subarctic gyre in the North Pacific poleward of 40°N consists of the Alaska Gyre to the east and the Western Subarctic Gyre (WSG). Since 1993, the cyclonic Alaska Gyre has intensified while decreasing in size. The shrinking is seen in the northward shift of the North Pacific Current (NPC, the high gradient region centred about 40°N in Figure 3.10) and has been described using the satellite altimeter, XBT/hydrography, and, more recently, Argo profiling float data (Douglass et al., 2006; Cummins and Freeland, 2007). A similar 20-year trend is detected in the WSG, with the northern WSG in the Bering Sea having intensified while the southern WSG south of the Aleutian Islands has weakened. These decadal changes are attributable to strengthening and northward expansion of the Pacific High and Aleutian Low atmospheric pressure systems over the subarctic North Pacific Ocean (Carton et al., 2005).

The subtropical gyre in the North Pacific also expanded along its southern boundary over the past two decades. The North Equatorial Current (NEC) shifted southward along the 137°E meridian (Qiu and Chen, 2012, also note the SSH increase east of the Philippines in Figure 3.10 indicating the southward shift). The NEC's bifurcation latitude along the Philippine coast migrated southward from a mean latitude of 13°N in the early 1990s to 11°N in the late 2000s (Qiu and Chen, 2010). These changes are due to a recent strengthening of the Walker circulation generating a positive wind stress curl anomaly (Tanaka et al., 2004; Mitas and Clement, 2005). The enhanced regional sea level rise, $>10 \text{ mm yr}^{-1}$ in the western tropical North Pacific Ocean (Timmermann et al., 2010, Figure 3.10), is indicative of the changes in ocean circulation. The 20-year timescale expansion of the North Pacific subtropical gyre has *high confidence* due to the good agreement seen in satellite altimetry, subsurface ocean data, and wind stress changes. This sea level increase in the western tropical Pacific also indicates a strengthening of the equatorward geostrophic limb of the subtropical cells. However, the 20-year increase reversed a longer term weakening of the subtropical cells (Feng et al., 2010), illustrating the high difficulty of separating secular trends from multi-decadal variability.

Variability in the mid-latitude South Pacific over the past two decades is characterized by a broad increase in SSH in the 35°S–50°S band and a lesser increase south of 50°S along the path of the ACC (Figure 3.10). These SSH fluctuations are induced by the intensification in the Southern Hemisphere westerlies (i.e., the SAM, see also Section 3.4.4), generating positive and negative wind stress curl anomalies north and south of 50°S. In response, the southern limb of the South Pacific subtropical gyre has intensified in the past two decades (Cai, 2006; Qiu and Chen, 2006; Roemmich et al., 2007) along with a southward expansion of the East Australian Current (EAC) into the Tasman Sea (Hill et al., 2008). The intensification in the South

Pacific gyre extends to a greater depth (>1800 m) than that in the North Pacific gyre (Roemmich and Gilson, 2009). As in the north, the 20-year changes in the South Pacific are seen with *high confidence* as they occur consistently in multiple lines of medium and high quality data. Multiple linear regression analysis of the 20-year Pacific SSH field (Zhang and Church, 2012) indicated that interannual and decadal modes explain part of the circulation variability seen in SSH gradients, and once the aliasing by these modes is removed, the SSH trends are weaker and more spatially uniform than in a single variable trend analysis.

The strengthening of southern hemisphere westerlies is a multi-decadal signal, as seen in sea level pressure difference between middle and high southern latitudes from 1949 to 2009 (Gillett and Stott, 2009; also Section 3.4.4). The multi-decadal warming in the Southern Ocean (e.g., Figure 3.1, and Gille, 2008, for the past 50–70 years) is consistent with a poleward displacement of the ACC and the southern limb of the subtropical gyres, by about 1° of latitude per 40 years (Gille, 2008). The warming and corresponding sea level rise signals are not confined to the South Pacific, but are seen globally in zonal mean fields (e.g., at 40°S–50°S in Figure 3.9 I and 3.10). Alory et al. (2007) describe the broad warming consistent with a southward shift of the ACC in the South Indian Ocean. In the Atlantic, a southward trend in the location of the Brazil-Malvinas confluence (at around 39°S) is described from surface drifters and altimetry by Lumpkin and Garzoli (2011), and in the location of the Brazil Current separation point from sea surface temperature and altimetry by Goni et al. (2011). Enhanced surface warming and poleward displacement, globally, of the western boundary currents is described by Wu et al. (2012).

Changes in Pacific Ocean circulation over the past two decades since 1993, observed with *medium to high confidence*, include intensification of the North Pacific subpolar gyre, the South Pacific subtropical gyre, and the subtropical cells, plus expansion of the North Pacific subtropical gyre and a southward shift of the ACC. It is *likely* that these wind-driven changes are predominantly due to interannual-to-decadal variability, and in the case of the subtropical cells represent reversal of earlier multi-decadal change. Sustained time-series of wind stress forcing and ocean circulation will permit increased skill in separating interannual and decadal variability from long-term trends (e.g. Zhang and Church, 2012).

3.6.3 The Atlantic Meridional Overturning Circulation (AMOC)

The AMOC consists of an upper limb with net northward transport between the surface and approximately 1200 m depth, and a lower limb of denser, colder, fresher waters returning southward between 1200 m and 5000 m. The AMOC is responsible for most of the meridional transport of heat and carbon by the mid-latitude northern hemisphere ocean and associated with the production of about half of the global ocean's deep waters in the northern North Atlantic. Coupled climate models find that a slowdown of the AMOC in the next decades is very likely, though with uncertain magnitude (Section 11.3.3.3). Observations of the AMOC are directed toward detecting possible long-term changes in its amplitude, its northward energy transport, and in the ocean's capacity to absorb excess heat and greenhouse gases, as well as characterizing short-term variability and its relationship to changes in forcing.

[INSERT FIGURE 3.11 HERE]

Figure 3.11: **a)** Volume transport in Sverdrups (Sv; where 1 Sv = $10^6 \text{ m}^3 \text{ s}^{-1}$) of the Florida Current between Florida and the Bahamas, from dropsonde measurements (symbols) and cable voltages (continuous line), extending the time-series shown in Meinen et al. (2010) **b)** AMOC transport estimates (Sv): 1. RAPID/MOCHA (Rapid Climate Change programme/Meridional Ocean Circulation and Heatflux Array) at 26.5°N (red). The array monitors the top-to-bottom Atlantic wide circulation, ensuring a closed mass balance across the section, and hence a direct measure of the upper and lower limbs of the AMOC. 2. 41°N (black): An index of maximum AMOC strength from Argo float measurements in the upper 2000 m only, combined with satellite altimeter data. The lower limb is not measured. 3. Meridional Overturning Variability Experiment (MOVE) at 16°N (blue) measuring transport of North Atlantic Deep Water in the lower limb of the AMOC between 1100 m and 4800 m depth between the Caribbean and the mid-Atlantic Ridge. This transport is thought to be representative of maximum MOC variability based on model validation experiments. The temporal resolution of the three timeseries is ten days for 16°N and 26°N and one month for 41°N. The data have been three month low-pass filtered. Means and standard deviations for the common period of 2 April 2004 to 1 April 2010 are $17.5 \pm 3.8 \text{ Sv}$, $13.8 \pm 3.3 \text{ Sv}$, and $-20.3 \pm 4.8 \text{ Sv}$ (negative indicating the southward lower limb) for 26.5°N, 41°N, and 16°N respectively. Means over this period are indicated by the horizontal line on each timeseries.

Presently, variability in the full AMOC and meridional heat flux are being estimated on the basis of direct observations at 26.5°N by the RAPID/MOCHA array (Cunningham et al., 2007; Kanzow et al., 2007; Johns

et al., 2011). The array showed a mean AMOC magnitude of 18 ± 1.0 Sv (± 1 standard deviation of annual means) between April 2004 and April 2009, with 10-day values ranging from 3–32 Sv (McCarthy et al., 2012). Earlier estimates of AMOC strength from 5 shipboard expeditions over 47 years at 24°N (Bryden et al., 2005) were in the range of variability seen by RAPID/MOCHA. For the 1-year period 1 April 2009 to 31 March 2010, the AMOC mean strength decreased to 12.8 Sv. This decrease was manifest in a shift of southward interior transport from the deep layers to the upper 1000 m. While the AMOC weakening in 2009/2010 was large, it subsequently rebounded and with the large year-to-year changes no trend is detected in the updated time-series (Figure 3.11b).

Observations targeting one limb of the AMOC include Willis (2010) at 41°N combining velocities from Argo drift trajectories, Argo temperature/salinity profiles, and satellite altimeter data (Figure 3.11b). Here the upper limb AMOC magnitude is 15.5 Sv ± 2.4 from 2002 to 2009 (Figure 3.11b). This study suggests an increase in the AMOC strength by about 2.6 Sv from 1993 to 2010, though with *low confidence* because it is based on SSH alone in the pre-Argo interval of 1993–2001. At 16°N , geostrophic array-based estimates of the southward transport of the AMOC's lower limb, in the depth range 1100–4700 m, have been made continuously since 2000 (Kanzow et al., 2008). These are the longest continuous measurements of the southward flow of NADW in the western basin. While the period 2000 to mid-2009 suggested a downward trend (Send et al., (2011)), the updated time-series (Figure 3.11b) has no apparent trend. In the South Atlantic at 35°S , estimates of the AMOC upper limb were made using 27 high resolution XBT transects, 2002–2011, and Argo float data (Garzoli et al., 2013). The upper-limb AMOC magnitude was 18.1 Sv ± 2.3 (1 standard deviation based on cruise values), consistent with the northern hemisphere estimates.

The continuous AMOC estimates at 16°N , 26.5°N , and 41°N have time series of length eleven, seven, and nine years respectively (Figure 3.11b). All show a substantial variability of ~ 3 – 5 Sv for three month low-pass time series, with a peak-to-peak interannual variability of 5 Sv. The shortness of these time series and the relatively large interannual variability emerging in them suggests that trend estimates be treated cautiously, and no trends are seen at 95% confidence in any of the time series.

Continuous time series of AMOC components, longer than those of the complete system at 26.5°N , have been obtained using moored instrumentation. These include the inflow into the Arctic through Fram Strait (since 1997, Schauer and Beszczynska-Möller, 2009) and through the Barents Sea (since 1997, Ingvaldsen et al., 2004; Mauritzen et al., 2011), dense inflows across sills between Greenland and Scotland (since 1999 and 1995 respectively, Olsen et al., 2008; Jochumsen et al., 2012), and North Atlantic Deep Water carried southward within the Deep Western Boundary Current - at 53°N (since 1997, Fischer et al., 2010), at 39°N (Line W, since 2004, Toole et al., 2011). The longest time-series of observations of ocean transport in the world (dropsonde and cable voltage measurements in the Florida Straits), extend from the mid-1960s to the present (Meinen et al., 2010), with small decadal variability of about 1 Sv and no evidence of a multi-decadal trend (Figure 3.11a). Similarly, none of the other direct, continuous transport estimates of single components of the AMOC exhibit long-term trends at 95% significance.

Indirect estimates of the annual average AMOC strength and variability can be made (Grist et al., 2009; Josey et al., 2009) from diapycnal transports driven by air-sea fluxes (NCEP-NCAR reanalysis fields from 1960 to 2007) or by inverse techniques (Lumpkin and Speer, 2007). Decadal fluctuations of up to 2 Sv are seen, but no trend. Consistent with Grist et al. (2009), the sea level index of the strength of the AMOC, based on several coherent western boundary tide gauge records between 39°N and 43°N at the American coast (Bingham and Hughes, 2009) shows no long-term trend from 1960 to 2007.

In summary, measurements of the AMOC and of circulation elements contributing to it, at various latitudes and covering different time periods, agree that the range of inter-annual variability is 5 Sv (Figure 3.11b). These estimates do not have trends, in either the subtropical or the subpolar gyre. However, the observational record of AMOC variability is short, and there is insufficient evidence to support a finding of change in the transport of the AMOC.

3.6.4 The Antarctic Meridional Overturning Circulation

Sinking of AABW near Antarctica supplies about half of the deep and abyssal waters in the global ocean (Orsi et al., 1999). AABW spreads northward as part of the global overturning circulation and ventilates the

bottom-most portions of much of the ocean. Observed widespread warming of AABW in recent decades (Section 3.5.4) implies a concomitant reduction in its northward spread. Reductions of 1–4 Sv in northward transports of AABW across 24°N have been estimated by geostrophic calculations using repeat oceanographic section data between 1981 and 2010 in the North Atlantic Ocean (Johnson et al., 2008b; Frajka-Williams et al., 2011) and between 1985 and 2005 in the North Pacific (Kouketsu et al., 2009). A global full-depth ocean data assimilation study shows a reduction of northward AABW flow across 35°S of >2 Sv in the South Pacific starting around 1985 and >1 Sv in the western South Atlantic since around 1975 (Kouketsu et al., 2011). This reduction is consistent with the contraction in volume of AABW (Purkey and Johnson, 2012) discussed in Section 3.5.4.

Several model studies have suggested that changes in wind stress over the Southern Ocean (Section 3.4) may drive a change in the Southern Ocean overturning circulation (e.g. Le Quéré et al., 2007). A recent analysis of changes in chlorofluorocarbon (CFC) concentrations in the Southern Ocean supports the idea that the overturning cell formed by upwelling of deep water and sinking of intermediate waters has slowed, but does not quantify the change in transport (Waugh et al., 2013).

3.6.5 Water Exchange Between Ocean Basins

3.6.5.1 The Indonesian Throughflow (ITF)

The transport of water from the Pacific to the Indian Ocean via the Indonesian archipelago is the only low-latitude exchange between oceans, and is significant because it is a fluctuating sink/source for very warm tropical water in the two oceans. ITF transport has been estimated from hydrographic and XBT transects between Australia and Indonesia, and as a synthesis of these together with satellite altimetry, wind stress, and other data (Wunsch, 2010), and from moorings in the principal Indonesian passages. The most comprehensive observations were obtained in 2004–2006 in three passages by the INSTANT mooring array (Sprintall et al., 2009), and show a westward transport of 15.0 (±4) Sv. For the main passage, Makassar Strait, Susanto et al. (2012) find 13.3 (±3.6) Sv in the period 2004–2009, with small year-to-year differences. On a longer timescale, the Wunsch (2010) estimate for 1992–2007 was 11.5 Sv (±2.4) westward, and thus consistent with INSTANT. Wainwright et al. (2008) analyzed data between Australia and Indonesia beginning in the early 1950's, and found a change in the slope of the thermocline for data before and after 1976, indicating a decrease in geostrophic transport by 23%, consistent with a weakening of the tradewinds (e.g., Vecchi et al., 2006), who described a downward trend in the Walker circulation since the late 19th century). Other transport estimates based on the IX1 transect show correlation with ENSO variability (Potemra and Schneider, 2007) and no significant trend for the period since 1984 having continuous sampling along IX1 (Sprintall et al., 2002). Overall, the limited evidence provides *low confidence* that a trend in ITF transport has been observed.

3.6.5.2 The Antarctic Circumpolar Current (ACC)

There is *medium confidence* that the westerly winds in the Southern Ocean have increased since the early 1980s (Section 3.4.4), associated with a positive trend in the SAM (Marshall, 2003); also see Sections 3.4.4 and 3.6.3). While a few observational studies have found evidence for correlation between SAM and ACC transport on subseasonal to interannual scales (e.g., Hughes et al., 2003; Meredith et al., 2004), there is no significant observational evidence of an increase in ACC transport associated with the multi-decadal trend in wind forcing over the Southern Ocean. Repeat hydrographic sections spread unevenly over 35 years in Drake Passage (e.g., Cunningham et al., 2003; Koshlyakov et al., 2007; Gladyshev et al., 2008; Koshlyakov et al., 2011), south of Africa (Swart et al., 2008) and south of Australia (Rintoul et al., 2002) reveal moderate variability but no significant trends in these sparse and discontinuous records. A comparison of recent Argo data and a long-term climatology showed that the slope of density surfaces (hence baroclinic transport) associated with the ACC had not changed in recent decades (Böning et al., 2008). Eddy-resolving models suggest the ACC transport is relatively insensitive to trends in wind forcing, consistent with the ACC being in an “eddy-saturated” state where increases in wind forcing are compensated by changes in the eddy field (Hallberg and Gnanadesikan, 2006; Farneti et al., 2010; Spence et al., 2010). While there is limited evidence for (or against) multi-decadal changes in transport of the ACC, observations of changes in temperature, salinity and sea surface height indicate the current system has shifted poleward (Böning et al., 2008; Gille, 2008; Morrow et al., 2008; Sokolov and Rintoul, 2009; Kazmin, 2012).

3.6.5.3 North Atlantic / Nordic Seas Exchange

There is no observational evidence of changes during the past two decades in the flow across the Greenland-Scotland Ridge, which connects the North Atlantic with the Norwegian and Greenland Seas. Direct current measurements since the mid-1990s have not shown any significant trends in volume transport for any of the three inflow branches (Østerhus et al., 2005; Hansen et al., 2010; Mauritzen et al., 2011; Jónsson and Valdimarsson, 2012).

The two primary pathways for the deep southward overflows across the Greenland-Scotland Ridge are the Denmark Strait and Faroe Bank Channel. Moored measurements of the Denmark Strait overflow demonstrate significant interannual transport variations (Macrander et al., 2005; Jochumsen et al., 2012), but the time-series is not long enough to detect a multi-decadal trend. Similarly, a ten-year time-series of moored measurements in the Faroe Bank channel (Olsen et al., 2008) does not show a trend in transport.

3.6.6 Conclusion

Recent observations have greatly increased the knowledge of the amplitude of variability in major ocean circulation systems on time scales from years to decades. It is *very likely* that the subtropical gyres in the North Pacific and South Pacific have expanded and strengthened since 1993, but it is *about as likely as not* that this reflects a decadal oscillation linked to changes in wind forcing, including changes in winds associated with the modes of climate variability. There is no evidence for a long-term trend in the AMOC amplitude, based on a decade of continuous observations plus several decades of sparse hydrographic transects, or in the longer records of components of the AMOC such as the Florida Current (since 1965), although there are large interannual fluctuations. Nor is there evidence of a trend in the transports of the ITF (over ~20 years), the ACC (~30 years sparsely sampled), or between the Atlantic and Nordic Seas (~20 years). Given the short duration of direct measurements of ocean circulation, we have *very low confidence* that multi-decadal trends can be separated from decadal variability.

3.7 Sea Level Change, Including Extremes

3.7.1 Introduction and Overview of Sea Level Measurements

Sea level varies as the ocean warms or cools, as water is transferred between the ocean and continents, between the ocean and ice sheets, and as water is redistributed within the ocean due to the tides and changes in the oceanic and atmospheric circulation. Sea level can rise or fall on time scales ranging from hours to centuries, spatial scales from <1 km to global, and with height changes from a few mm to a meter or more (due to tides). Sea level integrates and reflects multiple climatic and dynamical signals. Measurements of sea level are the longest-running ocean observation system. This section assesses interannual and longer variations in non-tidal sea level from the instrumented period (late 18th century to the present). Chapter 4 (Sections 4.3.4 and 4.4.2) assesses contributions of glaciers and ice sheets to sea level, Chapter 5 (Section 5.6) assesses reconstructions of sea level from the geological record, Chapter 10 (Section 10.4.3) assesses detection and attribution of human influences on sea level change, and Chapter 13 synthesizes results and assesses projections of sea level change.

The sea level observing system has evolved over time. There are intermittent records of sea level at four sites in Northern Europe starting in the 1700s. By the late 1800s, there were more tide gauges were being operated in Northern Europe, on both North American coasts, and in Australia and New Zealand in the Southern Hemisphere (Appendix 3.A). Tide gauges began to be placed on islands far from continental coasts starting in the early 20th century, but a majority of deep-ocean islands did not have an operating tide gauge suitable for climate studies until the early 1970s.

Tide gauge records measure the combined effect of ocean volume change and vertical land motion (VLM). For detecting climate related variability of the ocean volume, the VLM signal must be removed. One component that can be accounted for to a certain extent is the VLM associated with glacial isostatic adjustment (GIA) (Peltier, 2001). In some areas, however, VLM from tectonic activity, ground-water mining, or hydrocarbon extraction is greater than GIA (e.g., Wöppelmann et al., 2009; King et al., 2012);

these effects can be reduced by selecting gauges with no known tectonic or subsidence issues (e.g. Douglas, 2001) or by selecting gauges where GIA models have small differences (Spada and Galassi, 2012). More recently, global positioning system (GPS) receivers have been installed at tide gauge sites to measure VLM as directly as possible (e.g., Wöppelmann et al., 2009; King et al., 2012). However, these measurements of VLM are only available since the late 1990s at the earliest, and either have to be extrapolated into the past to apply to older records, or used to identify sites without extensive VLM.

Satellite radar altimeters in the 1970s and 1980s made the first nearly global observations of sea level, but these early measurements were highly uncertain and of short duration. The first precise record began with the launch of TOPEX/Poseidon (T/P) in 1992. This satellite and its successors (Jason-1, Jason-2) have provided continuous measurements of sea level variability at 10-day intervals between approximately $\pm 66^\circ$ latitude. Additional altimeters in different orbits (ERS-1, ERS-2, Envisat, Geosat Follow-on) have allowed for measurements up to $\pm 82^\circ$ latitude and at different temporal sampling (3 to 35 days), although these measurements are not as accurate as those from the T/P and Jason satellites. Unlike tide gauges, altimetry measures sea level relative to a geodetic reference frame (classically a reference ellipsoid that coincides with the mean shape of the Earth, defined within a globally realized terrestrial reference frame) and thus will not be affected by VLM, although a small correction which depends on the area covered by the satellite ($\sim 0.3 \text{ mm yr}^{-1}$) must be added to account for the change in location of the ocean bottom due to GIA relative to the reference frame of the satellite (Peltier, 2001; see also Chapter 13.1.2).

Tide gauges and satellite altimetry measure the combined effect of ocean warming and mass changes on ocean volume. Although variations in the density related to upper-ocean salinity changes cause regional changes in sea level, when globally averaged their effect on sea level rise is an order of magnitude or more smaller than thermal effects (Lowe and Gregory, 2006). The thermal contribution to sea level can be calculated from in situ temperature measurements (Section 3.2). It has only been possible to directly measure the mass component of sea level since the launch of the Gravity Recovery and Climate Experiment (GRACE) in 2002 (Chambers et al., 2004). Before that, estimates were based either on estimates of glacier and ice sheet mass losses or using residuals between sea level measured by altimetry or tide gauges and estimates of the thermosteric component (e.g., Willis et al., 2004; Domingues et al., 2008), which allowed for the estimation of seasonal and interannual variations as well. GIA also causes a gravitational signal in GRACE data that must be removed in order to determine present-day mass changes; this correction is of the same order of magnitude as the expected trend and is still uncertain at the 30% level (Chambers et al., 2010).

3.7.2 Trends in Global Mean Sea Level and Components

Tide gauges with the longest nearly continuous records of sea level show increasing sea level over the 20th century (Figure 3.12; Woodworth et al., 2009; Mitchum et al., 2010). There are, however, significant interannual and decadal-scale fluctuations about the average rate of sea level rise in all records. Different approaches have been used to compute the mean rate of 20th century global mean sea level (GMSL) rise from the available tide gauge data: computing average rates from only very long, nearly continuous records (Douglas, 2001; Holgate, 2007); using more numerous but shorter records and filters to separate nonlinear trends from decadal-scale quasi-periodic variability (Jevrejeva et al., 2006; Jevrejeva et al., 2008); neural network methods (Wenzel and Schroeter, 2010); computing regional sea level for specific basins then averaging (Jevrejeva et al., 2006; Jevrejeva et al., 2008; Merrifield et al., 2009; Wöppelmann et al., 2009); or projecting tide gauge records onto empirical orthogonal functions (EOFs) computed from modern altimetry (Church et al., 2004; Church and White, 2011; Ray and Douglas, 2011) or EOFs from ocean models (Llovel et al., 2009; Meyssignac et al., 2012). Different approaches show very similar long-term trends, but noticeably different interannual and decadal-scale variability (Figure 3.13a). Only the time-series from Church and White (2011) extends to 2010, so it is used in the assessment of rates of sea level rise. The rate from 1901 to 2010 is $1.7 [1.5 \text{ to } 1.9] \text{ mm yr}^{-1}$ (Table 3.1), which is unchanged from the value in AR4. Rates computed using alternative approaches over the longest common interval (1900–2003) agree with this estimate within the uncertainty.

[INSERT FIGURE 3.12 HERE]

Figure 3.12: 3-year running mean sea level anomalies (in mm) relative to 1900–1905 from long tide gauge records representing each ocean basin from the Permanent Service for Mean Sea Level (PSMSL) (<http://www.psmsl.org>), obtained May 2011. Data have been corrected for Glacial Isostatic Adjustment (GIA) (Peltier, 2004), using values

available from http://www.psmsl.org/train_and_info/geo_signals/gia/peltier/. Error bars reflect the 5 to 95% confidence interval, based on the residual monthly variability about the 3-year running mean.

Since AR4, significant progress has been made in quantifying the uncertainty in GMSL associated with unknown VLM and uncertainty in GIA models. Differences between rates of GMSL rise computed with and without VLM from GPS are smaller than the estimated uncertainties (Merrifield et al., 2009; Wöppelmann et al., 2009). Use of different GIA models to correct tide gauge measurements results in differences less than 0.2 mm yr^{-1} (one standard error), and rates of GMSL rise computed from uncorrected tide gauges differ from rates computed from GIA-corrected gauges by only 0.4 mm yr^{-1} (Spada and Galassi, 2012), again within uncertainty estimates. This agreement gives increased confidence that the 20th century rate of GMSL rise is not biased high due to unmodeled VLM at the gauges.

Satellite altimetry can resolve interannual fluctuations in GMSL better than tide gauge records because less temporal smoothing is required (Figure 3.13b). It is clear that deviations from the long-term trend can exist for periods of several years, especially during El Niño (e.g., 1997–1998) and La Niña (e.g., 2011) events (Nerem et al., 1999; Boening et al., 2012; Cazenave et al., 2012). The rate of GMSL rise from 1993–2010 is $3.2 [2.8 \text{ to } 3.6] \text{ mm yr}^{-1}$ based on the average of altimeter time series published by multiple groups (Ablain et al., 2009; Beckley et al., 2010; Leuliette and Scharroo, 2010; Nerem et al., 2010; Church and White, 2011; Masters et al., 2012, Figure 3.13). As noted in AR4, this rate continues to be statistically higher than that for the 20th century (Table 3.1). There is *high confidence* that this change is real and not an artefact of the different sampling or change in instrumentation, as the trends estimated over the same period from tide gauges and altimetry are consistent. Although the rate of GMSL rise has a slightly lower trend between 2005 and 2010 (Nerem et al., 2010), this variation is consistent with earlier interannual fluctuations in the record (e.g., 1993–1997), mostly attributable to El Niño/La Niña cycles (Box 9.2). At least 15 years of data are required to reduce the impact of interannual variations associated with El Niño or La Niña on estimated trends (Nerem et al., 1999).

Since AR4, estimates of both the thermosteric component and mass component of GMSL rise have improved, although estimates of the mass component are possible only since the start of the GRACE measurements in 2002. After correcting for biases in older XBT data [3.2], the rate of thermosteric sea level rise in the upper 700 m since 1971 is 50% higher than estimates used for AR4 (Domingues et al., 2008; Wijffels et al., 2008). Because of much sparser upper ocean measurements before 1971, we only estimate the trend since then (Section 3.2). The warming of the upper 700 m from 1971 to 2010 caused an estimated mean thermosteric rate of rise of $0.6 [0.4 \text{ to } 0.8] \text{ mm yr}^{-1}$ (90% confidence), which is 30% of the observed rate of GMSL rise for the same period (Table 3.1; Figure 3.13c). Although still a short record, more numerous, better distributed, and higher quality profile measurements from the Argo program are now being used to estimate the steric component for the upper 700 m as well as for the upper 2000 m (Domingues et al., 2008; Willis et al., 2008; Cazenave et al., 2009; Leuliette and Miller, 2009; Willis et al., 2010; Leuliette and Willis, 2011; Llovel et al., 2011; von Schuckmann and Le Traon, 2011; Levitus et al., 2012). However, these data have been shown to be best suited for global analyses after 2005 due to a combination of interannual variability and large biases when using data before 2005 due to sparser sampling (Leuliette and Miller, 2009; von Schuckmann and Le Traon, 2011). Comparison of sparse but accurate temperature measurements from the World Ocean Circulation Experiment in the 1990s with Argo data from 2006–2008 also indicates a significant rise in global thermosteric sea level, although the estimate is uncertain owing to relatively sparse 1990s sampling (Freeland and Gilbert, 2009).

Observations of the contribution to sea level rise from warming below 700 m are still uncertain due to limited historical data, especially in the Southern Ocean (Section 3.2). Before Argo, they are based on 5-year averages to 2000 m depth (Levitus et al., 2012). From 1971 to 2010, the estimated trend for the contribution between 700 m and 2000 m is $0.1 [0 \text{ to } 0.2] \text{ mm yr}^{-1}$ (Table 3.1; Levitus et al., 2012). To measure the contribution of warming below 2000 m, much sparser but very accurate temperature profiles along repeat hydrographic sections are utilized (Purkey and Johnson, 2010; Kouketsu et al., 2011). The studies have found a significant warming trend between 1000 and 4000 m within and south of the Sub-Antarctic Front (Figure 3.3). The estimated total contribution of warming below 2000 m to global mean sea level rise between circa 1992 and 2005 is $0.1 [0.0 \text{ to } 0.2] \text{ mm yr}^{-1}$ (95% confidence as reported by authors; Purkey and Johnson, 2010).

Detection of the mass component of sea level from the GRACE mission was not assessed in AR4, as the record was too short and there was still considerable uncertainty in the measurements and corrections required. Considerable progress has been made since AR4, and the mass component of sea level measured by GRACE has been increasing at a rate between 1 and 2 mm yr⁻¹ since 2002 (Willis et al., 2008; Cazenave et al., 2009; Leuliette and Miller, 2009; Chambers et al., 2010; Llovel et al., 2010; Willis et al., 2010; Leuliette and Willis, 2011). Differences between studies are due partially to the time periods used to compute trends, as there are significant interannual variations in the mass component of GMSL (Willis et al., 2008; Chambers et al., 2010; Llovel et al., 2010; Boening et al., 2012), but also to substantial differences in GIA corrections applied, of order 1 mm yr⁻¹. Recent evaluations of the GIA correction have found explanations for the difference (Chambers et al., 2010; Peltier et al., 2012), but uncertainty of 0.3 mm yr⁻¹ is still probable. Measurements of sea level from altimetry and the sum of observed steric and mass components are also consistent at monthly-scales during the time-period when Argo data have global distribution (Figure 3.13d), which gives *high confidence* that the current ocean observing system is capable of resolving the rate of sea level rise and its components.

[INSERT FIGURE 3.13 HERE]

Figure 3.13: Global mean sea level anomalies (in mm) from the different measuring systems as they have evolved in time, plotted relative to 5-year mean values that start at **a)** 1900, **b)** 1993, **c)** 1970, and **d)** 2005. **a)** Yearly average GMSL reconstructed from tide gauges (1900–2010) by three different approaches (Jevrejeva et al., 2008; Church and White, 2011; Ray and Douglas, 2011), **b)** GMSL (1993–2010) from tide gauges and altimetry (Nerem et al., 2010) with seasonal variations removed and smoothed with a 60-day running mean **c)** GMSL (1970–2010) from tide gauges along with the thermosteric component to 700 m, (3-year running mean) estimated from in situ temperature profiles (updated from Domingues et al., 2008), **d)** the GMSL (nonseasonal) from altimetry and that computed from the mass component (GRACE) and steric component (Argo) from 2005–2010 (Leuliette and Willis, 2011), all with a 3-month running mean filter. All uncertainty bars are one standard error as reported by the authors. The thermosteric component is just a portion of total sea level, and is not expected to agree with total sea level.

3.7.3 Regional Distribution of Sea Level Change

Large-scale spatial patterns of sea level change are known to high precision only since 1993, when satellite altimetry became available (Figure 3.10). These data have shown a persistent pattern of change since the early 1990s in the Pacific, with rates of rise in the Warm Pool of the western Pacific up to three times larger than those for GMSL, while rates over much of the eastern Pacific are near zero or negative (Beckley et al., 2010). The increasing sea level in the Warm Pool started shortly before the launch of TOPEX/Poseidon (Merrifield, 2011), and is caused by an intensification of the trade winds (Merrifield and Maltrud, 2011) since the late 1980s that may be related to the Pacific Decadal Oscillation (PDO) (Merrifield et al., 2012; Zhang and Church, 2012). The lower rate of sea level rise since 1993 along the western coast of the United States has also been attributed to changes in the wind stress curl over the North Pacific associated with the PDO (Bromirski et al., 2011). While global maps can be created using EOF analysis (e.g. Church et al., 2004; Llovel et al., 2009), pre-1993 results are still uncertain, as the method assumes that the EOFs since 1993 are capable of representing the patterns in previous decades, and results may be biased in the middle of the ocean where there are no tide gauges to constrain the estimate (Ray and Douglas, 2011). Several studies have examined individual long tide gauge records in the North Atlantic and found coherent decadal-scale fluctuations along both the U.S. east coast (Sturges and Hong, 1995; Hong et al., 2000; Miller and Douglas, 2007), the European coast (Woodworth et al., 2010; Sturges and Douglas, 2011; Calafat et al., 2012), and the marginal seas in the western North Pacific (Marcos et al., 2012), all related to natural climate variability.

There is still considerable uncertainty on how long large-scale patterns of regional sea level change can persist, especially in the Pacific where the majority of tide gauge records are less than 40-years long. Based on analyses of the longest-records in the Atlantic, Indian, and Pacific oceans (including the available gauges in the Southern Ocean) there are significant multidecadal variations in regional sea level (Holgate, 2007; Woodworth et al., 2009; Mitchum et al., 2010; Woodworth et al., 2011; Chambers et al., 2012). Hence local rates of sea level rise can be considerably higher or lower than the global mean rate for periods of a decade or more.

The discussion above of regional sea level trends has focused on effects that appear to be related to regional ocean volume change, and not those due to vertical land motion. As discussed in Section 3.7.1, vertical land motion can dramatically affect local sea level change. Some extreme examples of vertical land motion are in

Neah Bay, Washington, where the signal is $+3.8 \text{ mm yr}^{-1}$ (uplift from tectonic activity); Galveston, Texas, where the value is -5.9 mm yr^{-1} (subsidence from groundwater mining); and Nedre Gavle, Sweden where the value is $+7.1 \text{ mm yr}^{-1}$ (uplift from GIA), all computed from nearby GPS receivers (Wöppelmann et al., 2009). These areas will all have long-term rates of sea level rise that are significantly higher or lower than those due to ocean volume change alone, but as these rates are not related to climate change, they are not discussed here.

3.7.4 Assessment of Evidence for Accelerations in Sea Level Rise

AR4 concluded that there was “*high confidence* that the rate of global sea level rise increased from the 19th to the 20th century” but could not be certain as to whether the higher rate since 1993 was reflective of decadal variability or a further increase in the longer-term trend. Since AR4, there has been considerable effort to quantify the level of decadal and multi-decadal variability and to detect acceleration in GMSL and mean sea level at individual tide gauges. It has been clear for some time that there was a significant increase in the rate of sea level rise in the four oldest records from Northern Europe starting in the early to mid-19th century (Ekman, 1988; Woodworth, 1990, 1999; Mitchum et al., 2010). Estimates of the change in the rate have been computed, either by comparing trends over 100-year intervals for the Stockholm site (Ekman, 1988; Woodworth, 1990), or by fitting a quadratic term to all the long records starting before 1850 (Woodworth, 1990, 1999). The results are consistent and indicate a significant acceleration that started in the early to mid-19th century (Woodworth, 1990, 1999), although some have argued it may have started in the late 1700s (Jevrejeva et al., 2008). The increase in the rate of sea level rise at Stockholm (the longest record that extends past 1900) has been based on differencing 100-year trends from 1774–1884 and 1885–1985. The estimated change is $1.0 [0.7 \text{ to } 1.3] \text{ mm yr}^{-1}$ per century (1 standard error, as calculated by Woodworth, 1990). Although sites in other ocean basins do show an increased trend after 1860 (e.g., Figure 3.12), it is impossible to detect a change in the early- to mid-1800s in other parts of the ocean using tide gauge data alone, as there are no observations.

Numerous studies have attempted to quantify if a detectable acceleration has continued into the 20th century, typically by fitting a quadratic to data at individual tide gauges (Woodworth, 1990; Woodworth et al., 2009; Houston and Dean, 2011; Watson, 2011; Woodworth et al., 2011) as well as to reconstructed time-series of GMSL (Church and White, 2006; Jevrejeva et al., 2008; Church and White, 2011; Rahmstorf and Vermeer, 2011), or by examining differences in long-term rates computed at different tide gauges (Sallenger et al., 2012). Woodworth et al. (2011) find significant quadratic terms at the sites that begin before 1860 (all in the Northern Hemisphere). Other authors using more numerous but significantly shorter records have found either insignificant or small negative quadratic terms in sea level around the United States and Australia since 1920 (Houston and Dean, 2011; Watson, 2011), or large positive quadratic values since 1950 along the U.S. east coast (Sallenger et al., 2012). However, fitting a quadratic term to tide gauge data after 1920 results in highly variable, insignificant quadratic terms (Rahmstorf and Vermeer, 2011), and so only studies that use data before 1920 and that extend until 2000 or beyond are suitable for evaluating long-term acceleration of sea level.

A long time-scale is needed because significant multidecadal variability appears in numerous tide gauge records during the 20th century (Holgate, 2007; Woodworth et al., 2009; Mitchum et al., 2010; Woodworth et al., 2011; Chambers et al., 2012). The multidecadal variability is marked by an increasing trend starting in 1910–1920, a downward trend (i.e., leveling of sea level if a long-term trend is not removed) starting around 1950, and an increasing trend starting around 1980. The pattern can be seen in New York, Mumbai, and Fremantle records, for instance (Figure 3.12), as well as 14 other gauges representing all ocean basins (Chambers et al., 2012), and in all reconstructions (Figure 3.14). It is also seen in an analysis of upper 400 m temperature (Gouretski et al., 2012; Section 3.3.2). Although the calculations of 18-year rates of GMSL rise based on the different reconstruction methods disagree by as much as 2 mm yr^{-1} before 1950 and on details of the variability (Figure 3.14), all do indicate 18-year trends that were significantly higher than the 20th century average at certain times (1920–1950, 1990–present) and lower at other periods (1910–1920, 1955–1980), *likely* related to multidecadal variability. Several studies have suggested these variations may be linked to climate fluctuations like the Atlantic Multidecadal Oscillation (AMO) and/or Pacific Decadal Oscillation (PDO, Box 2.5) (Holgate, 2007; Jevrejeva et al., 2008; Chambers et al., 2012), but these results are not conclusive.

[INSERT FIGURE 3.14 HERE]

Figure 3.14: 18-year trends of GMSL rise estimated at 1-year intervals. The time is the start date of the 18-year period, and the shading represents the 90% confidence. The estimate from satellite altimetry is also given, with the 90% confidence given as an error bar. Uncertainty is estimated by the variance of the residuals about the fit, and accounts for serial correlation in the residuals as quantified by the lag-1 autocorrelation.

While technically correct that these multidecadal changes represent acceleration/deceleration of sea level, they should not be interpreted as change in the longer-term rate of sea level rise, as a time series longer than the variability is required to detect those trends. Using data extending from 1900 to after 2000, the quadratic term computed from both individual tide gauge records and GMSL reconstructions is significantly positive (Jevrejeva et al., 2008; Church and White, 2011; Rahmstorf and Vermeer, 2011; Woodworth et al., 2011). Church and White (2006) report that the estimated acceleration term in GMSL (twice the quadratic parameter) is 0.009 [0.006 to 0.012] mm yr⁻² (1 standard deviation) from 1880 to 2009, which is consistent with the other published estimates (e.g., Jevrejeva et al., 2008; Woodworth et al., 2009) that use records longer than 100 years. Chambers et al. (2012) find that modelling a period near 60 years removes much of the multidecadal variability of the 20th century in the tide gauge reconstruction time series. When a 60-year oscillation is modeled along with an acceleration term, the estimated acceleration in GMSL since 1900 ranges from: 0.000 [-0.002 to 0.002] mm yr⁻² in the Ray and Douglas (2011) record, 0.013 [0.007 to 0.019] mm yr⁻² in the Jevrejeva et al. (2008) record, and 0.012 [0.009 to 0.015] mm yr⁻² in the Church and White (2011) record. Thus, while there is more disagreement on the value of a 20th century acceleration in GMSL when accounting for multi-decadal fluctuations, two out of three records still indicate a significant positive value. The trend in GMSL observed since 1993, however, is not significantly larger than the estimate of 18-year trends in previous decades (e.g., 1920-1950).

3.7.5 Changes in Extreme Sea Level

Aside from non-climatic events like tsunamis, extremes in sea level (i.e., coastal flooding, storm surge, high water events, etc.) tend to be caused by large storms, especially when they occur at times of high tide. However, any low-pressure system offshore with associated high winds can cause a coastal flooding event depending on the duration and direction of the winds. Evaluation of changes in frequency and intensity of storms have been treated in Chapter 2 (Section 2.6.3, 2.6.4), as well as SREX Chapter 3 (Section 3.5.2). The main conclusions from both are that there is *low confidence* of any trend or long term change in tropical or extra-tropic storm frequency or intensity in any ocean basin, although there is robust evidence for an increase in the most intense tropical cyclones in the North Atlantic basin since the 1970s. The magnitude and frequency of extreme events can still increase without a change in storm intensity, however, if the mean water level is also increasing. AR4 concluded that the highest water levels have been increasing since the 1950s in most regions of the world, caused mainly by increasing mean sea level. Studies published since AR4 continue to support this conclusion, although higher regional extremes are also caused by large interannual and multidecadal variations in sea level associated with climate fluctuations such as ENSO, the North Atlantic Oscillation, and the Atlantic Multidecadal Oscillation, among others (e.g. Abeyirigunawardena and Walker, 2008; Haigh et al., 2010; Menéndez and Woodworth, 2010; Park et al., 2011).

Global analyses of the changes in extreme sea level are limited, and most reports are based on analysis of regional data (see Lowe et al., 2010 for a review). Estimates of changes in extremes rely either on the analysis of local tide gauge data, or on multi-decadal hindcasts of a dynamical model (WASA-Group, 1998). Most analyses have focused on specific regions and find that extreme values have been increasing since the 1950s, using various statistical measures such as annual maximum surge, annual maximum surge-at-high-water, monthly mean high water level, changes in number of high storm surge events, or changes in 99th percentile events (e.g. Church et al., 2006; D'Onofrio et al., 2008; Marcos et al., 2009; Haigh et al., 2010; Letetrel et al., 2010; Tsimplis and Shaw, 2010; Vilibic and Sepic, 2010; Grinsted et al., 2012). A global analysis of tide gauge records has been performed for data from the 1970s onwards when the global data sampling has been robust and finds that the magnitude of extreme sea level events has increased in all regions studied since that time (Woodworth and Blackman, 2004; Menéndez and Woodworth, 2010; Woodworth et al., 2011).

The height of a 50-year flood event has increased anywhere from 2 to more than 10 cm per decade since 1970 (Figure 3.15a), although some areas have seen a negative rate because vertical land motion is much larger than the rate of mean sea level rise. However, when the annual median height at each gauge is removed to reduce the effect of local mean sea level rise, interannual and decadal fluctuations, and vertical land motion, the rate of extreme sea level change drops in 49% of the gauges to below significance (Figure 3.15b), while at 45% it fell to less than 5 mm yr⁻¹. Only 6% of tide gauge records evaluated had a change in the amplitude of more than 5 mm yr⁻¹ after removing mean sea level variations, mainly in the southeast United States, the western Pacific, southeast Asia, and a few locations in northern Europe. The higher rates in the southeastern United States have been linked to larger storm surge events unconnected to global sea level rise (Grinsted et al., 2012).

[INSERT FIGURE 3.15 HERE]

Figure 3.15: Estimated trends (cm per decade) in the height of a 50-year event in extreme sea level from (a) total elevation and (b) total elevation after removal of annual medians. Black dots indicate trends are not significant at the 95% confidence level. Data are from Menéndez and Woodworth (2010).

3.7.6 Conclusions

It is *virtually certain* that globally averaged sea level has risen over the 20th century, with a *very likely* mean rate between 1900 and 2010 of 1.7 [1.5 to 1.9] mm yr⁻¹ and 3.2 [2.8 and 3.6] mm yr⁻¹ between 1993 and 2010. This assessment is based on high agreement among multiple studies using different methods, and from independent observing systems (tide gauges and altimetry) since 1993. It is *likely* that a rate comparable to that since 1993 occurred between 1920 and 1950, possibly due to a multi-decadal climate variation, as individual tide gauges around the world and all reconstructions of GMSL show increased rates of sea level rise during this period. Although local vertical land motion can cause even larger rates of sea level rise (or fall) relative to the coastline, it is *very likely* that this does not affect the estimates of the global average rate, based on multiple estimations of the average with and without VLM corrections.

It is *virtually certain* that interannual and decadal changes in the large-scale winds and ocean circulation can cause significantly higher or lower rates over shorter periods at individual locations, as this has been observed in tide gauge records around the world. Warming of the upper 700 m of the ocean has *very likely* contributed an average of 0.6 [0.4 to 0.8] mm yr⁻¹ of sea level change since 1971. Warming between 700 m and 2000 m has *likely* been contributing an additional 0.1 mm yr⁻¹ [0 to 0.2] of sea level rise since 1971, and warming below 2000 m *likely* has been contributing another 0.1 [0.0 to 0.2] mm yr⁻¹ of sea level rise since the early 1990s.

It is *very likely* that the rate of mean sea level rise along Northern European coastlines has accelerated since the early 1800s and that this has continued through the 20th century, as the increased rate since 1875 has been observed in multiple long tide gauge records and by different groups using different analysis techniques. It is *likely* that sea level rise throughout the Northern Hemisphere has also accelerated since 1850, as this is also observed in a smaller number of gauges along the coast of North America. Two of the three time series based on reconstructing GMSL from tide gauge data back to 1900 or earlier indicate a significant positive acceleration, while one does not. The range is -0.002 to 0.019 mm yr⁻², so it is *likely* that GMSL has accelerated since 1900. Finally, it is *likely* that extreme sea levels have increased since 1970, largely as a result of the rise in mean sea level.

[INSERT TABLE 3.1 HERE]

Table 3.1: Estimated trends in GMSL and components over different periods from representative time-series. Trends and uncertainty have been estimated from a time-series provided by the authors using ordinary least squares with the uncertainty representing the 90% confidence interval. The model fit for yearly averaged time-series was a bias + trend; the model fit for monthly and 10-day averaged data was a bias + trend + seasonal sinusoids. Uncertainty accounts for correlations in the residuals.

3.8 Ocean Biogeochemical Changes, Including Anthropogenic Ocean Acidification

The oceans can store large amounts of carbon dioxide. The reservoir of inorganic carbon in the ocean is roughly 50 times that of the atmosphere (Sabine et al., 2004). Therefore even small changes in the ocean reservoir can have an impact on the atmospheric concentration of CO₂. The ocean also provides an important

sink for carbon dioxide released by human activities, the anthropogenic CO₂ (C_{ant}). Currently, an amount of CO₂ equivalent to approximately 25% of the total human emissions of CO₂ to the atmosphere is accumulating in the ocean (Mikaloff-Fletcher et al., 2006; Le Quéré et al., 2010). In this section, observations of change in the ocean uptake of carbon, the inventory of C_{ant}, and ocean acidification are assessed, as well as changes in oxygen and nutrients. Chapter 6 provides a synthesis of the overall carbon cycle, including the ocean, atmosphere and biosphere and considering both past trends and future projections.

3.8.1 Carbon

3.8.1.1 Ocean Uptake of Carbon

The air-sea flux of CO₂ is computed from the observed difference in the partial pressure of CO₂ across the air-water interface ($\Delta p\text{CO}_2 = p\text{CO}_{2,\text{sw}} - p\text{CO}_{2,\text{air}}$), the solubility of CO₂ in seawater, and the gas transfer velocity (Wanninkhof et al., 2009). However, the limited geographic and temporal coverage of the $\Delta p\text{CO}_2$ measurement as well as uncertainties in wind forcing and transfer velocity parameterizations mean that uncertainties in global and regional fluxes calculated from measurements of $\Delta p\text{CO}_2$ can be as large as $\pm 50\%$ (Wanninkhof et al., 2013). Using $\Delta p\text{CO}_2$ data in combination with the riverine input Gruber et al. (2009) estimated a global uptake rate of 1.9 [1.2 to 2.5] PgC yr⁻¹ for the time period 1995–2000 and Takahashi et al. (2009) found 2.0 [1.0 to 3.0] PgC yr⁻¹ normalized to the year 2000. Uncertainties in fluxes calculated from $\Delta p\text{CO}_2$ are too large to detect trends in global ocean carbon uptake.

Trends in surface ocean $p\text{CO}_2$ are calculated from ocean time series stations and repeat hydrographic sections in the North Atlantic and North Pacific (Table 3.2). At all locations and for all time periods shown, $p\text{CO}_2$ in both the atmosphere and ocean has increased, while pH and $[\text{CO}_3^{2-}]$ have decreased. At some sites, oceanic surface $p\text{CO}_2$ increased faster than the atmospheric trend, implying a decreasing uptake of atmospheric CO₂ at those locations. The oceanic $p\text{CO}_2$ trend can differ from that in the atmosphere owing to changes in the intensity of biological production and changes in physical conditions, for instance between El Niño and La Niña (Keeling et al., 2004; Midorikawa et al., 2005; Yoshikawa-Inoue and Ishii, 2005; Takahashi et al., 2006; Schuster and Watson, 2007; Ishii et al., 2009; Takahashi et al., 2009; McKinley et al., 2011; Bates, 2012; Lenton et al., 2012).

While local variations of $\Delta p\text{CO}_2$ with time have little effect on the atmospheric CO₂ growth rate in the short term, they provide important information on the dynamics of the ocean carbon cycle and the potential for longer-term climate feedbacks. For example, El Niño and La Niña can drive large changes in the efflux of CO₂ in the Pacific. Differences in $\Delta p\text{CO}_2$ can exceed 100 μatm in the eastern and central equatorial Pacific between El Niño and La Niña; an increase in $\Delta p\text{CO}_2$ observed between 1998 and 2004 was attributed to wind and circulation changes associated with the Pacific Decadal Oscillation (Feely et al., 2006). CO₂ uptake in the North Atlantic decreased by 0.24 [0.19 – 0.29] PgC yr⁻¹ between 1994 and 2003 (Schuster and Watson, 2007) and has partially recovered since then (Watson et al., 2009). Linear trends for the North Atlantic from 1995 to 2009 reveal an increased uptake (Schuster et al., 2013). Uptake of CO₂ in the Subtropical Mode Water (STMW) of the North Atlantic was enhanced during the 1990s, a predominantly positive phase of the NAO, and much reduced in the 2000s when the NAO phase was neutral or negative (Bates, 2012). Observations in the Indian and Pacific sectors of the Southern Ocean were interpreted as evidence for reduced winter-time CO₂ uptake as a result of increased winds, increased upwelling, and outgassing of natural CO₂ (Metzl, 2009; Lenton et al., 2012).

3.8.1.2 Changes in the Oceanic Inventory of Anthropogenic Carbon Dioxide

Ocean carbon uptake and storage is inferred from changes in the inventory of anthropogenic carbon. C_{ant} cannot be measured directly but is calculated from observations of ocean properties (Appendix 3.A discusses the sampling on which the ocean carbon inventory is based). Two independent data-based methods to calculate anthropogenic carbon inventories exist: the ΔC^* method (Sabine et al., 2004), and the transit time distribution (TTD) method (Waugh et al., 2006). The Green's function approach that applies the maximum entropy de-convolution methodology (Khatiwala et al., 2009) is related to the latter. These approaches use different tracer data, for instance the TTD method is mostly based on chlorofluorocarbon measurements. Changes due to variability in ocean productivity (Chavez et al., 2011) are not considered.

Estimates of the global inventory of C_{ant} (including marginal seas) calculated using these methods have a mean value of 118 PgC and a range of 93–137 PgC in 1994 and a mean of 160 PgC and range of 134–186 PgC in 2010 (Sabine et al., 2004; Waugh et al., 2006; Khatiwala et al., 2009; Khatiwala et al., 2013). When combined with model results (Mikaloff-Fletcher et al., 2006; Doney et al., 2009; Gerber et al., 2009; Graven et al., 2012), Khatiwala et al. (2013) arrive at a “best” estimate of the global ocean inventory (including marginal seas) of anthropogenic carbon from 1750 to 2010 of 155 PgC with an uncertainty of $\pm 20\%$ (Figure 3.16). While the estimates of total inventory agree within their uncertainty, the different methods result in significant differences in the inferred spatial distribution of C_{ant} , particularly at high latitudes.

The C_{ant} inventory “best” estimate of 155 PgC (Khatiwala et al., 2013; Figure 3.16) corresponds to an uptake rate of 2.3 (range of 1.7 to 2.9) PgC yr^{-1} from 2000 to 2010, in close agreement with an independent estimate of 2.5 (range of 1.8 to 3.2) PgC yr^{-1} based on atmospheric O_2/N_2 measurements obtained for the same period (Ishidoya et al., 2012). The O_2/N_2 method resulted in $2.2 \pm 0.6 \text{ PgC yr}^{-1}$ for the time period 1990 to 2000 and 2.5 ± 0.6 for the period from 2000 to 2010 (Keeling and Manning, 2014). These estimates are also consistent with an independent estimate of $1.9 \pm 0.4 \text{ PgC yr}^{-1}$ for the period between 1970 and 1990 based on depth-integrated $\delta^{13}\text{C}$ changes (Quay et al., 2003) and with estimates inferred from $\Delta p\text{CO}_2$.

[INSERT FIGURE 3.16 HERE]

Figure 3.16: Compilation of the 2010 column inventories (mol m^{-2}) of anthropogenic CO_2 : the global Ocean excluding the marginal seas (updated from Khatiwala et al., 2009) $150 \pm 26 \text{ PgC}$; Arctic Ocean (Tanhua et al., 2009) 2.7–3.5 PgC; the Nordic Seas (Olsen et al., 2010) 1.0–1.6 PgC; the Mediterranean Sea (Schneider et al., 2010) 1.6–2.5 PgC; the East Sea (Sea of Japan) (Park et al., 2006) $0.40 \pm 0.06 \text{ PgC}$. From Khatiwala et al. (2013).

The storage rate of anthropogenic carbon dioxide is assessed by calculating the change in C_{ant} concentration between two time periods. Regional observations of the storage rate are in general agreement with that expected from the increase in atmospheric CO_2 concentrations and with the tracer-based estimates. However, there are significant spatial and temporal variations in the degree to which the inventory of C_{ant} tracks changes in the atmosphere (Figure 3.17). The North Atlantic, in particular, is an area with high variability in circulation and deep water formation, influencing the C_{ant} inventory. As a result of the decline in Labrador Sea Water (LSW) formation since 1997 (Rhein et al., 2011), the C_{ant} increase between 1997 and 2003 was smaller in the subpolar North Atlantic than expected from the atmospheric increase, in contrast to the subtropical and equatorial Atlantic (Steinfeldt et al., 2009). Perez et al. (2010) also noted the dependence of the C_{ant} storage rate in the North Atlantic on the NAO, with high C_{ant} storage rate during phases of high NAO (i.e., high LSW formation rates) and low storage during phases of low NAO (low formation). Wanninkhof et al. (2010) found a smaller inventory increase in the North Atlantic compared to the South Atlantic between 1989 and 2005.

Ocean observations are insufficient to assess whether there has been a change in the rate of total (anthropogenic plus natural) carbon uptake by the global ocean. Evidence from regional ocean studies (often covering relatively short time periods), atmospheric observations and models is equivocal, with some studies suggesting the ocean uptake rate of total CO_2 may have declined (Le Quéré et al., 2007; Schuster and Watson, 2007; McKinley et al., 2011) while others conclude that there is little evidence for a decline (Knorr, 2009; Gloor et al., 2010; Sarmiento et al., 2010). A study based on atmospheric CO_2 observations and emission inventories concluded that global carbon uptake by land and oceans doubled from 1960 to 2010, implying that it is *unlikely* that on a global scale both land and ocean sinks decreased (Ballantyne et al., 2012).

[INSERT FIGURE 3.17 HERE]

Figure 3.17: Maps of storage rate distribution of anthropogenic carbon ($\text{mol m}^{-2} \text{ y}^{-1}$) for the three ocean basins (left to right: Atlantic, Pacific, and Indian Ocean) averaged over 1980–2005 estimated by the Green’s function approach (Khatiwala et al., 2009). Note that a different color scale is used in each basin.

In summary, the high agreement between multiple lines of independent evidence for increases in the ocean inventory of C_{ant} underpins the conclusion that it is *virtually certain* that the ocean is sequestering anthropogenic carbon dioxide and *very likely* that the oceanic C_{ant} inventory increased from 1994 to 2010. Oceanic carbon uptake rates calculated using different data sets and methods agree within their uncertainties and *very likely* range between 1.0 and 3.2 PgC yr^{-1} .

3.8.2 Anthropogenic Ocean Acidification

The uptake of CO₂ by the ocean changes the chemical balance of seawater through the thermodynamic equilibrium of CO₂ with seawater. Dissolved CO₂ forms a weak acid (H₂CO₃) and, as CO₂ in seawater increases, the pH, carbonate ion (CO₃²⁻), and CaCO₃ saturation state of seawater decrease while bicarbonate ion (HCO₃⁻) increases (FAQ 3.2). Variations in oceanic total dissolved inorganic carbon (C_T = CO₂ + CO₃²⁻ + HCO₃⁻) and pCO₂ reflect changes in both the natural carbon cycle and the uptake of anthropogenic CO₂ from the atmosphere. The mean pH (total scale) of surface waters ranges between 7.8 and 8.4 in the open ocean, so the ocean remains mildly basic (pH > 7) at present (Orr et al., 2005a; Feely et al., 2009). Ocean uptake of CO₂ results in gradual acidification of seawater; this process is termed ocean acidification (Box 3.2) (Broecker and Clark, 2001; Caldeira and Wickett, 2003). The observed decrease in ocean pH of 0.1 since the beginning of the industrial era corresponds to a 26% increase in the hydrogen ion concentration [H⁺] concentration of seawater (Orr et al., 2005b; Feely et al., 2009). The consequences of changes in pH, CO₃²⁻, and the saturation state of CaCO₃ minerals for marine organisms and ecosystems are just beginning to be understood (see WGII Chapters 5, 6, 28 and 30).

A global mean decrease in surface water pH of 0.08 from 1765 to 1994 was calculated based on the inventory of anthropogenic CO₂ (Sabine et al., 2004), with the largest reduction (−0.10) in the northern North Atlantic and the smallest reduction (−0.05) in the subtropical South Pacific. These regional variations in the size of the pH decrease are consistent with the generally lower buffer capacities of the high latitude oceans compared to lower latitudes (Egleston et al., 2010).

Direct measurements on ocean time-series stations in the North Atlantic and North Pacific record decreasing pH with rates ranging between −0.0014 and −0.0024 yr^{−1} (Table 3.2, Figure 3.18; Bates, 2007; Santana-Casiano et al., 2007; Dore et al., 2009; Olafsson et al., 2009; González-Dávila et al., 2010; Bates, 2012). Directly measured pH differences in the surface mixed layer along repeat transects in the central North Pacific Ocean between Hawaii and Alaska showed a −0.0017 yr^{−1} decline in pH between 1991 and 2006, in agreement with observations at the time-series sites (Byrne et al., 2010). This rate of pH change is also consistent with repeat transects of CO₂ and pH measurements in the western North Pacific (winter: −0.0018 ± 0.0002 yr^{−1}; summer: −0.0013 ± 0.0005 yr^{−1}) (Midorikawa et al., 2010). The pH changes in southern ocean surface waters are less certain because of the paucity of long-term time-series observations there, but pCO₂ measurements collected by ships-of-opportunity indicate similar rates of pH decrease there (Takahashi et al., 2009).

[INSERT FIGURE 3.18 HERE]

Figure 3.18: Long-term trends of surface seawater pCO₂ (top), pH (middle), and carbonate ion (bottom) concentration at three subtropical ocean time series in the North Atlantic and North Pacific Oceans, including: **a)** Bermuda Atlantic Time-series Study (BATS, 31°40'N, 64°10'W; **green**) and Hydrostation S (32°10', 64°30'W) from 1983 to present (updated from Bates, 2007); **b)** Hawaii Ocean Time-series (HOT) at Station ALOHA (A Long-term Oligotrophic Habitat Assessment; 22°45'N, 158°00'W; **orange**) from 1988 to present (updated from Dore et al., 2009), and; **c)** European Station for Time series in the Ocean (ESTOC, 29°10'N, 15°30'W; **blue**) from 1994 to present (updated from González-Dávila et al., 2010). Atmospheric pCO₂ (**black**) from the Mauna Loa Observatory Hawaii is shown in the top panel. Lines show linear fits to the data, whereas Table 3.2 give results for harmonic fits to the data (updated from Orr, 2011).

Uptake of anthropogenic CO₂ is the dominant cause of observed changes in the carbonate chemistry of surface waters (Doney et al., 2009). Changes in carbonate chemistry in subsurface waters can also reflect local physical and biological variability. As an example, while pH changes in the mixed layer of the North Pacific Ocean can be explained solely by equilibration with atmospheric CO₂, declines in pH between 800 m and the mixed layer in the time period 1991–2006 were attributed in approximately equal measure to anthropogenic and natural variations (Byrne et al., 2010). Figure 3.19 shows the portion of pH changes between the surface and 1000 m that were attributed solely to the effects of anthropogenic CO₂. Seawater pH and [CO₃²⁻] decreased by 0.0014–0.0024 yr^{−1} and ~0.4–0.9 μmoles kg^{−1} yr^{−1}, respectively, between 1988 and 2009 (Table 3.2). A global mean decrease in surface water pH of 0.08 from 1765 to 1994 was calculated based on the anthropogenic CO₂ storage (Sabine et al., 2004), with the largest reduction (−0.10) in the northern North Atlantic and the smallest reduction (−0.05) in the subtropical South Pacific. The regional variations in the size of the pH decrease are consistent with the generally lower buffer capacities of the high

latitude oceans compared to lower latitudes (Eggleston et al., 2010). Over longer time periods, anthropogenic changes in ocean chemistry are expected to become increasingly prominent relative to changes imparted by physical and biological variability. Over longer time periods, anthropogenic changes in ocean chemistry are expected to become increasingly prominent relative to changes imparted by physical and biological variability.

Based on the consistency of these observations, it is *very likely* that the pH of surface waters has decreased as a result of ocean uptake of anthropogenic CO₂ from the atmosphere.

[START BOX 3.2 HERE]

Box 3.2: Ocean Acidification

Ocean acidification refers to a reduction in pH of the ocean over an extended period, typically decades or longer, caused primarily by the uptake of carbon dioxide from the atmosphere. Ocean acidification can also be caused by other chemical additions or subtractions from the oceans that are natural (e.g., increased volcanic activity, methane hydrate releases, long-term changes in net respiration) or human-induced (e.g., release of nitrogen and sulphur compounds into the atmosphere). Anthropogenic ocean acidification refers to the component of pH reduction that is caused by human activity (IPCC, 2011).

Since the beginning of the industrial era, the release of carbon dioxide (CO₂) from industrial and agricultural activities has resulted in atmospheric CO₂ concentrations that have increased from approximately 280 ppm to about 392 ppm in 2012 (Chapter 6). The oceans have absorbed approximately 155 PgC from the atmosphere over the last two and a half centuries (Sabine et al., 2004; Khatiwala et al., 2013). This natural process of absorption has benefited humankind by significantly reducing the greenhouse gas levels in the atmosphere and abating some of the impacts of global warming. However, the ocean's uptake of carbon dioxide is having a significant impact on the chemistry of seawater. The average pH of ocean surface waters has already fallen by about 0.1 units, from about 8.2 to 8.1 (total scale), since the beginning of the industrial revolution (Orr et al., 2005a; Figure 1; Feely et al., 2009). Estimates of future atmospheric and oceanic carbon dioxide concentrations indicate that, by the end of this century, the average surface ocean pH could be lower than it has been for more than 50 million years (Caldeira and Wickett, 2003).

The major controls on seawater pH are atmospheric CO₂ exchange, the production and respiration of dissolved and particulate organic matter in the water column, and the formation and dissolution of calcium carbonate minerals. Oxidation of organic matter lowers dissolved oxygen concentrations, adds CO₂ to solution, reduces pH, carbonate ion (CO₃²⁻) and CaCO₃ saturation states (Box 3.2, Figure 2), and lowers the pH of seawater in subsurface waters (Byrne et al., 2010). As a result of these processes, minimum pH values in the oceanic water column are generally found near the depths of the oxygen minimum layer. When CO₂ reacts with seawater it forms carbonic acid (H₂CO₃), which is highly reactive and reduces the concentration of carbonate ion (Box 3.2, Figure 2) and can affect shell formation for marine animals such as corals, plankton, and shellfish. This process could affect fundamental biological and chemical processes of the sea in coming decades (Fabry et al., 2008; Doney et al., 2009; WGII Chapters 5, 6, 28 and 30).

[INSERT BOX 3.2, FIGURE 1 HERE]

Box 3.2, Figure 1: National Center for Atmospheric Research Community Climate System Model 3.1 (CCSM3)-modeled decadal mean pH at the sea surface centered around the years 1875 (top) and 1995 (middle). Global Ocean Data Analysis Project (GLODAP)-based pH at the sea surface, nominally for 1995 (bottom). Deep and shallow-water coral reefs are indicated with magenta dots. White areas indicate regions with no data (after Feely et al., 2009).

[INSERT BOX 3.2, FIGURE 2 HERE]

Box 3.2, Figure 2: Distribution of: **a)** pH and **b)** CO₃²⁻ ion concentration in the Pacific, Atlantic, and Indian Oceans. The data are from the World Ocean Circulation Experiment/Joint Global Ocean Flux Study/Ocean Atmosphere Carbon Exchange Study global CO₂ survey (Sabine et al., 2005). The lines show the mean pH (red solid line top panel), mean CO₃²⁻ (red solid line bottom panel), and aragonite and calcite (black solid and dashed lines bottom panel) saturation values for each of these basins (modified from Feely et al., 2009). The shaded areas show the range of values within the ocean basins. Dissolution of aragonite and calcite shells and skeletons occurs when CO₃²⁻ concentrations drop below the saturation level, reducing the ability of calcifying organisms to produce their shells and skeletons.

[INSERT TABLE 3.2 HERE]

Table 3.2: Published and updated long-term trends of atmospheric ($p\text{CO}_2^{\text{atm}}$) and seawater carbonate chemistry (i.e., surface-water $p\text{CO}_2$, and corresponding calculated pH, CO_3^{2-} , and aragonite saturation state (Ω_a) at four ocean time series in the North Atlantic and North Pacific oceans: (1) Bermuda Atlantic Time-series Study (BATS, 31°40'N, 64°10'W) and Hydrostation S (32°10'N, 64°30'W) from 1983 to present (Bates, 2007); (2) Hawaii Ocean Time-series (HOT) at Station ALOHA (A Long-term Oligotrophic Habitat Assessment; 22°45'N, 158°00'W) from 1988 to present (Dore et al., 2009); (3) European Station for Time-series in the Ocean (ESTOC, 29°10'N, 15°30'W) from 1994 to present (González-Dávila et al., 2010); and (4) Iceland Sea (IS, 68.0°N, 12.67°W) from 1985 to 2006 (Olafsson et al., 2009). Trends at the first three time-series sites are from observations with the seasonal cycle removed. Also reported are the wintertime trends in the Iceland Sea as well as the pH difference trend for the North Pacific Ocean between transects in 1991 and 2006 (Byrne et al., 2010) and repeat sections in the western North Pacific between 1983 and 2008 (Midorikawa et al., 2010).

3.8.3 Oxygen

As a consequence of the early introduction of standardized methods and the relatively wide interest in the distribution of dissolved oxygen, the historical record of marine oxygen observations is generally richer than that of other biogeochemical parameters, although still sparse compared to measurements of temperature and salinity (Appendix 3.A). Dissolved oxygen changes in the ocean thermocline have generally decreased since 1960, but with strong regional variations (Keeling et al., 2010; Keeling and Manning, 2014). Oxygen concentrations at 300 dbar decreased between 50°S and 50°N at a mean rate of $0.63 \mu\text{mol kg}^{-1}$ per decade between 1960 and 2010 (Stramma et al., 2012). For the period 1970 to 1990, the mean annual global oxygen loss between 100m and 1000m was calculated to be $0.55 \pm 0.13 \times 10^{14} \text{ mol yr}^{-1}$ (Helm et al., 2011).

The long-term deoxygenation of the open ocean thermocline is consistent with the expectation that warmer waters can hold less dissolved oxygen (solubility effect), and that warming-induced stratification leads to a decrease in the transport of dissolved oxygen from surface to subsurface waters (stratification effect) (Matear and Hirst, 2003; Deutsch et al., 2005; Frölicher et al., 2009). Observations of oxygen change suggested that about 15% of the oxygen decline between 1970 and 1990 could be explained by warming and the remainder by reduced ventilation due to increased stratification (Helm et al., 2011; see Table 6.14).

Oxygen concentrations in the tropical ocean thermocline decreased in each of the ocean basins over the last 50 years (Ono et al., 2001; Stramma et al., 2008; Keeling et al., 2010; Helm et al., 2011), resulting in an expansion of the dissolved oxygen minimum zones. A comparison of data between 1960 and 1974 with those from 1990 to 2008 showed that oxygen concentrations decreased in most tropical regions at an average rate of $2\text{--}3 \mu\text{mol kg}^{-1}$ per decade (Figure 3.20; Stramma et al., 2010). Data from one of the longest time-series sites in the subpolar North Pacific (Station Papa, 50°N, 145°W) reveal a persistent declining oxygen trend in the thermocline over the last 50 years (Whitney et al., 2007), superimposed on oscillations with time-scales of a few years to two decades. Stando and Gruber (2012) found dissolved oxygen decreases in upper water masses of the North Atlantic and increases in intermediate water masses. The changes were caused by changes in solubility as well as changes in ventilation and circulation over time. In contrast to the widely-distributed oxygen declines, oxygen increased in the thermoclines of the Indian and South Pacific Oceans from the 1990s to the 2000s (McDonagh et al., 2005; Álvarez et al., 2011), apparently due to strengthened circulation driven by stronger winds (Cai, 2006; Roemmich et al., 2007). In the southern Indian Ocean below the thermocline, east of 75°E, oxygen decreased between 1960 and 2010 most prominently on the isopycnals $\sigma_\theta = 26.9 - 27.0$ (Kobayashi et al., 2012). While some studies suggest a widespread decline of oxygen in the Southern Ocean (e.g. Helm et al., 2011), other studies show regions of alternating sign (e.g. Stramma et al., 2010), reflecting differences in data and period considered.

[INSERT FIGURE 3.20 HERE]

Figure 3.20: Dissolved oxygen (DO) distributions (in $\mu\text{mol kg}^{-1}$) between 40°S and 40°N for: **a**) the climatological mean (Boyer et al., 2006) at 200 dbar, as well as changes between 1960 and 1974 and 1990 and 2008 of **b**) dissolved

oxygen (ΔDO) at 200 dbar, and **c**) ΔDO vertically-averaged over 200–700 dbar. In **b**)-**c**) increases are red and decreases blue, and areas with differences below the 95% confidence interval are shaded by black horizontal lines (after Stramma et al., 2010).

Coastal regions have also experienced long-term dissolved oxygen changes. Bograd et al. (2008) reported a substantial reduction of the thermocline oxygen content in the southern part of the California Current from 1984 to 2002, resulting in a shoaling of the hypoxic boundary (marked by oxygen concentrations of about $60 \mu\text{mol kg}^{-1}$). Off the British Columbia coast, oxygen concentrations in the near bottom waters decreased an average of $1.1 \mu\text{mol kg}^{-1} \text{yr}^{-1}$ over a 30-year period (Chan et al., 2008). These changes along the west coast of North America appear to have been largely caused by the open ocean dissolved oxygen decrease and local processes associated with decreased vertical dissolved oxygen transport following near-surface warming and increased stratification. Gilbert et al. (2010) found evidence that for the time period 1976–2000 oxygen concentrations between 0 and 300 m depth were declining about 10 times faster in the coastal ocean than in the open ocean, and an increase in the number of hypoxic zones was observed since the 1960s (Diaz and Rosenberg, 2008).

3.8.4 Nutrients

Nutrient concentrations in the surface ocean surface are influenced by human impacts on coastal runoff and on atmospheric deposition, and by changing nutrient supply from the ocean's interior into the mixed layer (for instance due to increased stratification). Changing nutrient distributions might influence the magnitude and variability of the ocean's biological carbon pump.

Globally, the manufacture of nitrogen fertilizers has continued to increase (Galloway et al., 2008) accompanied by increasing eutrophication of coastal waters (Diaz and Rosenberg, 2008; Seitzinger et al., 2010; Kim et al., 2011), which amplifies the drawdown of CO_2 (Borges and Gypens, 2010; Provoost et al., 2010). In addition, atmospheric deposition of anthropogenic fixed nitrogen may now account for up to ~3% of oceanic new production, and this nutrient source is projected to increase (Duce et al., 2008).

Satellite observations of chlorophyll reveal that oligotrophic provinces in four of the world's major oceans expanded at average rates of 0.8 to 4.3% yr^{-1} from 1998 to 2006 (Polovina et al., 2008; Irwin and Oliver, 2009), consistent with a reduction in nutrient availability owing to increases in stratification. Model and observational studies suggest interannual and multi-decadal fluctuations in nutrients are coupled with variability of mode water and the NAO in the Atlantic Ocean (Cianca et al., 2007; Pérez et al., 2010), climate modes of variability in the Pacific Ocean (Wong et al., 2007; Di Lorenzo et al., 2009), and variability of subtropical gyre circulation in the Indian Ocean (Álvarez et al., 2011). However, there are no published studies quantifying long-term trends in ocean nutrient concentrations.

3.8.5 Summary

Based on high agreement between independent estimates using different methods and data sets (e.g., oceanic carbon, oxygen, and transient tracer data), it is *very likely* that the global ocean inventory of anthropogenic carbon (C_{ant}) increased from 1994 to 2010. The oceanic C_{ant} inventory in 2010 is estimated to be 155 PgC with an uncertainty of $\pm 20\%$. The annual global oceanic uptake rates calculated from independent data sets (from oceanic C_{ant} inventory changes, from atmospheric O_2/N_2 measurements or from pCO_2 data) and for different time periods agree with each other within their uncertainties and *very likely* are in the range of 1.0–3.2 PgC yr^{-1} . (Section 3.8.1, Figures 3.16 and 3.17)

It is *very likely* that oceanic uptake of anthropogenic CO_2 results in gradual acidification of the ocean. The pH of seawater has decreased by 0.1 since the beginning of the industrial era, corresponding to a 26% increase in hydrogen ion concentration. The observed pH trends range between -0.0014 and -0.0024yr^{-1} in surface waters. In the ocean interior, natural physical and biological processes, as well as uptake of anthropogenic CO_2 , can cause changes in pH over decadal and longer time scales. (Section 3.8.2, Table 3.2, Box 3.2, Figures 3.18 and 3.19, FAQ 3.2)

High agreement among analyses provides *medium confidence* that oxygen concentrations have decreased in the open ocean thermocline in many ocean regions since the 1960s. The general decline is consistent with the

expectation that warming-induced stratification leads to a decrease in the supply of oxygen to the thermocline from near surface waters, that warmer waters can hold less oxygen, and that changes in wind-driven circulation affect oxygen concentrations. It is *likely* that the tropical oxygen minimum zones have expanded in recent decades. (Section 3.8.3, Figure 3.20)

3.9 Synthesis

Substantial progress has been made since AR4 in documenting and understanding change in the ocean. The major findings of this chapter are largely consistent with those of AR4, but in many cases statements can now be made with greater confidence because more data are available, biases in historical data have been identified and reduced, and new analytical approaches have been applied.

Changes have been observed in a number of ocean properties of relevance to climate. It is *virtually certain* that the upper ocean (0–700 m) has warmed from 1971 to 2010 (Section 3.2.2, Figures 3.1 and 3.2). Warming between 700 and 2000 m *likely* contributed about 30% of the total increase in global ocean heat content between 1957 and 2009 (Section 3.2.4, Figure 3.2). Global mean sea level has risen by 0.19 [0.17 to 0.21] m over the period 1901–2010. It is *very likely* that the mean rate was 1.7 [1.5 to 1.9] mm yr⁻¹ between 1901 and 2010 and increased to 3.2 [2.8 to 3.6] mm yr⁻¹ between 1993 and 2010 (Section 3.7, Figure 3.13). The rise in mean sea level can explain most of the observed increase in extreme sea levels (Figure 3.15). Regional trends in sea surface salinity have *very likely* enhanced the mean geographical contrasts in sea surface salinity since the 1950s: saline surface waters in evaporation-dominated regions have become more saline, while fresh surface waters in rainfall-dominated regions have become fresher. It is *very likely* that trends in salinity have also occurred in the ocean interior. These salinity changes provide indirect evidence that the pattern of evaporation minus precipitation over the oceans has been enhanced since the 1950s (Section 3.4, Figures 3.4 and 3.5). Observed changes in water mass properties *likely* reflect the combined effect of long-term trends in surface forcing (e.g., warming and changes in evaporation minus precipitation) and variability associated with climate modes (Section 3.5, Figure 3.9). It is *virtually certain* that the ocean is storing anthropogenic CO₂ and *very likely* that the ocean inventory of anthropogenic CO₂ increased from 1994 to 2010 (Section 3.8, Figures 3.16 and 3.17). The uptake of anthropogenic CO₂ has *very likely* caused acidification of the ocean (Section 3.8.2, Box 3.2).

For some ocean properties, the short and incomplete observational record is not sufficient to detect trends. For example, there is no observational evidence for or against a change in the strength of the AMOC (Section 3.6, Figure 3.11). However, recent observations have strengthened evidence for variability in major ocean circulation systems and water mass properties on time scales from years to decades. Much of the variability observed in ocean currents and in water masses can be linked to changes in surface forcing, including wind changes associated with the major modes of climate variability such as the NAO, SAM, ENSO, PDO, and the AMO (Section 3.6, Box 2.5).

The consistency between the patterns of change in a number of independent ocean parameters enhances confidence in the assessment that the physical and biogeochemical state of the oceans has changed. This consistency is illustrated here with two simple figures (Figures 3.21 and 3.22). Four global measures of ocean change have increased since the 1950s: the inventory of anthropogenic carbon dioxide, global mean sea level, upper ocean heat content, and the salinity contrast between regions of high and low sea surface salinity (Figure 3.21). High agreement among multiple lines of evidence based on independent data and different methods provides *high confidence* in the observed increase in these global metrics of ocean change.

[INSERT FIGURE 3.21 HERE]

Figure 3.21: Time series of changes in large-scale ocean climate properties. From top to bottom: global ocean inventory of anthropogenic carbon dioxide, updated from Khatiwala et al. (2009); global mean sea level (GMSL), from Church and White (2011); global upper ocean heat content anomaly, updated from Domingues et al. (2008); the difference between salinity averaged over regions where the sea surface salinity is greater than the global mean sea surface salinity (“High Salinity”) and salinity averaged over regions values below the global mean (“Low Salinity”), from Boyer et al. (2009).

The distributions of trends in subsurface water properties, summarized in a schematic zonally averaged view in Figure 3.22, are consistent both with each other and with well-understood dynamics of ocean circulation and water mass formation. The largest changes in temperature, salinity, anthropogenic carbon dioxide, and

other properties are observed along known ventilation pathways (indicated by arrows in Figure 3.22), where surface waters are transferred to the ocean interior, or in regions where changes in ocean circulation (e.g., contraction or expansion of gyres, or a southward shift of the Antarctic Circumpolar Current) result in large anomalies. Zonally averaged warming trends are widespread throughout the upper 2000 m, with largest warming near the sea surface. Water masses formed in the precipitation-dominated mid- to high-latitudes have freshened, while water masses formed in the evaporation-dominated subtropics have become saltier. Anthropogenic carbon dioxide has accumulated in surface waters and been transferred into the interior, primarily by water masses formed in the North Atlantic and Southern Oceans.

[INSERT FIGURE 3.22 HERE]

Figure 3.22: Summary of observed changes in zonal averages of global ocean properties. Temperature trends ($^{\circ}\text{C}$ per decade) are indicated in color (red = warming, blue = cooling); salinity trends are indicated by contour lines (dashed = fresher; solid = saltier) for the upper 2000 m of the water column (50-year trends from data set of Durack and Wijffels (2010); trends significant at >90% confidence are shown). Arrows indicate primary ventilation pathways. Changes in other physical and chemical properties are summarised to the right of the figure, for each depth range (broken axes symbols delimit changes in vertical scale). Increases are shown in red, followed by a plus sign; decreases are shown in blue, followed by a minus sign; the number of + and - signs indicates the level of confidence associated with the observation of change (+++, *high confidence*; ++, *medium confidence*; +, *low confidence*). T = temperature, S = salinity, Strat = stratification, C_{ant} = anthropogenic carbon, CO_3^{2-} = carbonate ion, NA = North Atlantic, SO = Southern Ocean, AABW = Antarctic Bottom Water. $S > S_{\text{mean}}$ refers to the salinity averaged over regions where the sea surface salinity is greater than the global mean sea surface salinity; $S < S_{\text{mean}}$ refers to the average over regions with values below the global mean.

In summary, changes have been observed in ocean properties of relevance to climate during the past forty years, including temperature, salinity, sea level, carbon, pH, and oxygen. The observed patterns of change are consistent with changes in the surface ocean (warming, changes in salinity, and an increase in C_{ant}) in response to climate change and variability and with known physical and biogeochemical processes in the ocean, providing *high confidence* in this assessment. Chapter 10 discusses the extent to which these observed changes can be attributed to human or natural forcing.

Improvements in the quality and quantity of ocean observations has allowed for a more definitive assessment of ocean change than was possible in AR4. However, substantial uncertainties remain. In many cases, the observational record is still too short or incomplete to detect trends in the presence of energetic variability on time-scales of years to decades. Recent improvements in the ocean observing system, most notably the Argo profiling float array, mean that temperature and salinity are now being sampled routinely in most of the ocean above 2000 m depth for the first time. However, sparse sampling of the deep ocean and of many biogeochemical variables continues to limit the ability to detect and understand changes in the global ocean.

[START FAQ 3.1 HERE]

FAQ 3.1: Is the Ocean Warming?

Yes, the ocean is warming over many regions, depth ranges, and time periods, although neither everywhere, nor constantly. The signature of warming emerges most clearly when considering global, or even ocean basin, averages over time spans of a decade or more.

Ocean temperature at any given location can vary greatly with the seasons. It can also fluctuate substantially from year to year—or even decade to decade—because of variations in ocean currents and the exchange of heat between ocean and atmosphere.

Ocean temperatures have been recorded for centuries, but it was not until around 1971 that measurements were sufficiently comprehensive to estimate the average global temperature of the upper several hundred meters of the ocean confidently for any given year. In fact, before the international Argo temperature/salinity profiling float array first achieved worldwide coverage in 2005, the global average upper ocean temperature for any given year was sensitive to the methodology used to estimate it.

Global mean upper ocean temperatures have increased over decadal time scales from 1971 to 2010. Despite large uncertainty in most yearly means, this warming is a robust result. In the upper 60 m of the ocean, the

global average warming trend has been around 0.1°C per decade over this time. That trend generally lessens from the surface to mid-depth, reducing to about 0.04°C per decade by 200 m, and to less than 0.02°C per decade by 500 m.

Temperature anomalies enter the subsurface ocean by paths in addition to mixing from above (FAQ3.1, Figure 1). Colder—hence denser—waters from high latitudes can sink from the surface, then spread toward the equator beneath warmer, lighter, waters at lower latitudes. At a few locations—the northern North Atlantic Ocean and the Southern Ocean around Antarctica—ocean water is cooled so much that it sinks to great depths, even to the sea floor. This water then spreads out to fill much of the rest of the deep ocean. As ocean surface waters warm, these sinking waters also warm with time, increasing temperatures in the ocean interior much more quickly than would downward mixing of surface heating alone.

In the North Atlantic, the temperature of these deep waters varies from decade to decade—sometimes warming, sometimes cooling—depending on prevailing winter atmospheric patterns. Around Antarctica, bottom waters have warmed detectably from circa 1992–2005, perhaps owing to the strengthening and southward shift of westerly winds around the Southern Ocean over the last several decades. This warming signal in the deepest coldest bottom waters of the world ocean is detectable, although it weakens northward in the Indian, Atlantic, and Pacific oceans. Deep warming rates are generally less pronounced than ocean surface rates (around 0.03°C per decade since the 1990s in the deep and bottom waters around Antarctica, and smaller in many other locations). However, they occur over a large volume, so deep ocean warming contributes significantly to the total increase in ocean heat.

[INSERT FAQ 3.1, FIGURE 1 HERE]

FAQ 3.1, Figure 1: Ocean heat uptake pathways. The ocean is stratified, with the coldest, densest water in the deep ocean (upper panels: use map at top for orientation). Cold Antarctic Bottom Water (dark blue) sinks around Antarctica then spreads northward along the ocean floor into the central Pacific (upper left panel: red arrows fading to white indicate stronger warming of the bottom water most recently in contact with the ocean surface) and western Atlantic oceans (upper right panel), as well as the Indian Ocean (not shown). Less cold, hence lighter, North Atlantic Deep Water (lighter blue) sinks in the northern North Atlantic Ocean (upper right panel: red and blue arrow in the deep water indicates decadal warming and cooling), then spreads south above the Antarctic Bottom Water. Similarly, in the upper ocean (lower left panel shows Pacific Ocean detail, lower right panel the Atlantic), cool Intermediate Waters (cyan) sink in sub-polar regions (red arrows fading to white indicating warming with time), before spreading toward the equator under warmer Subtropical Waters (green), which in turn sink (red arrows fading to white indicate stronger warming of the intermediate and subtropical waters most recently in contact with the surface) and spread toward the equator under tropical waters, the warmest and lightest (orange) in all three oceans. Excess heat or cold entering at the ocean surface (top curvy red arrows) also mixes slowly downward (sub-surface squiggly red arrows).

Estimates of historical changes in global average ocean temperature have become more accurate over the past several years, largely thanks to the recognition, and reduction, of systematic measurement errors. By carefully comparing less accurate measurements with sparser, more accurate ones at adjacent locations and similar times, scientists have reduced some spurious instrumental biases in the historical record. These improvements revealed that the global average ocean temperature has increased much more steadily from year to year than was reported prior to 2008. Nevertheless, the global average warming rate may not be uniform in time. In some years, the ocean appears to warm faster than average; in others, the warming rate seems to slow.

The ocean's large mass and high heat capacity allow it to store huge amounts of energy—more than 1000 times that in the atmosphere for an equivalent increase in temperature. The Earth is absorbing more heat than it is emitting back into space, and nearly all this excess heat is entering the oceans and being stored there. The ocean has absorbed about 93% of the combined heat stored by warmed air, sea, and land, and melted ice between 1971 and 2010.

The ocean's huge heat capacity and slow circulation lend it significant thermal inertia. It takes about a decade for near-surface ocean temperatures to adjust in response to climate forcing (Section 12.5), such as changes in greenhouse gas concentrations. Thus, if greenhouse gas concentrations could be held at present levels into the future, increases in Earth's surface temperature would begin to slow within about a decade. However, deep ocean temperature would continue to warm for centuries to millennia (Section 12.5), and thus sea levels would continue to rise for centuries to millennia as well (Section 13.5).

[END FAQ 3.1 HERE]

[START FAQ 3.2 HERE]

FAQ 3.2: How Does Anthropogenic Ocean Acidification Relate to Climate Change?

Both anthropogenic climate change and anthropogenic ocean acidification are caused by increasing carbon dioxide concentrations in the atmosphere. Rising levels of CO₂, along with other greenhouse gases, indirectly alter the climate system by trapping heat as it is reflected back from the Earth's surface. Anthropogenic ocean acidification is a direct consequence of rising CO₂ concentrations as seawater currently absorbs about 25% of the anthropogenic CO₂ from the atmosphere.

Ocean acidification refers to a reduction in pH over an extended period, typically decades or longer, caused primarily by the uptake of carbon dioxide from the atmosphere. pH is a dimensionless measure of acidity. Ocean acidification describes the direction of pH change rather than the end point; that is, ocean pH is decreasing but is not expected to become acidic (pH < 7). Ocean acidification can also be caused by other chemical additions or subtractions from the oceans that are natural (e.g., increased volcanic activity, methane hydrate releases, long-term changes in net respiration) or human-induced (e.g., release of nitrogen and sulfur compounds into the atmosphere). Anthropogenic ocean acidification refers to the component of pH reduction that is caused by human activity.

Since about 1750, the release of carbon dioxide (CO₂) from industrial and agricultural activities has resulted in global average atmospheric CO₂ concentrations that have increased from 278 to 390.5 ppm in 2011. The atmospheric concentration of CO₂ is now higher than experienced on Earth for at least the last 800,000 years and is expected to continue to rise because of our dependence on fossil fuels for energy. To date, the oceans have absorbed approximately 155 ± 30 PgC from the atmosphere, which corresponds to roughly 1/4 of the total amount of CO₂ emitted (565 ± 85 PgC) by human activities since preindustrial times. This natural process of absorption has significantly reduced the greenhouse gas levels in the atmosphere and minimized some of the impacts of global warming. However, the ocean's uptake of carbon dioxide is having a significant impact on the chemistry of seawater. The average pH of ocean surface waters has already fallen by about 0.1 units, from about 8.2 to 8.1 since the beginning of the industrial revolution. Estimates of projected future atmospheric and oceanic carbon dioxide concentrations indicate that, by the end of this century, the average surface ocean pH could be 0.2 to 0.4 lower than it is today. The pH scale is logarithmic, so a change of 1 unit corresponds to a ten-fold change in hydrogen ion concentration.

When atmospheric carbon dioxide exchanges across the air-sea interface it reacts with seawater through a series of four chemical reactions that increase the concentrations of the carbon species: dissolved carbon dioxide (CO_{2(aq)}), carbonic acid (H₂CO₃), and bicarbonate (HCO₃⁻):

Hydrogen ions (H⁺) are produced by these reactions. This increase in the ocean's hydrogen ion concentration corresponds to a reduction in pH, or an increase in acidity. Under normal seawater conditions, more than 99.99% of the hydrogen ions that are produced will combine with carbonate ion (CO₃²⁻) to produce additional HCO₃⁻. Thus, the addition of anthropogenic CO₂ into the oceans lowers the pH and consumes carbonate ion. These reactions are fully reversible and the basic thermodynamics of these reactions in seawater are well known, such that at a pH of approximately 8.1 approximately 90% the carbon is in the form of bicarbonate ion, 9% in the form of carbonate ion, and only about 1% of the carbon is in the form of dissolved CO₂. Results from laboratory, field, and modeling studies, as well as evidence from the geological

record, clearly indicate that marine ecosystems are highly susceptible to the increases in oceanic CO₂ and the corresponding decreases in pH and carbonate ion.

[INSERT FAQ 3.2, FIGURE 1 HERE]

FAQ 3.2, Figure 1: A smoothed time series of atmospheric CO₂ mole fraction (in ppm) at the atmospheric Mauna Loa Observatory (top red line), surface ocean partial pressure of CO₂ (pCO₂; middle blue line), and surface ocean pH (bottom green line) at Station ALOHA in the subtropical North Pacific north of Hawaii for the period from 1990–2011 (after Doney et al., 2009; data from Dore et al., 2009). The results indicate that the surface ocean pCO₂ trend is generally consistent with the atmospheric increase but is more variable due to large-scale interannual variability of oceanic processes.

Climate change and anthropogenic ocean acidification do not act independently. While the CO₂ that is taken up by the ocean does not contribute to greenhouse warming, ocean warming reduces the solubility of carbon dioxide in seawater; and thus reduces the amount of CO₂ the oceans can absorb from the atmosphere. For example, under doubled preindustrial CO₂ concentrations and a 2°C temperature increase, seawater absorbs about 10 percent less CO₂ (10% less total carbon, C_T) than it would with no temperature increase (compare columns 4 and 6 in Table 1), but the pH remains almost unchanged. Thus, a warmer ocean has less capacity to remove CO₂ from the atmosphere, yet still experiences ocean acidification. The reason for this is that bicarbonate is converted to carbonate in a warmer ocean, releasing a hydrogen ion thus stabilizing the pH.

FAQ 3.2, Table 1: Oceanic pH and carbon system parameter changes in surface water for a CO₂ doubling from the preindustrial atmosphere without and with a 2°C warming^a.

Parameter	preindustrial (280 ppmv) 20°C	2 × preindustrial (560 ppmv) 20°C	(% change relative to preindustrial)	2 × preindustrial (560 ppmv) 22°C	(% change relative to preindustrial)
pH	8.1714	7.9202	-	7.9207	-
H ⁺ (mol kg ⁻¹)	6.739e ⁻⁹	1.202e ⁻⁸	(78.4)	1.200e ⁻⁸	(78.1)
CO ₂ (aq) (μmol kg ⁻¹)	9.10	18.10	(98.9)	17.2	(89.0)
HCO ₃ ⁻ (μmol kg ⁻¹)	1723.4	1932.8	(12.15)	1910.4	(10.9)
CO ₃ ²⁻ (μmol kg ⁻¹)	228.3	143.6	(-37.1)	152.9	(-33.0)
C _T (μmol kg ⁻¹)	1960.8	2094.5	(6.82)	2080.5	(6.10)

Notes:

(a) CO₂(aq) = dissolved CO₂, H₂CO₃ = carbonic acid, HCO₃⁻ = bicarbonate, CO₃²⁻ = carbonate, C_T = total carbon = CO₂(aq) + HCO₃⁻ + CO₃²⁻.

[END FAQ 3.2 HERE]

[START FAQ 3.3 HERE]

FAQ 3.3: Is There Evidence for Changes in the Earth's Water Cycle?

The Earth's water cycle involves evaporation and precipitation of moisture at the Earth's surface. Changes in the atmosphere's water vapour content provide strong evidence that the water cycle is already responding to a warming climate. Further evidence comes from changes in the distribution of ocean salinity, which, due to a lack of long-term observations of rain and evaporation over the global oceans, has become an important proxy rain gauge.

The water cycle is expected to intensify in a warmer climate, because warmer air can be moister: the atmosphere can hold about seven per cent more water vapour for each degree Celsius of warming. Observations since the 1970s show increases in surface and lower atmospheric water vapour (FAQ 3.3, Figure 1a), at a rate consistent with observed warming. Moreover, evaporation and precipitation are projected to intensify in a warmer climate.

Recorded changes in ocean salinity in the last 50 years support that projection. Seawater contains both salt and fresh water, and its salinity is a function of the weight of dissolved salts it contains. Because the total

amount of salt—which comes from the weathering of rocks—does not change over human time scales, seawater's salinity can only be altered—over days or centuries—by the addition or removal of fresh water.

The atmosphere connects the ocean's regions of net fresh water loss to those of fresh water gain by moving evaporated water vapour from one place to another. The distribution of salinity at the ocean surface largely reflects the spatial pattern of evaporation minus precipitation, runoff from land, and sea ice processes. There is some shifting of the patterns relative to each other, because of the ocean's currents.

Subtropical waters are highly saline, because evaporation exceeds rainfall, whereas seawater at high latitudes and in the tropics—where more rain falls than evaporates—is less so (FAQ 3.3, Figure 1b, d). The Atlantic, the saltiest ocean basin, loses more fresh water through evaporation than it gains from precipitation, while the Pacific is nearly neutral (i.e., precipitation gain nearly balances evaporation loss), and the Southern Ocean (region around Antarctica) is dominated by precipitation.

Changes in surface salinity and in the upper ocean have reinforced the mean salinity pattern. The evaporation-dominated subtropical regions have become saltier, while the precipitation-dominated subpolar and tropical regions have become fresher. When changes over the top 500 m are considered, the evaporation-dominated Atlantic has become saltier, while the nearly neutral Pacific and precipitation-dominated Southern Ocean have become fresher (FAQ 3.3, Figure 1c).

Observing changes in precipitation and evaporation directly and globally is difficult, because most of the exchange of fresh water between the atmosphere and the surface happens over the 70% of the Earth's surface covered by ocean. Long-term precipitation records are only available from over the land, and there are no long-term measurements of evaporation.

Land-based observations show precipitation increases in some regions, and decreases in others, making it difficult to construct a globally integrated picture. Land-based observations have shown more extreme rainfall events, and more flooding associated with earlier snow melt at high northern latitudes, but there is strong regionality in the trends. Land-based observations are so far insufficient to provide evidence of changes in drought.

Ocean salinity, on the other hand, acts as a sensitive and effective rain gauge over the ocean. It naturally reflects and smoothes out the difference between water gained by the ocean from precipitation, and water lost by the ocean through evaporation, both of which are very patchy and episodic. Ocean salinity is also affected by water runoff from the continents, and by the melting and freezing of sea ice or floating glacial ice. Fresh water added by melting ice on land will change global-averaged salinity, but changes to date are too small to observe.

Data from the past 50 years show widespread salinity changes in the upper ocean, which are indicative of systematic changes in precipitation and runoff minus evaporation, as illustrated in FAQ 3.3, Figure 1.

FAQ 3.3 is based on observations reported in Chapters 2 and 3, and on model analyses in Chapters 9 and 12.

[INSERT FAQ 3.3, FIGURE 1 HERE]

FAQ 3.3, Figure 1: Changes in sea surface salinity are related to the atmospheric patterns of Evaporation minus Precipitation (E-P) and trends in total precipitable water: a) Linear trend (1988–2010) in total precipitable water (water vapor integrated from Earth's surface up through the entire atmosphere) (kg m^{-2} per decade) from satellite observations (Special Sensor Microwave Imager) (after Wentz et al., 2007) (blues wetter; yellows drier). b) The 1979–2005 climatological mean net E-P (cm yr^{-1}) from meteorological reanalysis (National Centers for Environmental Prediction/National Center for Atmospheric Research; Kalnay et al., 1996) (reds: net evaporation; blues: net precipitation). c) Trend (1950–2000) in surface salinity (PSS78 per 50years) (after Durack and Wijffels, 2010) (blues freshening; yellows-reds saltier). d) The climatological-mean surface salinity (PSS78) (blues <35; yellows-reds >35).

Appendix 3.A: Availability of Observations for Assessment of Change in the Oceans

Sampling of the ocean has been highly heterogeneous since 1950. The coverage in space, time, depth, and number of ocean variables has evolved over time, reflecting changes in technology and the contribution of major oceanographic research programs. Changes in the distribution and quality of ocean measurements over time complicate efforts to detect and interpret change in the ocean. This Appendix provides some illustrative examples of the evolution of the ocean observing system on which the assessment of ocean change in Chapter 3 is based. A more comprehensive discussion of ocean sampling is provided in the literature cited in Chapter 3. Sampling of sea surface temperature is discussed in Chapter 2.

3.A.1 Subsurface Ocean Temperature and Heat Content

Temperature is the best-sampled oceanographic variable, but even for temperature sampling is far from ideal or complete. Early oceanographic expeditions included the *Challenger* voyage around the world in the 1870s, the *Meteor* survey of the Atlantic in the 1920s, and the *Discovery* investigations of the Southern Ocean starting in the 1920s. More frequent basin-scale sampling commenced in the late 1950s with the International Geophysical Year. The number of profiles available for assessment of changes in temperature and ocean heat content in the upper 700 m generally increases with time since the 1950s (Figure 3.A.1). Near-global coverage of the upper half of the ocean was not achieved until the widespread deployment of Argo profiling floats in the 2000s (Figure 3.A.2).

[INSERT FIGURE 3.A.1 HERE]

Figure 3.A.1: Number of temperature profiles extending to 700 m depth in each $1^\circ \times 1^\circ$ square, by decade, between 65°N and 65°S .

[INSERT FIGURE 3.A.2 HERE]

Figure 3.A.2: (top) Percentage of global coverage of ocean temperature profiles as a function of depth in one degree latitude by one degree longitude by one-year bins (top panel) shown versus time. Different colors indicate profiles to different depths (middle panel). Percentage of global coverage as a function of depth and time, for the northern hemisphere. (bottom panel) As above, but for the southern hemisphere.

Early measurements of temperature were made using reversing thermometers and Nansen bottles that were lowered from ships on station (not moving). Starting in the 1960s conductivity-temperature-depth (CTD) instruments with Niskin bottles gradually gained dominance for high-quality data and deep data collected on station during oceanographic cruises. From at least 1950 through circa 1970, most subsurface measurements of ocean temperature were made with mechanical bathythermographs, an advance because these instruments could be deployed from a moving ship, albeit a slowly moving one, but these casts were generally limited to depths shallower than 250 m. Expendable bathythermographs (XBTs) that could be deployed from a rapidly moving ship and sampled to 400 m came into widespread use in the late 1960s, and those that sampled to 700 m became predominant in the 1990s, greatly expanding oceanographic sampling. Starting in 2000, Argo floats began sampling the ocean to a target depth of 2000 m, building to near-global coverage by 2005. Prior to the Argo era, sampling of the ocean below 700 m was almost solely achieved from ships on station deploying Nansen bottles with reversing thermometers or later using CTDs with Niskin bottles. Today ship-based station data still dominates sampling for waters deeper than 2000 m depth (the maximum depth currently sampled by Argo floats). An illustration of the limited data available for assessment of change in the deep ocean is provided in Figure 3.3, which shows locations of full-depth oceanographic CTD sections that have been occupied more than once since circa 1980. The depth coverage of the ocean observing system has changed over time (Figure 3A.2, top panel) with a hemispheric bias (Figure 3.A.2, middle and lower panels). The northern hemisphere has been consistently better-sampled than the southern hemisphere prior to the Argo era.

3.A.2 Salinity

Measurements of subsurface salinity have relied almost solely on data collected from bottle and CTD casts from ships on station (and, more recently, using profiling floats that sample both temperature and salinity with CTDs). Hence fewer measurements of salinity are available than of temperature (by roughly a factor of 3). However, the evolution with time of subsurface salinity sampling shows a similar progression to that of temperature (Figure 3.A.3). Coverage generally improves with time, but there is a strong northern

hemisphere bias, particularly in the North Atlantic. A shift in focus from basin-to-basin as major field programs were carried out is evident. Near-global coverage of ocean salinity above 2000 m was not achieved until after 2005, when the Argo array approached full deployment. For depths greater than 2000 m, outside the relatively well sampled North Atlantic, information on changes in ocean salinity is largely restricted to the repeat hydrographic transects (see Figure 3.3).

[INSERT FIGURE 3.A.3 HERE]

Figure 3.A.3: Hydrographic profile data used in the Durack and Wijffels (2010) study. Station locations for 5-year temporal bins from 1950–1955 (top left) to 2005–2010 (bottom right).

3.A.3 *Sea Level*

Direct observations of sea level are made using tide gauges since the 1700s and high-precision satellite altimeters since 1992. Tide gauge measurements are limited to coastlines and islands. There are intermittent records of sea level at Amsterdam from 1700 and at three more sites in Northern Europe starting after 1770. By the late 1800s, more tide gauges were being operated in Northern Europe and in North America, as well as in Australia and New Zealand (Figure 3.A.4). It was not until the late 1970s to early 1980s that a majority of deep-ocean islands had operating tide gauges suitable for climate studies. Although tide gauges have continued to be deployed since 1990, they have been complimented by continuous, near-global measurements of sea level from space since 1992. Measurements are made along the satellite's ground track on the Earth surface, typically averaged over approximately 7 km to reduce noise and improve precision. The maximum latitude extent of the measurement is limited by the inclination of the orbital plane, which has been between $\pm 66^\circ$ for the TOPEX/Poseidon and Jason series of altimeters. The spacing between ground tracks is much greater than the spacing along the ground track. As an example, the groundtrack separation of the TOPEX/Poseidon-type of orbits is about 300 km at the equator, but is less than 100 km at latitudes poleward of 50° latitude. On average, the spacing is between 100–200 km. Satellites are limited in the temporal sampling as well due to the orbit configuration. For a specific location along a groundtrack, the return time for a TOPEX/Poseidon-type of orbit is 9.9 days. If one relaxes the requirement to a measurement within a 300 km radius, the return time can be as short as a few hours at high latitudes to about 3 days at the equator. As noted in Section 3.6, satellite altimeter observations of sea level are also an important tool for observing large-scale ocean circulation.

[INSERT FIGURE 3.A.4 HERE]

Figure 3.A.4: Location of tide gauges (red dots) that had at least one year of observations within the decade indicated.

3.A.4 *Biogeochemistry*

The data available for assessing changes in biogeochemical parameters is less complete than for temperature and salinity. The global data base on which the Global Ocean Data Analysis Project (GLODAP, Key et al., 2004) ocean carbon inventory is based is illustrated in Figure 3.A.5. Changes in the ocean inventory of anthropogenic CO_2 have been estimated using measurements of carbon parameters and other tracers collected at these roughly 12000 stations, mostly occupied since 1990. The majority of these stations extend through the full water depth. A subset of these stations have been repeated one or more times. The distribution of oxygen measurements at 300 m depth in 10-year periods since 1960 is shown in Figure 3.A.6, as used in the global study of Stramma et al. (2012). As for temperature and salinity, the sampling is heterogeneous, coverage generally improves with time but shifts between basins as major field programs come and go, and tends to be concentrated in the northern hemisphere.

[INSERT FIGURE 3.A.6 HERE]

Figure 3.A.6: Distribution of oxygen measurements at 300 dbar for the decades 1950 to 1960 (upper left) to 2000 to 2010 (lower right frame). (From Stramma et al., 2012). [Note that additional oxygen data have become available for the 2000–2010 period since that study was completed.]

Tables

Table 3.1: Estimated trends in GMSL and components over different periods from representative time-series. Trends and uncertainty have been estimated from a time-series provided by the authors using ordinary least squares with the uncertainty representing the 90% confidence interval. The model fit for yearly averaged time-series was a bias + trend; the model fit for monthly and 10-day averaged data was a bias + trend + seasonal sinusoids. Uncertainty accounts for correlations in the residuals.

Quantity	Period	Trend (mm yr ⁻¹)	Source	Resolution
GMSL	1901–2010	1.7 [1.5 to 1.9]	Tide Gauge Reconstruction (Church and White, 2011)	Yearly
	1901–1990	1.5 [1.3 to 1.7]	Tide Gauge Reconstruction (Church and White, 2011)	Yearly
	1971–2010	2.0 [1.7 to 2.3]	Tide Gauge Reconstruction (Church and White, 2011)	Yearly
	1993–2010	2.8 [2.3 to 3.3]	Tide Gauge Reconstruction (Church and White, 2011)	Yearly
	1993–2010	3.2 [2.8 to 3.6] ^a	Altimetry (Nerem et al., 2010) time-series	10-day
Thermosteric Component (upper 700 m)	1971–2010	0.6 [0.4 to 0.8]	XBT Reconstruction (updated from Domingues et al., 2008)	3-year running means
	1993–2010	0.8 [0.5 to 1.1]	XBT Reconstruction (updated from Domingues et al., 2008)	3-year running means
Thermosteric Component (700–2000 m)	1971–2010	0.1 [0 to 0.2]	Objective mapping of historical temperature data (Levitus et al., 2012)	5-year averages
	1993–2010	0.2 [0.1 to 0.3]	Objective mapping of historical temperature data (Levitus et al., 2012)	5-year averages
Thermosteric Component (below 2000 m)	1992–2005	0.11 [0.01 to 0.21] ^b	Deep hydrographic sections (Purkey and Johnson, 2010)	Trend only
Thermosteric Component (whole depth)	1971–2010	0.8 [0.5 to 1.1] ^c	Combination of estimates from 0–700 m, 700–2000 m, and below 2000 m ^c	Trend Only
	1993–2010	1.1 [0.8 to 1.4] ^c	Combination of estimates from 0–700 m, 700–2000 m, and below 2000 m ^c	Trend Only

Notes:

(a) Uncertainty estimated from fit to Nerem et al. (2010) time series and includes potential systematic error owing to drift of altimeter, estimated to be ± 0.4 mm yr⁻¹ (Beckley et al., 2010; Nerem et al., 2010), applied as the root-sum-square (RSS) with the least squares error estimate. The uncertainty in drift contains uncertainty in the reference frame, orbit, and instrument.

(b) Trend value taken from Purkey and Johnson (2010), Table 1. Uncertainty represents the 2.5–97.5% confidence interval.

(c) Assumes no trend below 2000 m before 1 January 1992, then value from Purkey and Johnson (2010) afterwards. Uncertainty for 0–700 m, 700–2000 m, and below 2000 m is assumed to be uncorrelated, and uncertainty is calculated as RSS of the uncertainty for each layer.

Table 3.2: Published and updated long-term trends of atmospheric ($p\text{CO}_2^{\text{atm}}$) and seawater carbonate chemistry (i.e., surface-water $p\text{CO}_2$, and corresponding calculated pH, CO_3^{2-} , and aragonite saturation state (Ω_a) at four ocean time series in the North Atlantic and North Pacific oceans: (1) Bermuda Atlantic Time-series Study (BATS, 31°40'N, 64°10'W) and Hydrostation S (32°10'N, 64°30'W) from 1983 to present (Bates, 2007); (2) Hawaii Ocean Time-series (HOT) at Station ALOHA (A Long-term Oligotrophic Habitat Assessment; 22°45'N, 158°00'W) from 1988 to present (Dore et al., 2009); (3) European Station for Time-series in the Ocean (ESTOC, 29°10'N, 15°30'W) from 1994 to present (González-Dávila et al., 2010); and (4) Iceland Sea (IS, 68.0°N, 12.67°W) from 1985 to 2006 (Olafsson et al., 2009). Trends at the first three time-series sites are from observations with the seasonal cycle removed. Also reported are the wintertime trends in the Iceland Sea as well as the pH difference trend for the North Pacific Ocean between transects in 1991 and 2006 (Byrne et al., 2010) and repeat sections in the western North Pacific between 1983 and 2008 (Midorikawa et al., 2010).

Site	Period	$p\text{CO}_2^{\text{atm}}$ ($\mu\text{atm yr}^{-1}$)	$p\text{CO}_2^{\text{sea}}$ ($\mu\text{atm yr}^{-1}$)	pH* (yr^{-1})	$[\text{CO}_3^{2-}]$ ($\mu\text{mol kg}^{-1} \text{yr}^{-1}$)	Ω_a (yr^{-1})

Notes:

*pH on the total scale

(a) Bates (2007, Table 1) - simple linear fit

(b) Bates (2007, Table 2) - seasonally detrended (including linear term for time)

(c) Dore et al. (2009) - linear fit with calculated pH and $p\text{CO}_2$ from measured DIC and TA (full time series); corresponding Ω_a from Feely et al. (2009)

(d) Dore et al. (2009) - linear fit with measured pH (partial time series)

(e) Santana-Casiano et al. (2007) - seasonal detrending (including linear terms for time and temperature)

(f) González-Dávila et al. (2010) - seasonal detrending (including linear terms for time, temperature, and mixed-layer depth)

(g) Olafsson et al. (2009) - multivariable linear regression (linear terms for time and temperature) for winter data only

(h) Byrne et al. (2010) - meridional section originally occupied in 1991 and repeated in 2006

(i) Midorikawa et al. (2010) - winter and summer observations along 137°E

(j) Trends are for linear time term in seasonal detrending with harmonic periods of 12, 6, and 4 months. Harmonic analysis made after interpolating data to regular monthly grids (except for IS, which was sampled much less frequently):

1983–2009 = September 1983 to December 2009 (BATS/Hydrostation S sampling period),

1985–2009 = February 1985 to December 2009 (IS sampling period),

1988–2009 = November 1988 to December 2009 (ALOHA/HOT sampling period), and

1995–2009 = September 1995 to December 2009 (ESTOC sampling period).

(k) Ishii et al. (2011) - time-series observations in the coast of western N. Pacific, with the seasonal cycle removed

(l) Atmospheric $p\text{CO}_2$ trends computed from same harmonic analysis (12-, 6-, and 4-month periods) on the GLOBALVIEW- CO_2 (2010) data product for the marine boundary layer referenced to the latitude of the nearest atmospheric measurement station (BME for Bermuda, MLO for ALOHA, IZO for ESTOC, and ICE for Iceland)

(l) Winter ocean data, collected during dark period (between 19 January and 7 March), as per Olafsson et al. (2009) to reduce scatter from large interannual variations in intense short-term bloom events, undersampled in time, fit linearly ($y=at+bT+c$)

Figures

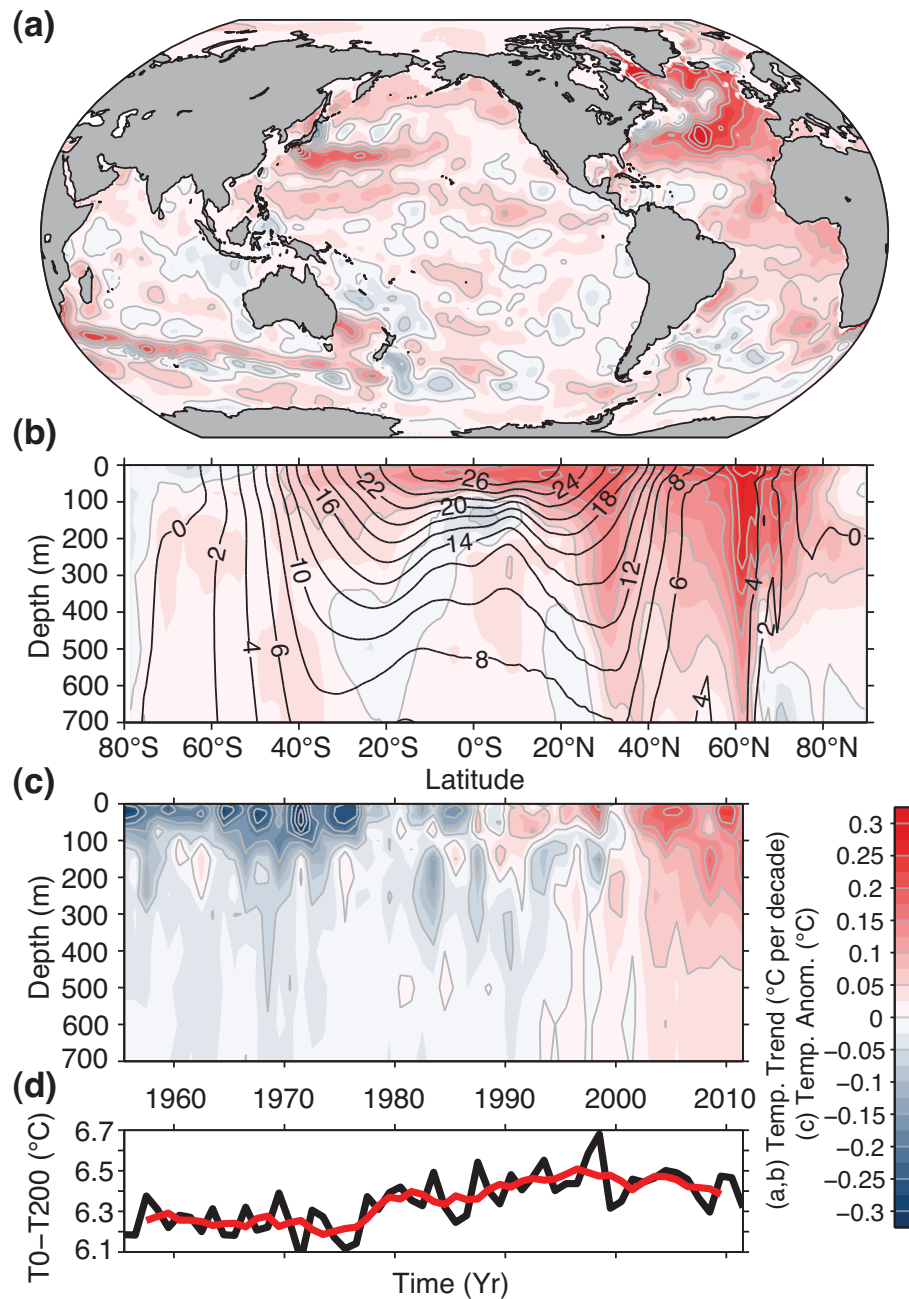

Figure 3.1: a) Depth-averaged 0–700 m temperature trend for 1971–2010 (longitude vs. latitude, colors and grey contours in °C per decade), b) Zonally-averaged temperature trends (latitude versus depth, colors and grey contours in °C per decade) for 1971–2010, with zonally averaged mean temperature over-plotted (black contours in °C). c) Globally-averaged temperature anomaly (time versus depth, colors and grey contours in °C) relative to the 1971–2010 mean. d) Globally-averaged temperature difference between the ocean surface and 200 m depth (black: annual values, red: 5-year running mean). All panels are constructed from an update of the annual analysis of Levitus et al. (2009).

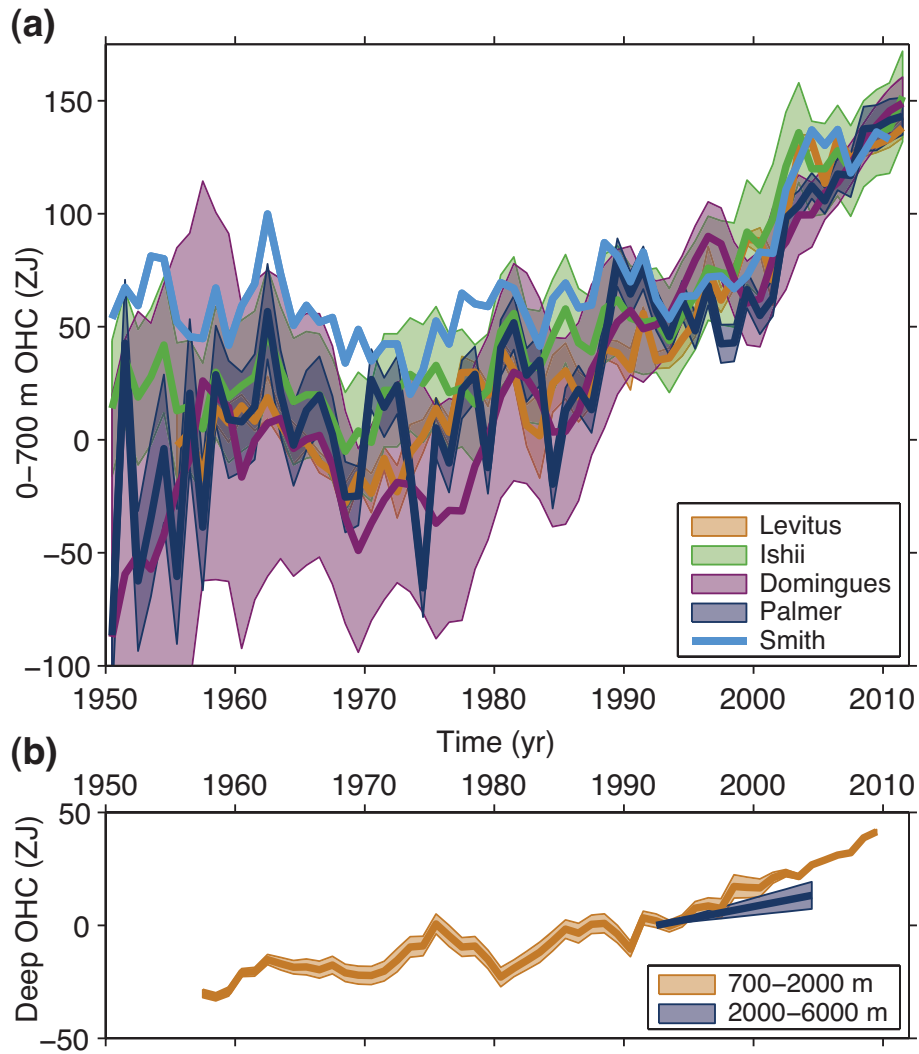

Figure 3.2: **a)** Observation-based estimates of annual global mean upper (0–700 m) ocean heat content in ZJ (1 ZJ = 10^{21} Joules) updated from (see legend): (Levitus et al., 2012), (Ishii and Kimoto, 2009), (Domingues et al., 2008), (Palmer et al., 2007), and (Smith and Murphy, 2007). Uncertainties are shaded, and plotted as published (at the one standard error level, except one standard deviation for Levitus, with no uncertainties provided for Smith). Estimates are shifted to align for 2006–2010, five years that are well measured by Argo, and then plotted relative to the resulting mean of all curves for 1971, the starting year for trend calculations. **b)** Observation-based estimates of annual five-year running mean global mean mid-depth (700–2000 m) ocean heat content in ZJ (Levitus et al., 2012) and the deep (2000–6000 m) global ocean heat content trend from 1992–2005 (Purkey and Johnson, 2010), both with one standard error uncertainties shaded (see legend).

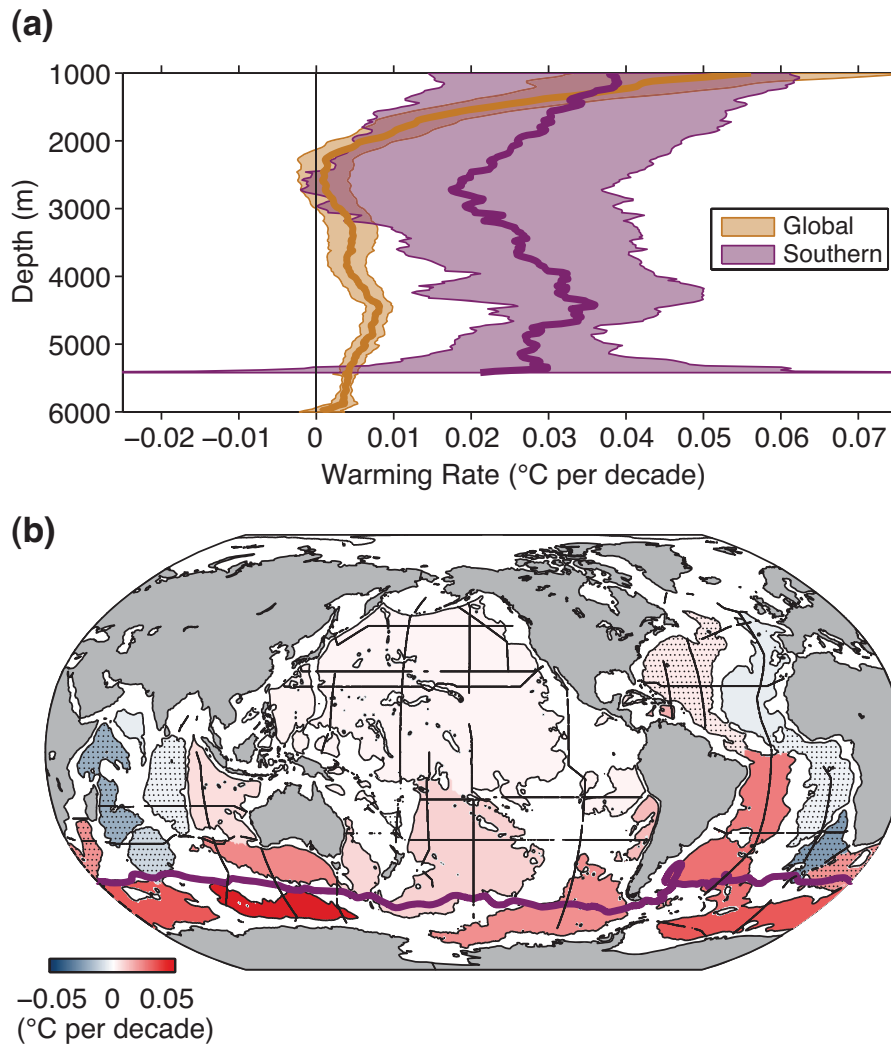

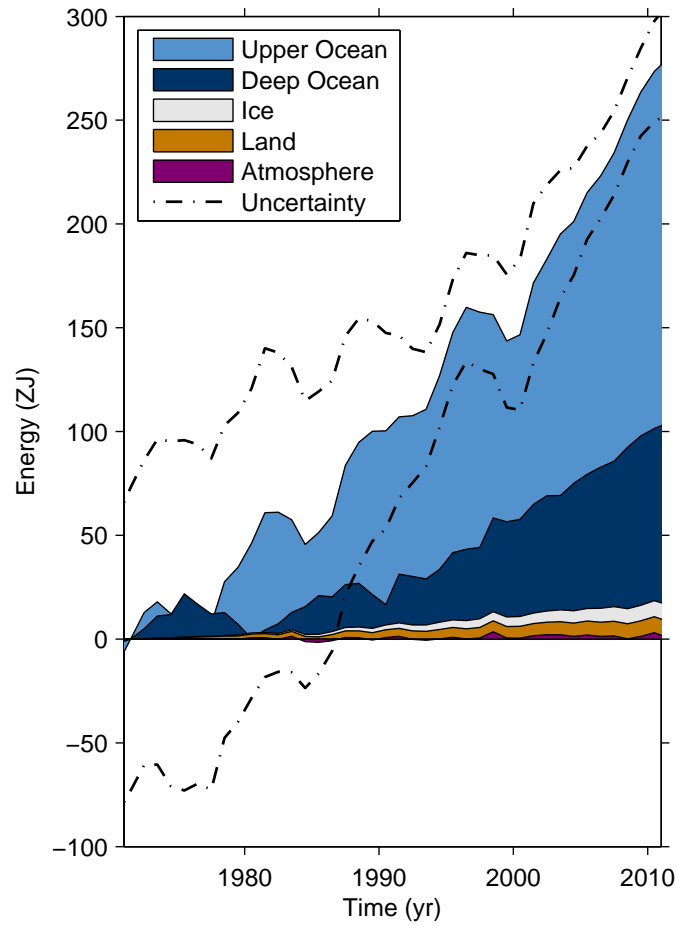

Figure 3.3: **a)** Areal mean warming rates (°C per decade) versus depth (thick lines) with 5 to 95% confidence limits (shading), both global (orange) and south of the Sub-Antarctic Front (purple), centred on 1992–2005. **b)** Mean warming rates (°C per decade) below 4000 m (colorbar) estimated for deep ocean basins (thin black outlines), centred on 1992–2005. Stippled basin warming rates are not significantly different from zero at 95% confidence. The positions of the Sub-Antarctic Front (purple line) and the repeat oceanographic transects from which these warming rates are estimated (thick black lines) also shown. Data from Purkey and Johnson (2010).

Box 3.1, Figure 1: Plot of energy accumulation in ZJ ($1 \text{ ZJ} = 10^{21} \text{ J}$) within distinct components of Earth's climate system relative to 1971 and from 1971–2010 unless otherwise indicated. See text for data sources. Ocean warming (heat content change) dominates, with the upper ocean (light blue, above 700 m) contributing more than the deep ocean (dark blue, below 700 m; including below 2000 m estimates starting from 1992). Ice melt (light grey; for glaciers and ice caps, Greenland and Antarctic ice sheet estimates starting from 1992, and Arctic sea ice estimate from 1979–2008); continental (land) warming (orange); and atmospheric warming (purple; estimate starting from 1979) make smaller contributions. Uncertainty in the ocean estimate also dominates the total uncertainty (dot-dashed lines about the error from all five components at 90% confidence intervals).

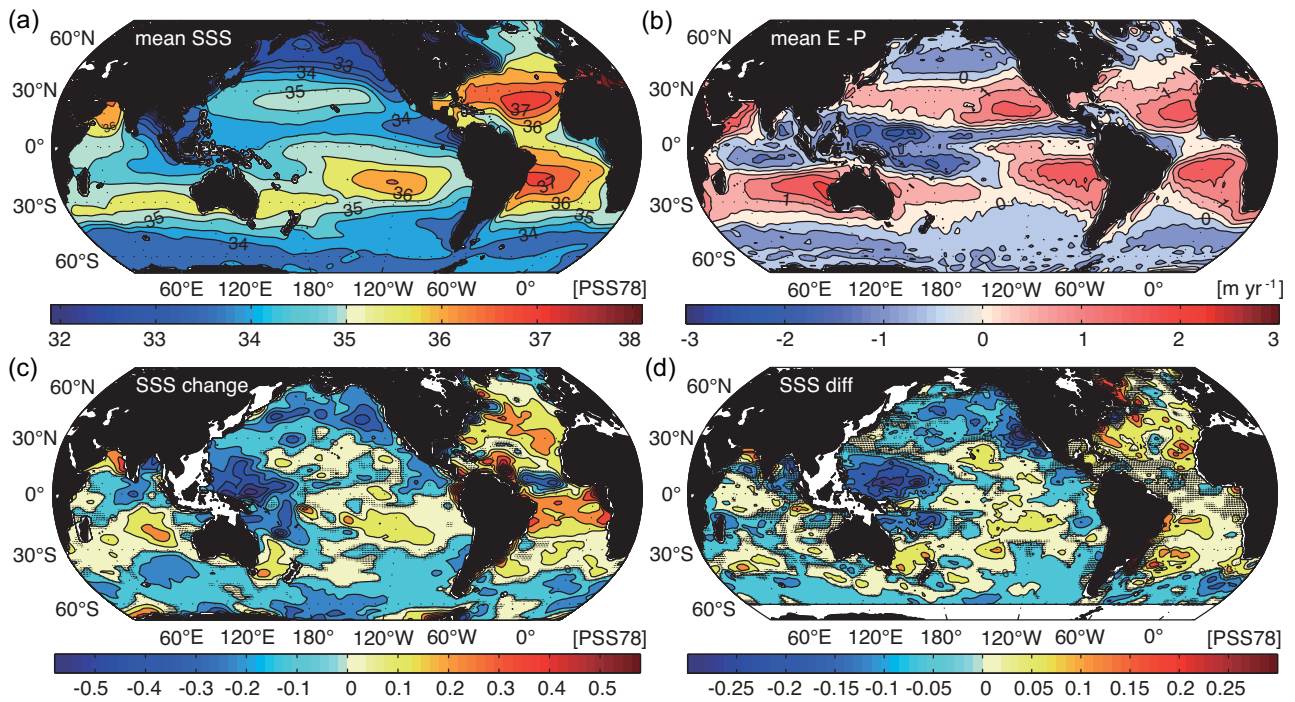

Figure 3.4: **a)** The 1955–2005 climatological-mean sea surface salinity (World Ocean Atlas 2009 of Antonov et al., 2010) color contoured at 0.5 PSS78 intervals (black lines). **b)** Annual mean evaporation-precipitation averaged over the period 1950–2000 (NCEP) color contoured at 0.5 m yr^{-1} intervals (black lines). **c)** The 58-year (2008 minus 1950) sea surface salinity change derived from the linear trend (PSS78), with seasonal and ENSO signals removed (Durack and Wijffels, 2010) color contoured at 0.116 PSS78 intervals (black lines). **d)** The 30-year (2003–2007 average centered at 2005, minus the 1960–1989 average, centered at 1975) sea surface salinity difference (PSS78) (Hosoda et al., 2009) color contoured at 0.06 PSS78 intervals (black lines). Contour intervals in (c) and (d) are chosen so that the trends can be easily compared, given the different time intervals in the two analyses. White areas in (c) – (d) are marginal seas where the calculations are not carried out. Regions where the change is not significant at the 99% confidence level are stippled in grey.

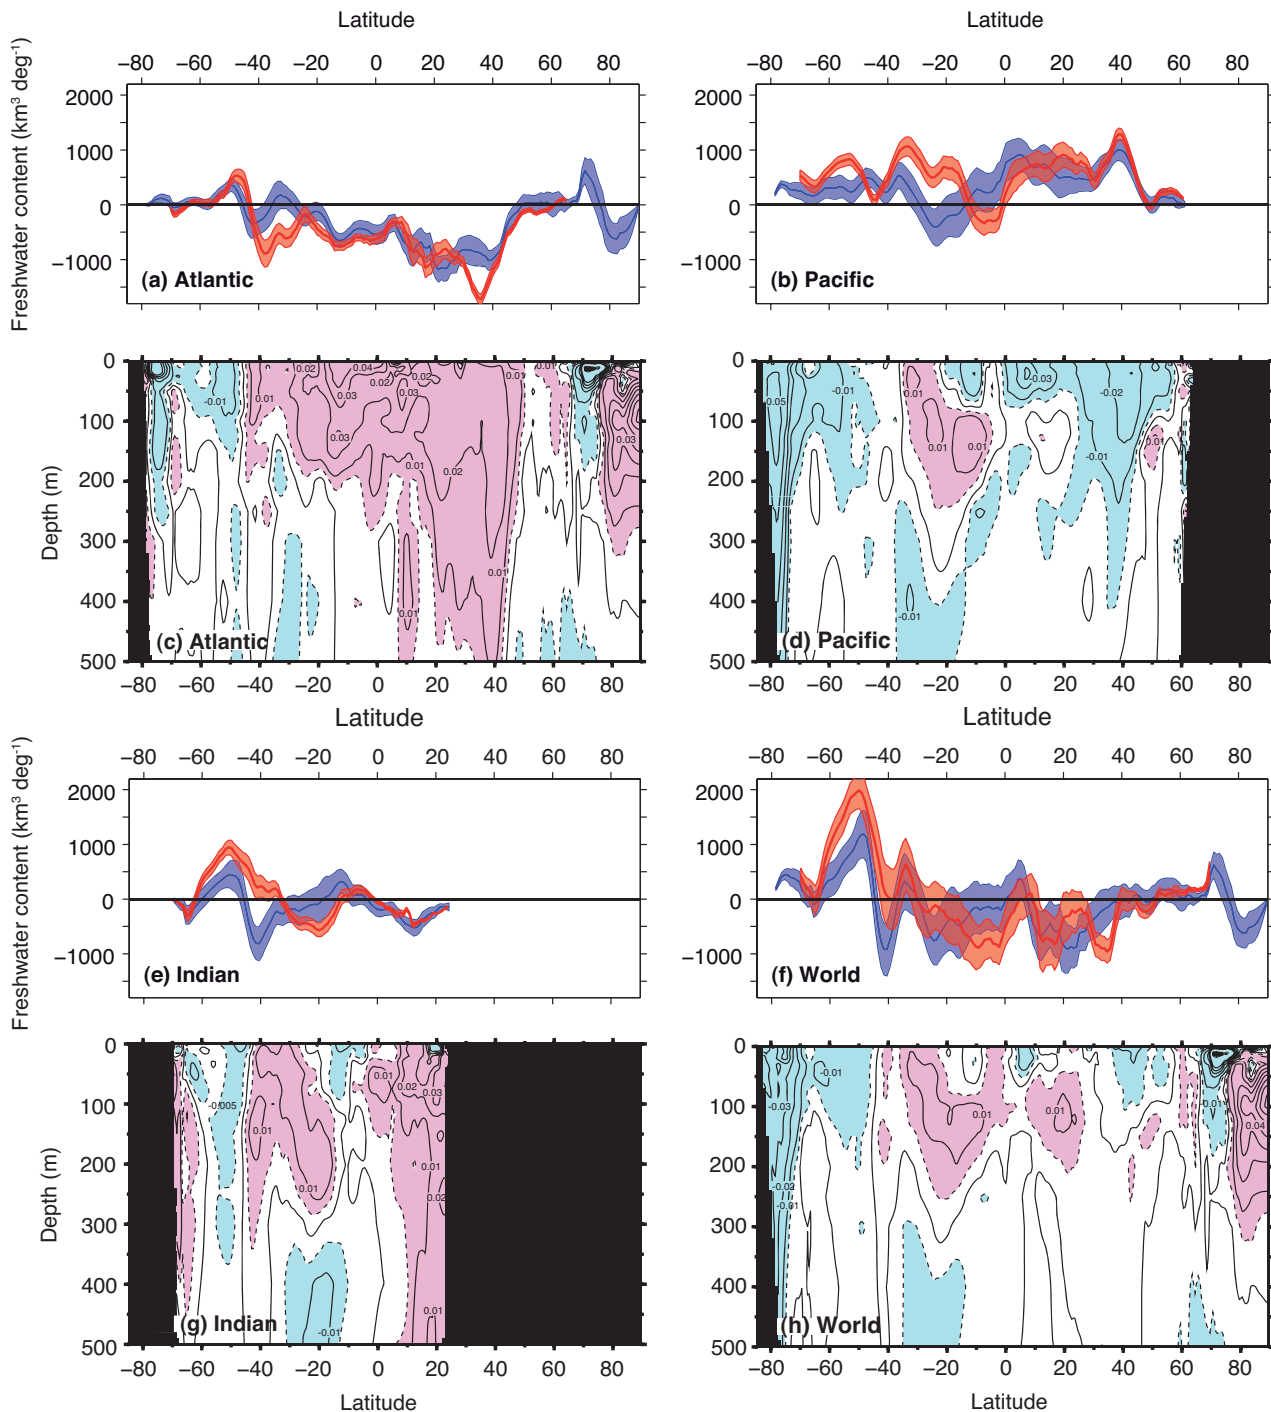

Figure 3.5: Zonally integrated freshwater content changes (FWCC; km^3 per degree of latitude) in the upper 500 m over one-degree zonal bands and linear trends (1955-2010) of zonally averaged salinity (PSS78; lower panels) in the upper 500 m of the **a c**) Atlantic, **b d**) Pacific, **e g**) Indian, and **f h**) World Oceans. The FWCC time period is from 1955 to 2010 (Boyer et al., 2005; blue lines) and 1950 to 2008 (Durack and Wijffels, 2010; red lines). Data are updated from Boyer et al. (2005) and calculations of FWCC are done according to the method of Boyer et al. (2007), using five-year averages of salinity observations and fitting a linear trend to these averages. Error estimates are 95% confidence intervals. The contour interval of salinity trend in the lower panels is 0.01 PSS78 per decade and dashed contours are 0.005 PSS78 per decade. Red shading indicates values equal to or greater than 0.05 PSS78 per decade and blue shading indicates values equal to or less than -0.005 PSS78 per decade.

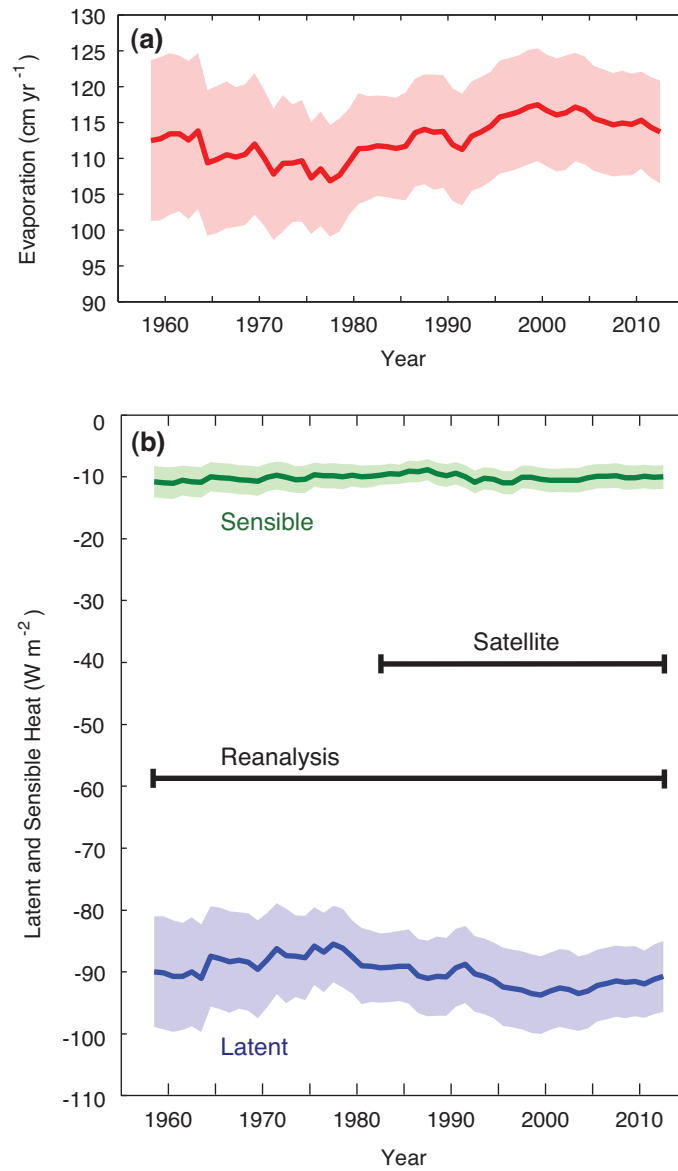

Figure 3.6: Time series of annual mean global ocean average evaporation (red line panel a), sensible heat flux (green line panel b) and latent heat flux (blue line panel b) from 1958 to 2012 determined by Yu from a revised and updated version of the original OAFlux dataset Yu and Weller (2007). Shaded bands show uncertainty estimates and the black horizontal bars in panel (b) show the time periods for which reanalysis output and satellite observations were employed in the OAFlux analysis; they apply to both panels.

Figure 3.7: Long term reconstruction of ocean precipitation anomaly averaged over 75°S–75°N from Smith et al. (2012) annual values – thin blue line, low-pass filtered (15 year running mean) values – bold blue line with uncertainty estimates (shading); Smith et al. (2009) low-pass filtered values – dotted grey line. Also shown is the corresponding GPCPv2.2 derived ocean precipitation anomaly time series averaged over the same latitudinal range (annual values – thin magenta line, low-pass filtered values – bold magenta line); note Smith et al. (2012) employed an earlier version of the GPCP dataset leading to minor differences relative to the published time series in their paper. Precipitation anomalies were taken relative to the 1979–2008 period.

Figure 3.8: Time series of annual average maximum zonal-mean zonal wind stress (N m^{-2}) over the Southern Ocean for various atmospheric reanalyses: CFSR (orange), NCEP1 (cyan), NCEP2 (red), ERAI (dark blue), MERRA (green), 20CR (gray), and mean of all reanalyses at a given time (thick black), see Box 2.3 for details of reanalyses. Updated version of Figure 1a in Swart and Fyfe (2012), with CFSR, MERRA and the mean of all reanalyses added.

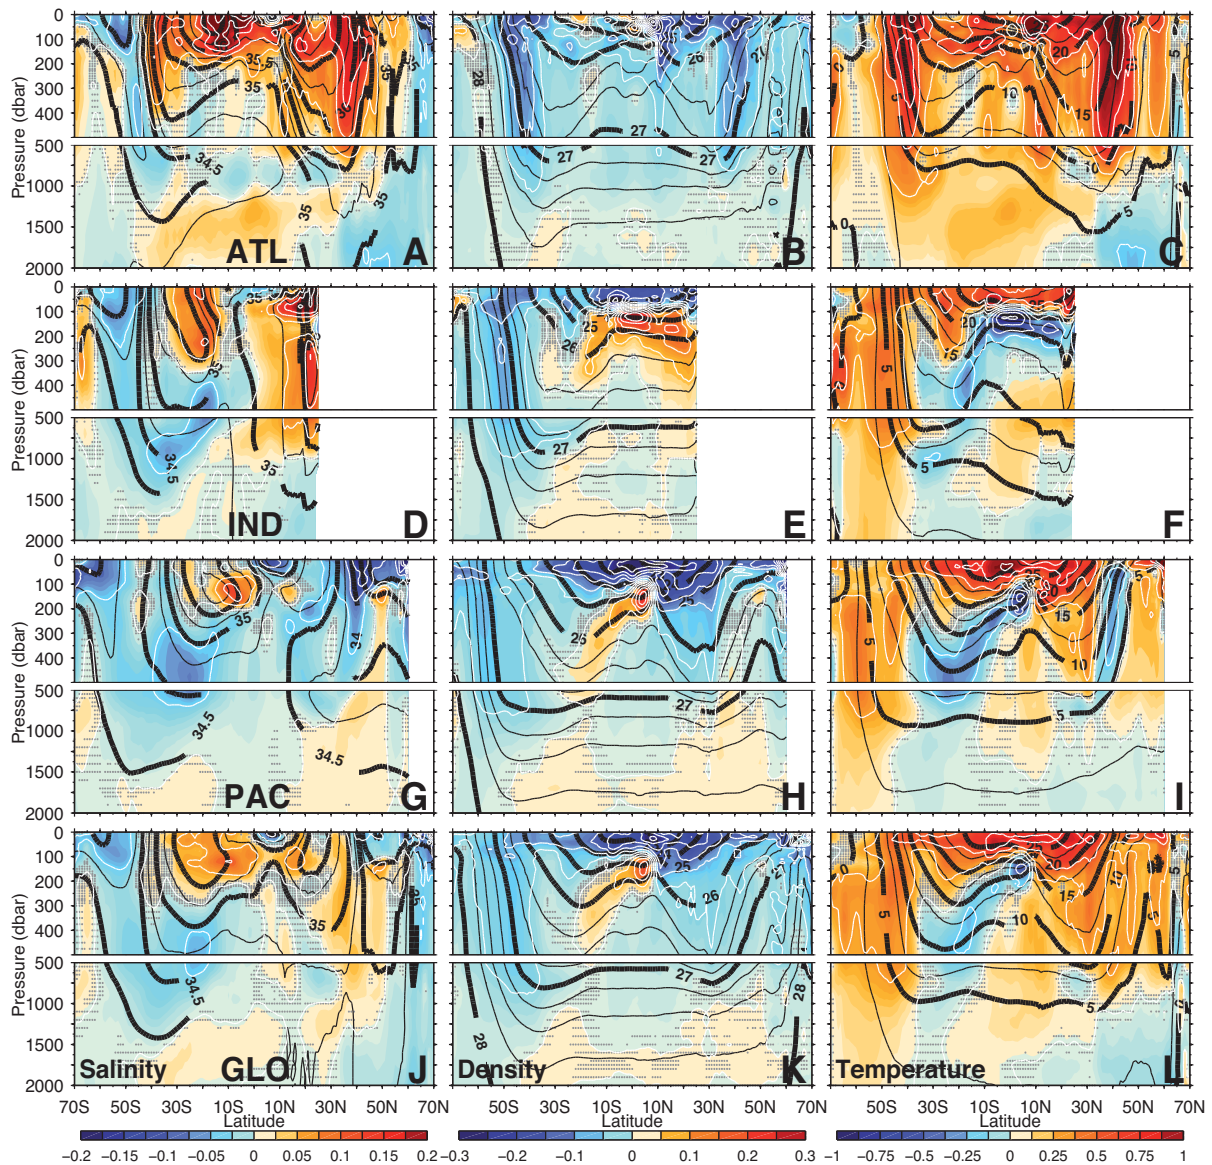

Figure 3.9: Upper 2000 m zonally averaged mean trend distribution, (year 2000 minus 1950; colours with white contours) of salinity (column 1), neutral density (column 2), and potential temperature (column 3), for the Atlantic Ocean (ATL) in row 1, Indian Ocean (IND), row 2, Pacific Ocean (PAC), row 3, and global ocean (GLO) in row 4. Mean fields are shown as black lines. Regions where the resolved linear trend is not significant at the 90% confidence level are stippled in gray. Salinity results are republished from Durack and Wijffels (2010) with the unpublished temperature and density results from this study also presented.

Figure 3.10: Mean steric height of the sea surface relative to 2000 decibars (black contours at 10 cm intervals) shows the pattern of geostrophic flow for the Argo era (2004–2012) based on Argo profile data, updated from Roemmich and Gilson (2009). The sea surface height (SSH) trend (cm per decade, color shading) for the period 1993–2011 is based on the AVISO altimetry “reference” product (Ducet et al., 2000). Spatial gradients in the SSH trend, divided by the (latitude-dependant) Coriolis parameter, are proportional to changes in surface geostrophic velocity. For display, the mean steric height contours and SSH trends are spatially smoothed over 5° longitude and 3° latitude.

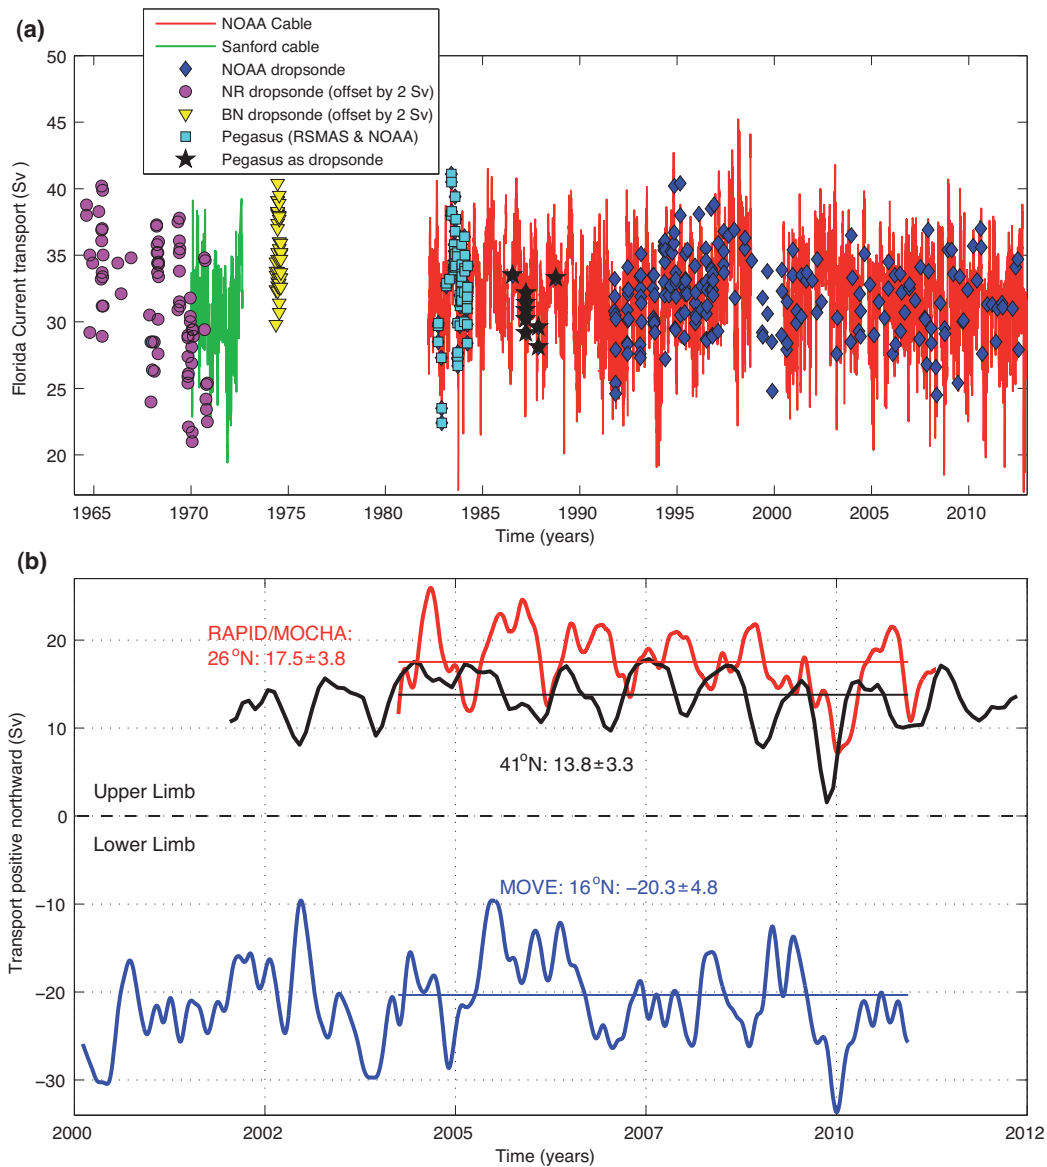

Figure 3.11: **a)** Volume transport in Sverdrups (Sv; where $1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$) of the Florida Current between Florida and the Bahamas, from dropsonde measurements (symbols) and cable voltages (continuous line), extending the time-series shown in Meinen et al. (2010) **b)** AMOC transport estimates (Sv): 1. RAPID/MOCHA (Rapid Climate Change programme/Meridional Ocean Circulation and Heatflux Array) at 26.5°N (red). The array monitors the top-to-bottom Atlantic wide circulation, ensuring a closed mass balance across the section, and hence a direct measure of the upper and lower limbs of the AMOC. 2. 41°N (black): An index of maximum AMOC strength from Argo float measurements in the upper 2000 m only, combined with satellite altimeter data. The lower limb is not measured. 3. Meridional Overturning Variability Experiment (MOVE) at 16°N (blue) measuring transport of North Atlantic Deep Water in the lower limb of the AMOC between 1100 m and 4800 m depth between the Caribbean and the mid-Atlantic Ridge. This transport is thought to be representative of maximum MOC variability based on model validation experiments. The temporal resolution of the three timeseries is ten days for 16°N and 26°N and one month for 41°N . The data have been three month low-pass filtered. Means and standard deviations for the common period of 2 April 2004 to 1 April 2010 are $17.5 \pm 3.8 \text{ Sv}$, $13.8 \pm 3.3 \text{ Sv}$, and $-20.3 \pm 4.8 \text{ Sv}$ (negative indicating the southward lower limb) for 26.5°N , 41°N , and 16°N respectively. Means over this period are indicated by the horizontal line on each timeseries.

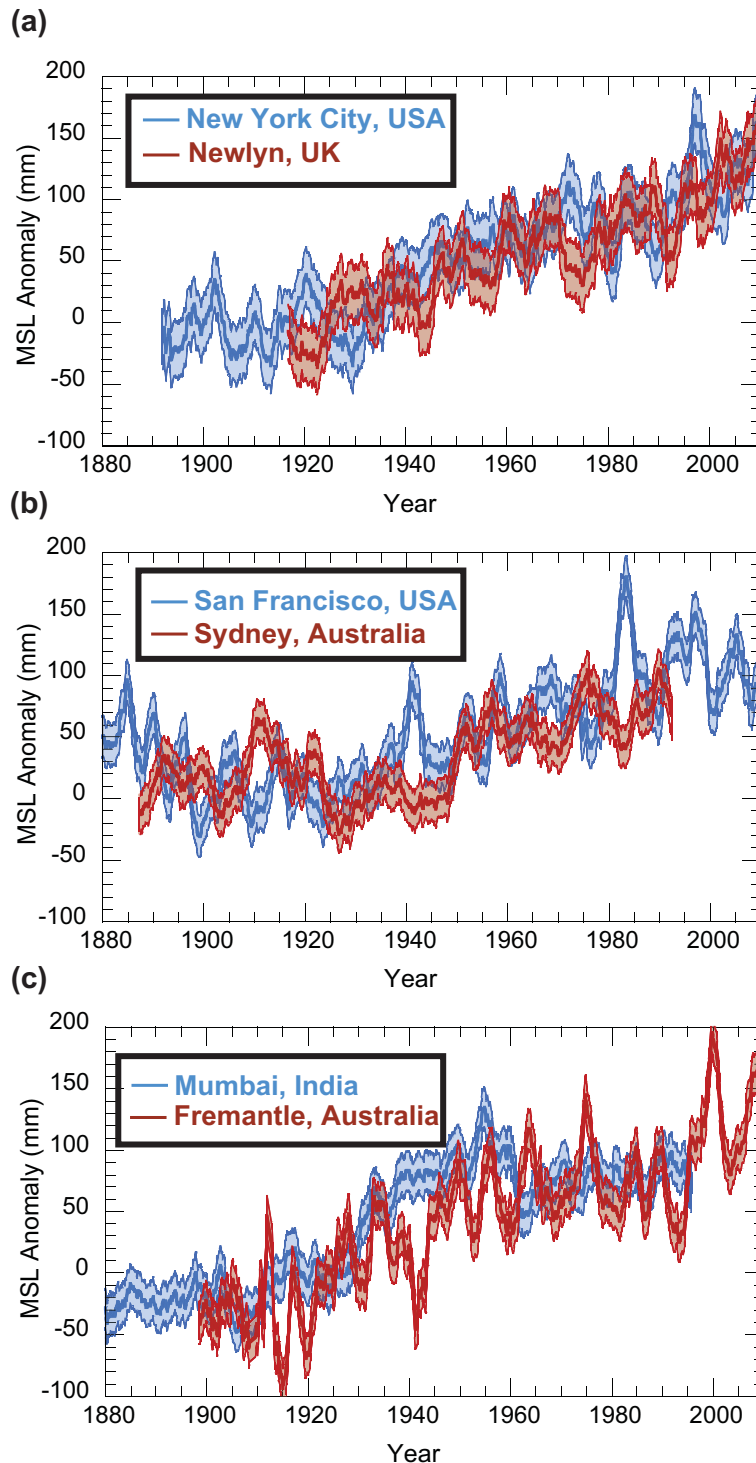

Figure 3.12: 3-year running mean sea level anomalies (in mm) relative to 1900–1905 from long tide gauge records representing each ocean basin from the Permanent Service for Mean Sea Level (PSMSL) (<http://www.psmsl.org>), obtained May 2011. Data have been corrected for Glacial Isostatic Adjustment (GIA) (Peltier, 2004), using values available from http://www.psmsl.org/train_and_info/geo_signals/gia/peltier/. Error bars reflect the 5 to 95% confidence interval, based on the residual monthly variability about the 3-year running mean.

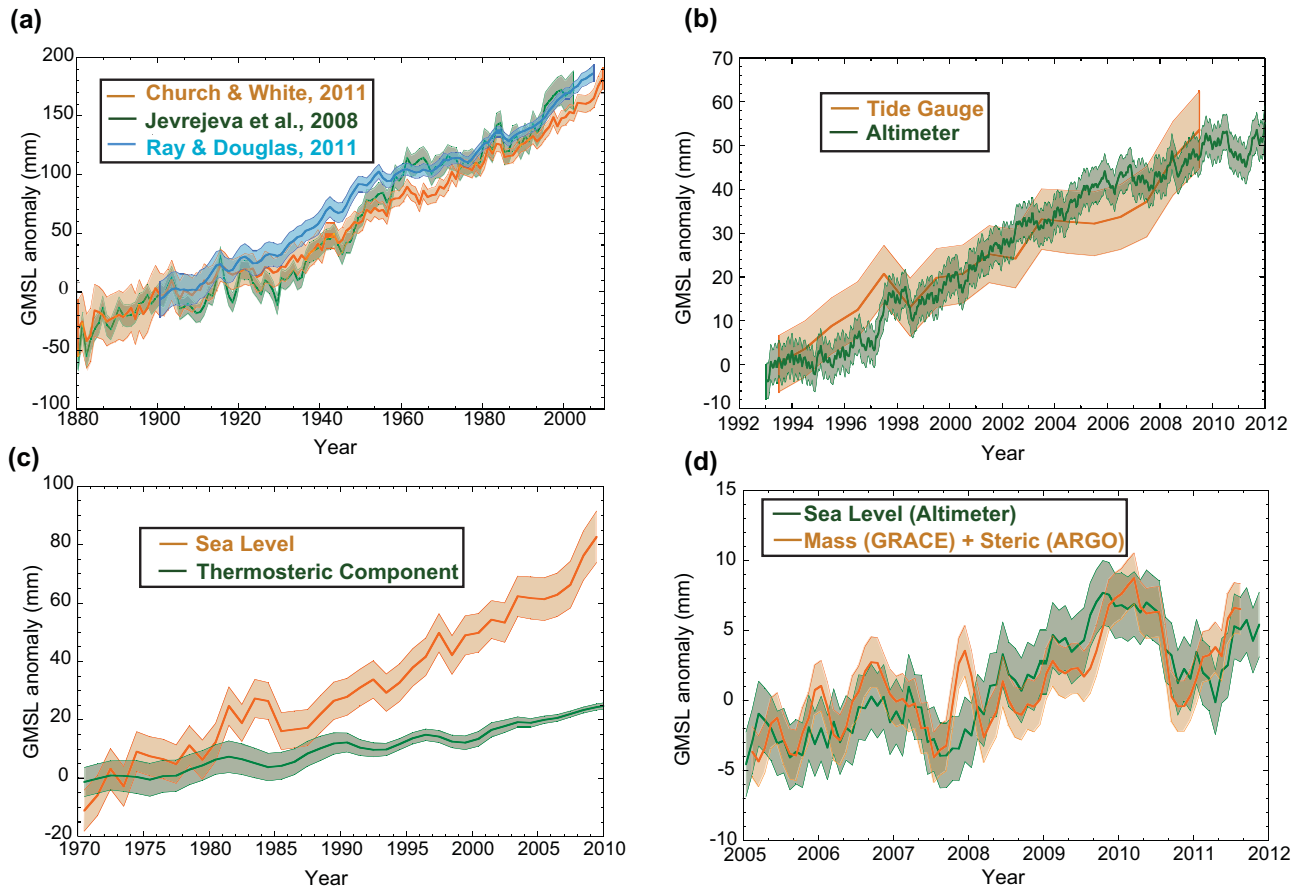

Figure 3.13: Global mean sea level anomalies (in mm) from the different measuring systems as they have evolved in time, plotted relative to 5-year mean values that start at **a)** 1900, **b)** 1993, **c)** 1970, and **d)** 2005. **a)** Yearly average GMSL reconstructed from tide gauges (1900–2010) by three different approaches (Jevrejeva et al., 2008; Church and White, 2011; Ray and Douglas, 2011), **b)** GMSL (1993–2010) from tide gauges and altimetry (Nerem et al., 2010) with seasonal variations removed and smoothed with a 60-day running mean **c)** GMSL (1970–2010) from tide gauges along with the thermosteric component to 700 m, (3-year running mean) estimated from in situ temperature profiles (updated from Domingues et al., 2008), **d)** the GMSL (nonseasonal) from altimetry and that computed from the mass component (GRACE) and steric component (Argo) from 2005–2010 (Leuliette and Willis, 2011), all with a 3-month running mean filter. All uncertainty bars are one standard error as reported by the authors. The thermosteric component is just a portion of total sea level, and is not expected to agree with total sea level.

Figure 3.14: 18-year trends of GMSL rise estimated at 1-year intervals. The time is the start date of the 18-year period, and the shading represents the 90% confidence. The estimate from satellite altimetry is also given, with the 90% confidence given as an error bar. Uncertainty is estimated by the variance of the residuals about the fit, and accounts for serial correlation in the residuals as quantified by the lag-1 autocorrelation.

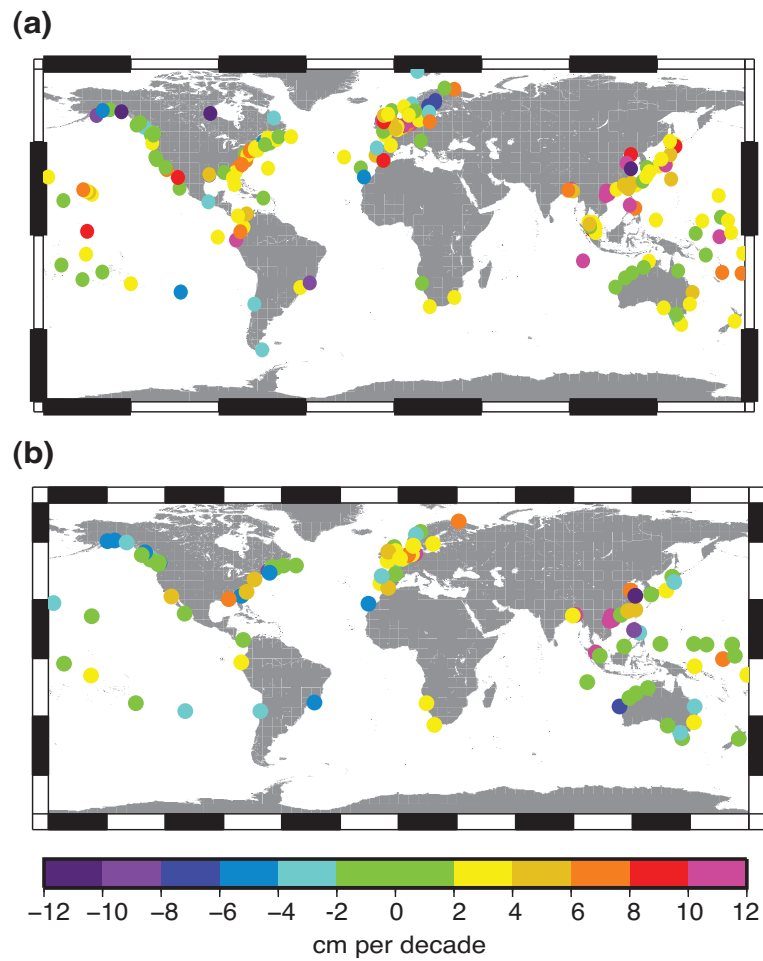

Figure 3.15: Estimated trends (cm per decade) in the height of a 50-year event in extreme sea level from (a) total elevation and (b) total elevation after removal of annual medians. Black dots indicate trends are not significant at the 95% confidence level. Data are from Menéndez and Woodworth (2010).

Figure 3.16: Compilation of the 2010 column inventories (mol m^{-2}) of anthropogenic CO_2 : the global Ocean excluding the marginal seas (updated from Khatiwala et al., 2009) 150 ± 26 PgC; Arctic Ocean (Tanhua et al., 2009) 2.7–3.5 PgC; the Nordic Seas (Olsen et al., 2010) 1.0–1.6 PgC; the Mediterranean Sea (Schneider et al., 2010) 1.6–2.5 PgC; the East Sea (Sea of Japan) (Park et al., 2006) 0.40 ± 0.06 PgC. From Khatiwala et al. (2013).

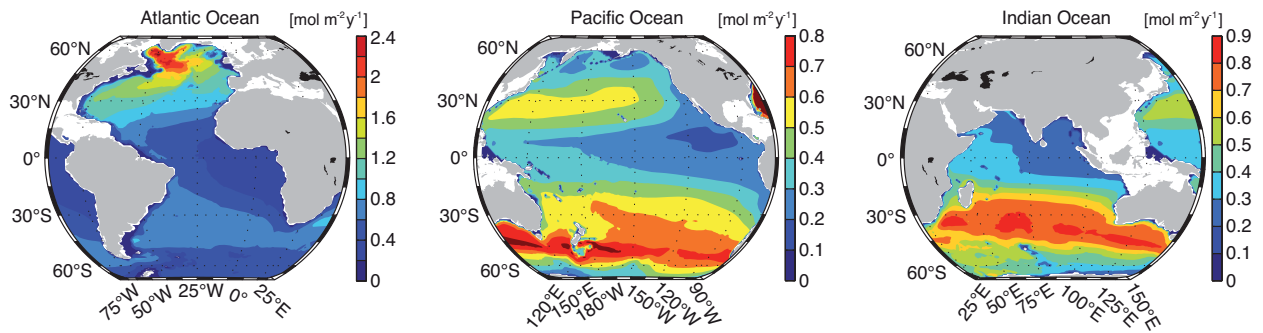

Figure 3.17: Maps of storage rate distribution of anthropogenic carbon ($\text{mol m}^{-2} \text{y}^{-1}$) for the three ocean basins (left to right: Atlantic, Pacific, and Indian Ocean) averaged over 1980–2005 estimated by the Green’s function approach (Khatiwala et al., 2009). Note that a different color scale is used in each basin.

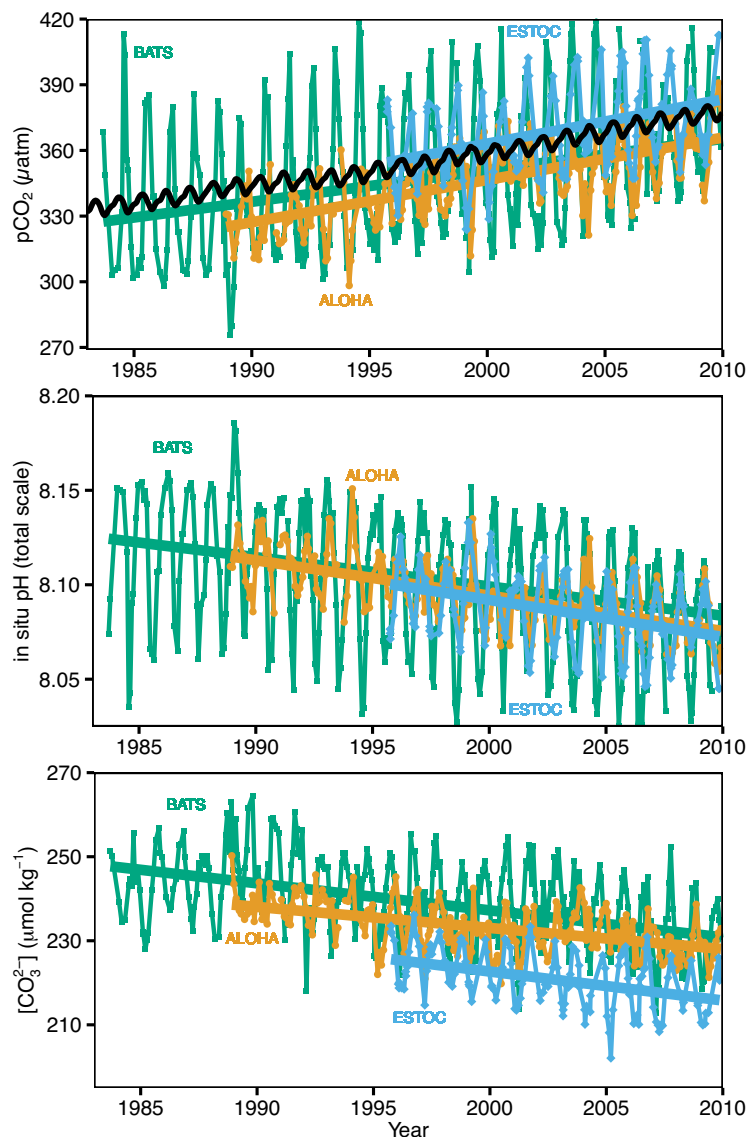

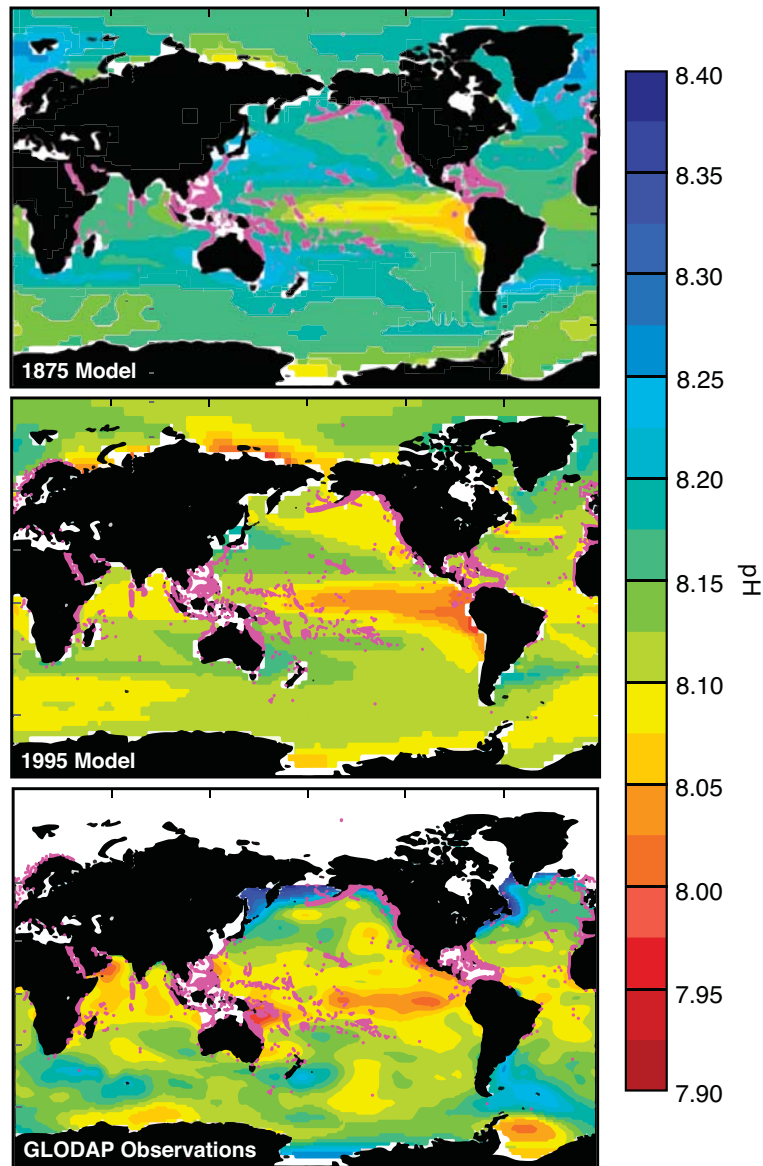

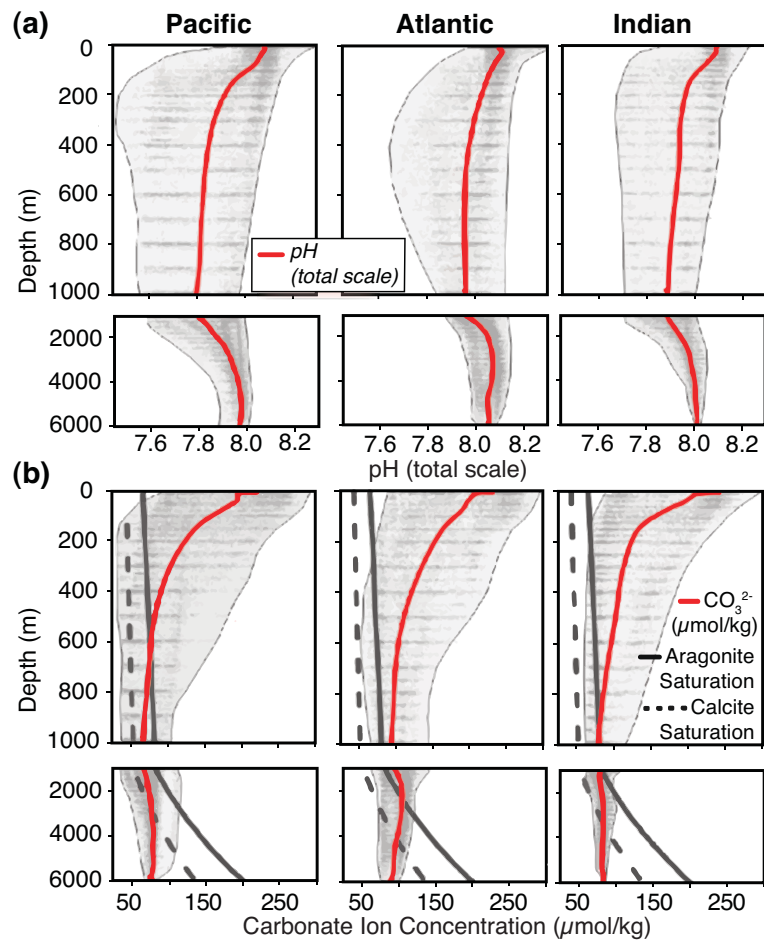

Figure 3.18: Long-term trends of surface seawater $p\text{CO}_2$ (top), pH (middle), and carbonate ion (bottom) concentration at three subtropical ocean time series in the North Atlantic and North Pacific Oceans, including: **a)** Bermuda Atlantic Time-series Study (BATS, $31^\circ 40' \text{N}$, $64^\circ 10' \text{W}$; **green**) and Hydrostation S ($32^\circ 10'$, $64^\circ 30' \text{W}$) from 1983 to present (updated from Bates, 2007); **b)** Hawaii Ocean Time-series (HOT) at Station ALOHA (A Long-term Oligotrophic Habitat Assessment; $22^\circ 45' \text{N}$, $158^\circ 00' \text{W}$; **orange**) from 1988 to present (updated from Dore et al., 2009), and; **c)** European Station for Time series in the Ocean (ESTOC, $29^\circ 10' \text{N}$, $15^\circ 30' \text{W}$; **blue**) from 1994 to present (updated from González-Dávila et al., 2010). Atmospheric $p\text{CO}_2$ (**black**) from the Mauna Loa Observatory Hawaii is shown in the top panel. Lines show linear fits to the data, whereas Table 3.2 give results for harmonic fits to the data (updated from Orr, 2011).

Box 3.2, Figure 1: National Center for Atmospheric Research Community Climate System Model 3.1 (CCSM3)-modeled decadal mean pH at the sea surface centered around the years 1875 (top) and 1995 (middle). Global Ocean Data Analysis Project (GLODAP)-based pH at the sea surface, nominally for 1995 (bottom). Deep and shallow-water coral reefs are indicated with magenta dots. White areas indicate regions with no data (after Feely et al., 2009).

Box 3.2, Figure 2: Distribution of: **a)** pH and **b)** CO_3^{2-} ion concentration in the Pacific, Atlantic, and Indian Oceans. The data are from the World Ocean Circulation Experiment/Joint Global Ocean Flux Study/Ocean Atmosphere Carbon Exchange Study global CO_2 survey (Sabine et al., 2005). The lines show the mean pH (red solid line top panel), mean CO_3^{2-} (red solid line bottom panel), and aragonite and calcite (black solid and dashed lines bottom panel) saturation values for each of these basins (modified from Feely et al., 2009). The shaded areas show the range of values within the ocean basins. Dissolution of aragonite and calcite shells and skeletons occurs when CO_3^{2-} concentrations drop below the saturation level, reducing the ability of calcifying organisms to produce their shells and skeletons.

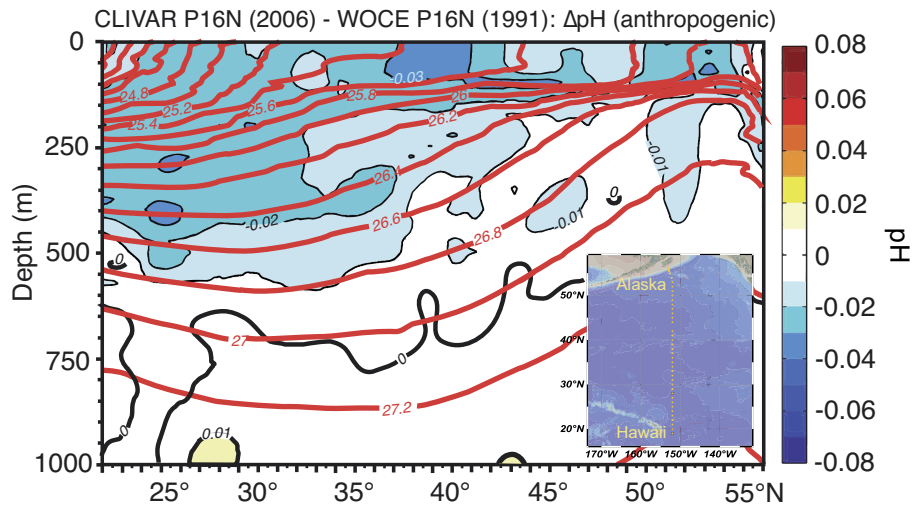

Figure 3.19: ΔpH_{ant} : pH change attributed to the uptake of anthropogenic carbon between 1991 and 2006, at about 150°W, Pacific Ocean (from Byrne et al., 2010). The red lines show the layers of constant density.

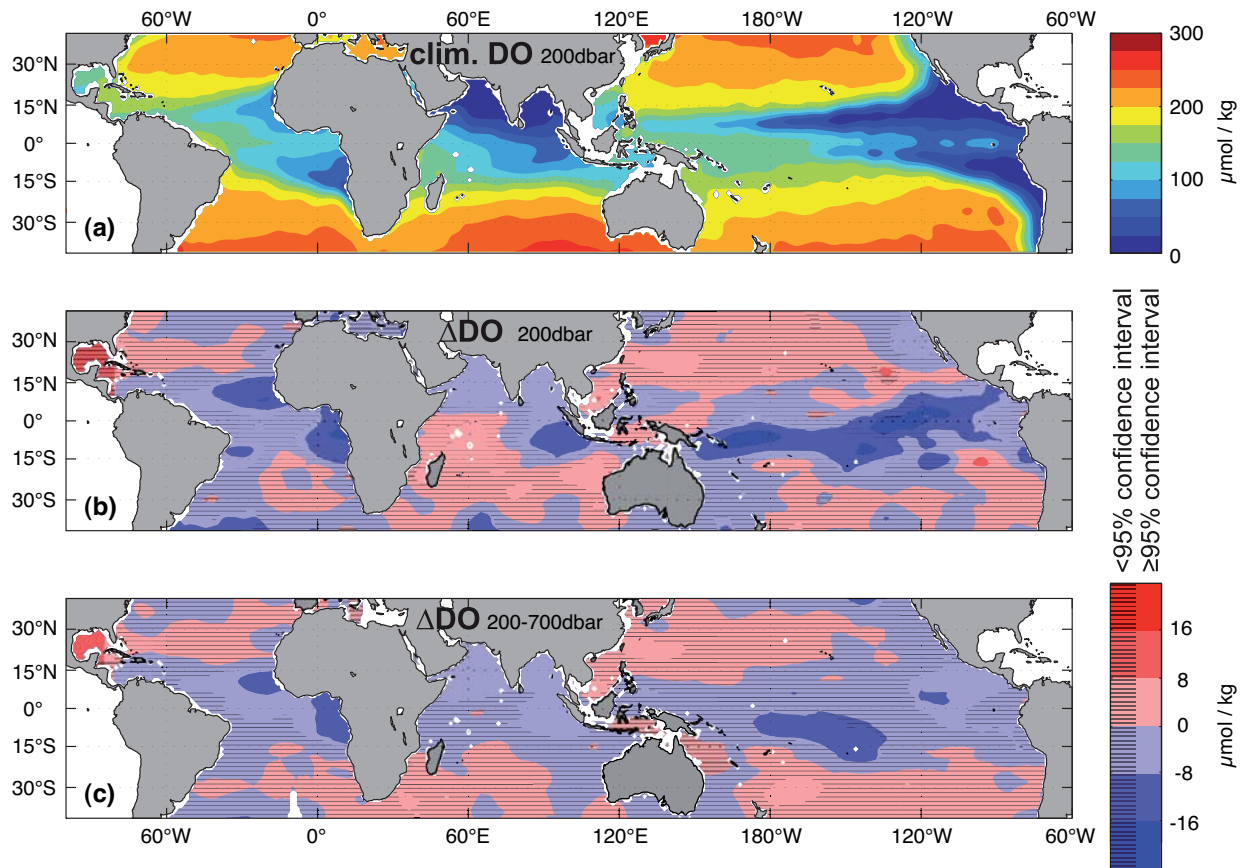

Figure 3.20: Dissolved oxygen (DO) distributions (in $\mu\text{mol kg}^{-1}$) between 40°S and 40°N for: **a)** the climatological mean (Boyer et al., 2006) at 200 dbar, as well as changes between 1960 and 1974 and 1990 and 2008 of **b)** dissolved oxygen (ΔDO) at 200 dbar, and **c)** ΔDO vertically-averaged over 200–700 dbar. In **b)**-**c)** increases are red and decreases blue, and areas with differences below the 95% confidence interval are shaded by black horizontal lines (after Stramma et al., 2010).

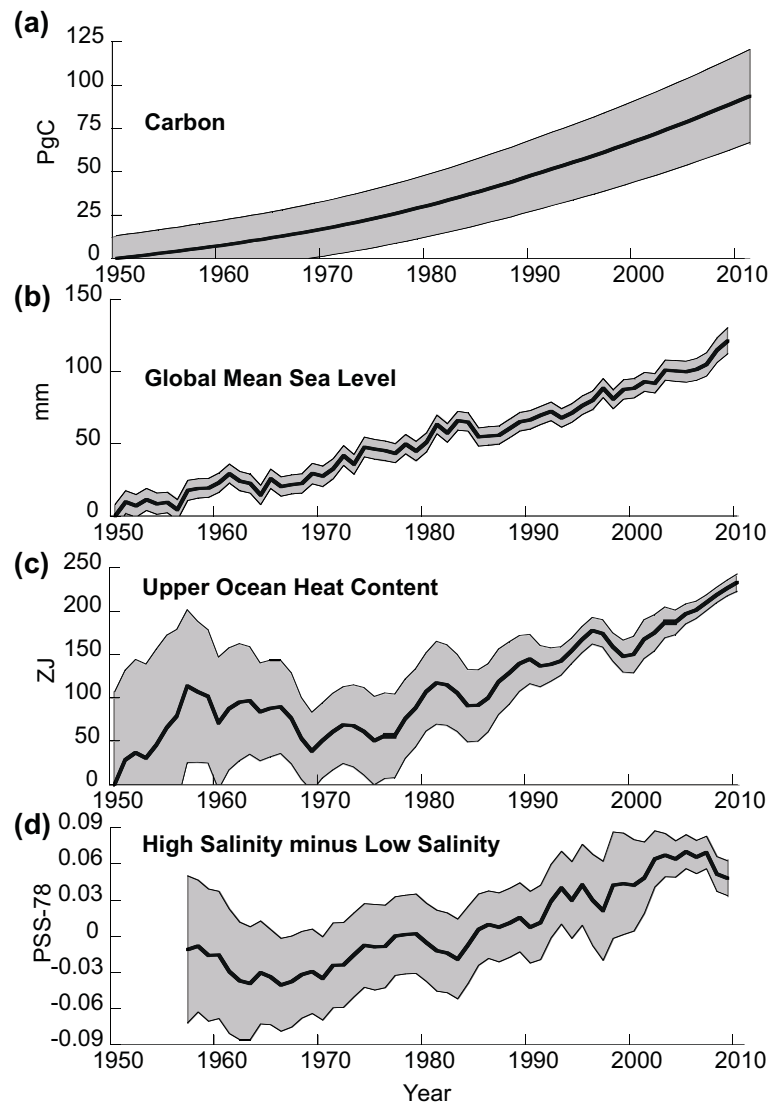

Figure 3.21: Time series of changes in large-scale ocean climate properties. From top to bottom: global ocean inventory of anthropogenic carbon dioxide, updated from Khatiwala et al. (2009); global mean sea level (GMSL), from Church and White (2011); global upper ocean heat content anomaly, updated from Domingues et al. (2008); the difference between salinity averaged over regions where the sea surface salinity is greater than the global mean sea surface salinity (“High Salinity”) and salinity averaged over regions values below the global mean (“Low Salinity”), from Boyer et al. (2009).

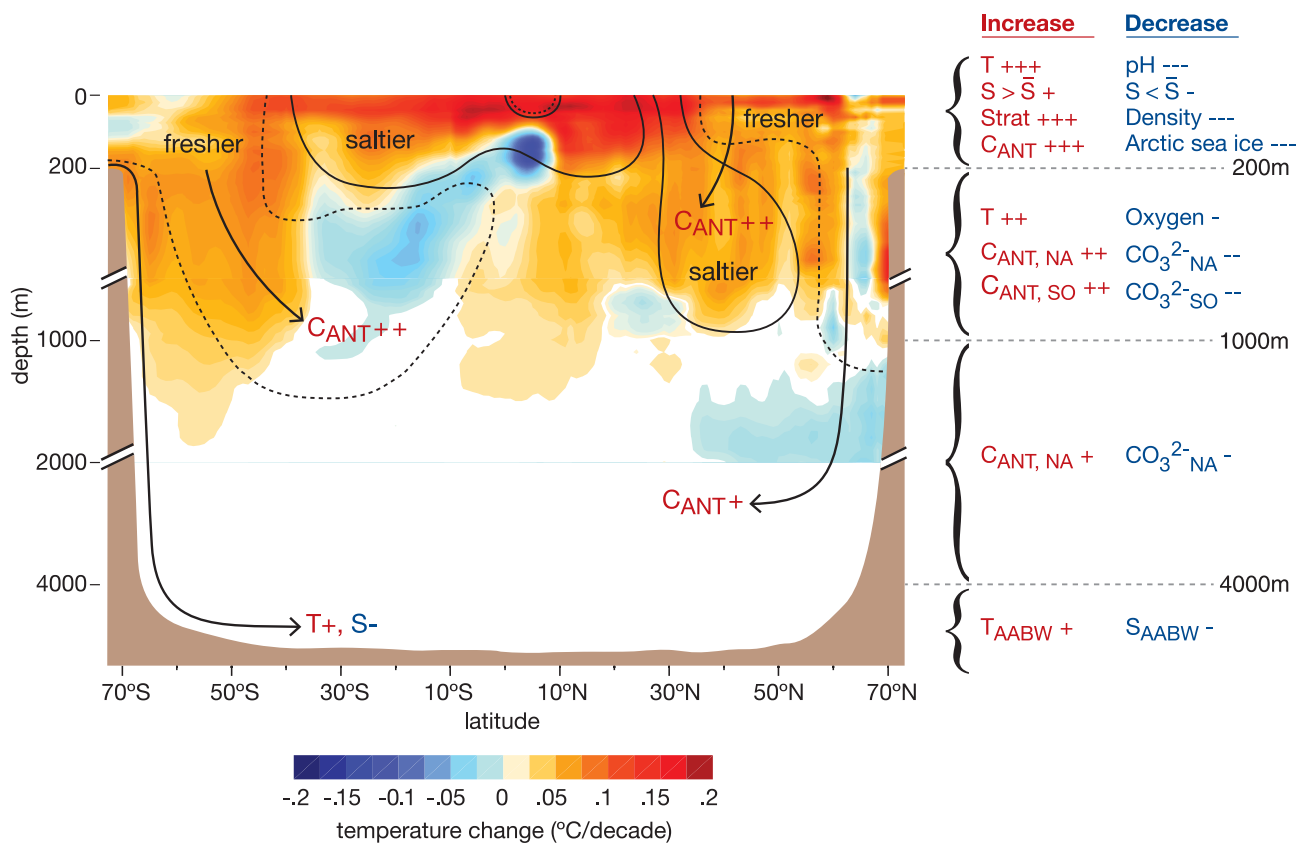

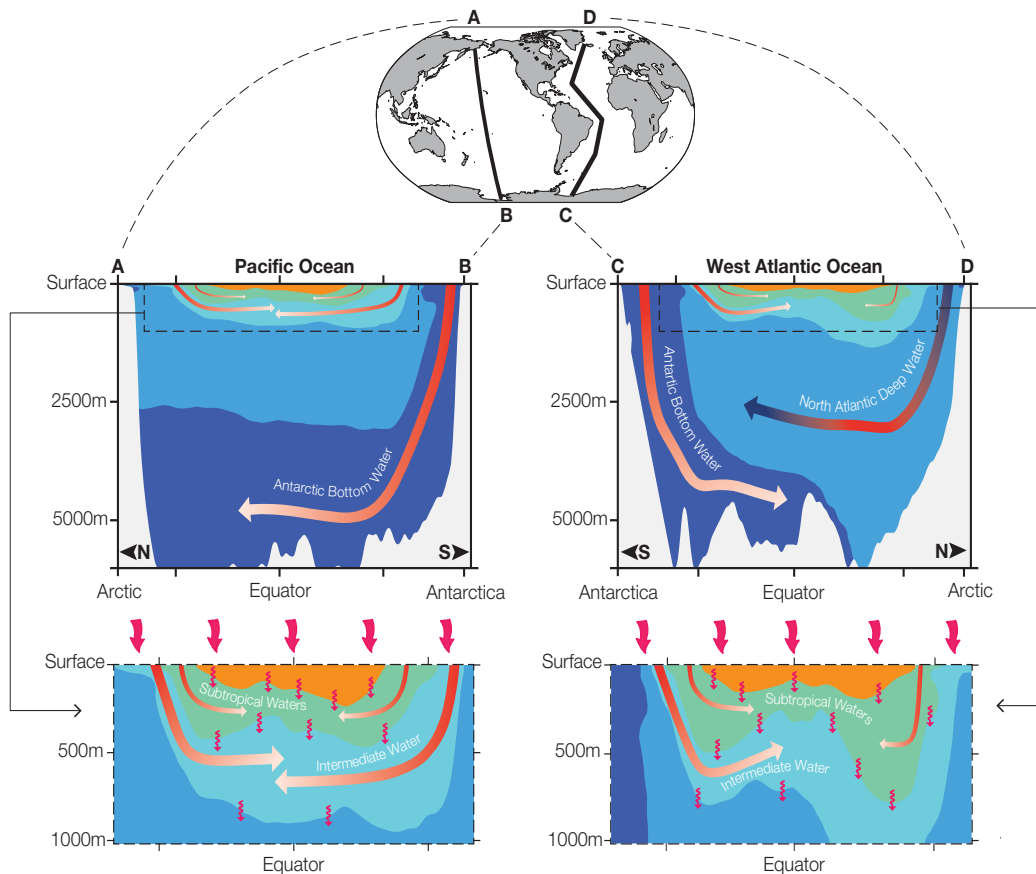

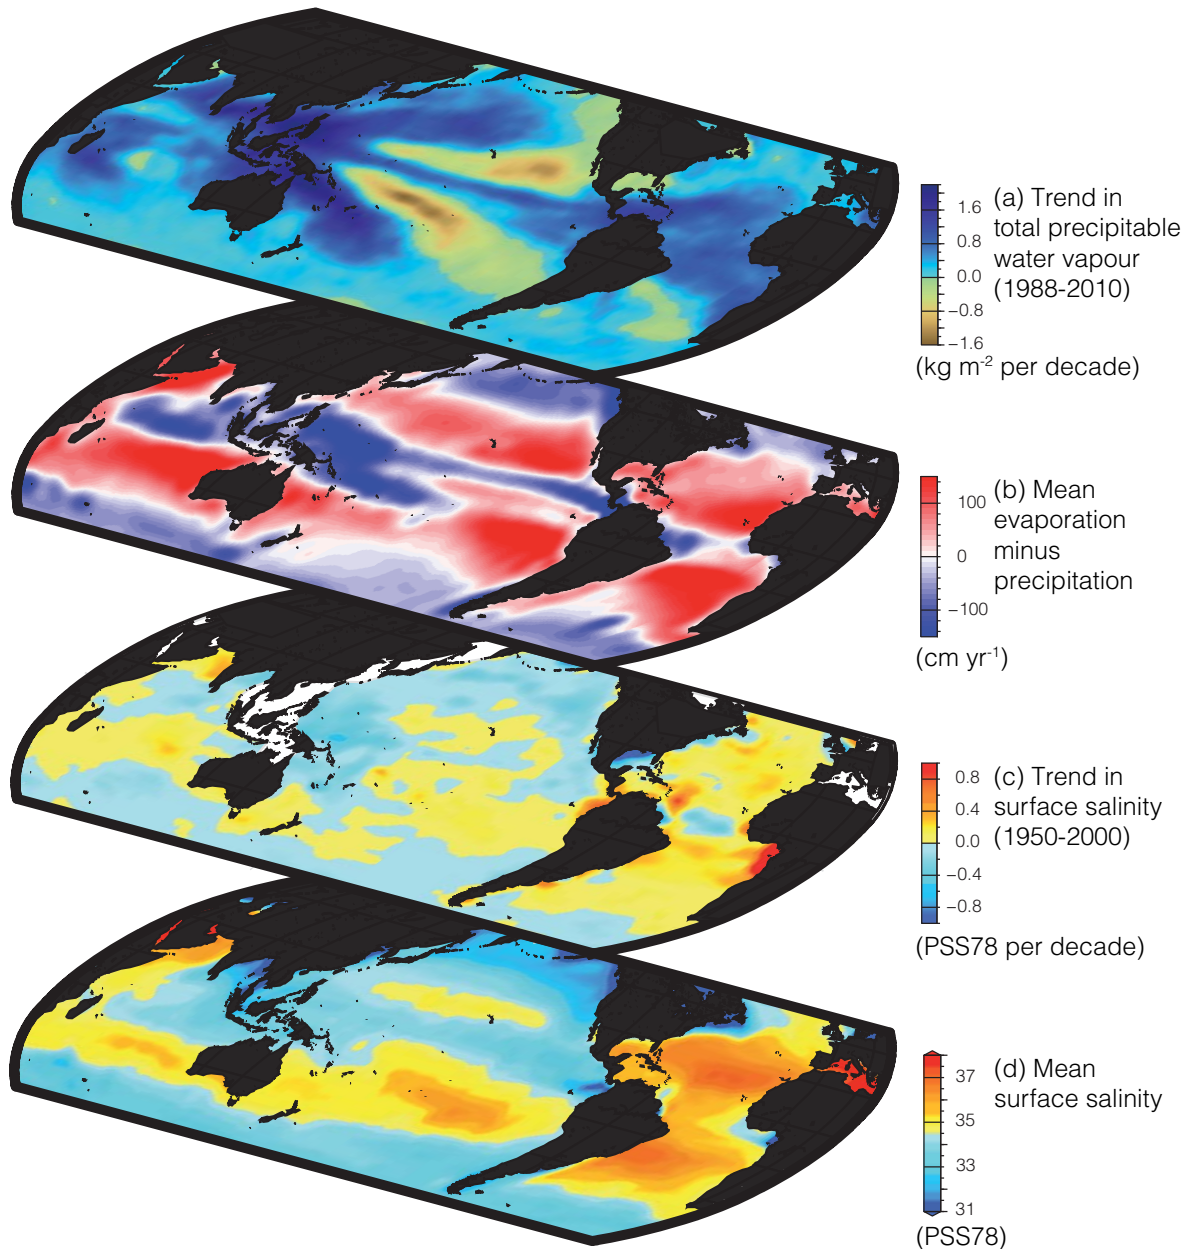

Figure 3.22: Summary of observed changes in zonal averages of global ocean properties. Temperature trends (°C per decade) are indicated in color (red = warming, blue = cooling); salinity trends are indicated by contour lines (dashed = fresher; solid = saltier) for the upper 2000 m of the water column (50-year trends from data set of Durack and Wijffels (2010); trends significant at >90% confidence are shown). Arrows indicate primary ventilation pathways. Changes in other physical and chemical properties are summarised to the right of the figure, for each depth range (broken axes symbols delimit changes in vertical scale). Increases are shown in red, followed by a plus sign; decreases are shown in blue, followed by a minus sign; the number of + and - signs indicates the level of confidence associated with the observation of change (+++, *high confidence*; ++, *medium confidence*; +, *low confidence*). T = temperature, S = salinity, Strat = stratification, C_{ant} = anthropogenic carbon, CO₃²⁻ = carbonate ion, NA = North Atlantic, SO = Southern Ocean, AABW = Antarctic Bottom Water. S > \bar{S} refers to the salinity averaged over regions where the sea surface salinity is greater than the global mean sea surface salinity; S < \bar{S} refers to the average over regions with values below the global mean.

FAQ 3.1, Figure 1: Ocean heat uptake pathways. The ocean is stratified, with the coldest, densest water in the deep ocean (upper panels: use map at top for orientation). Cold Antarctic Bottom Water (dark blue) sinks around Antarctica then spreads northward along the ocean floor into the central Pacific (upper left panel: red arrows fading to white indicate stronger warming of the bottom water most recently in contact with the ocean surface) and western Atlantic oceans (upper right panel), as well as the Indian Ocean (not shown). Less cold, hence lighter, North Atlantic Deep Water (lighter blue) sinks in the northern North Atlantic Ocean (upper right panel: red and blue arrow in the deep water indicates decadal warming and cooling), then spreads south above the Antarctic Bottom Water. Similarly, in the upper ocean (lower left panel shows Pacific Ocean detail, lower right panel the Atlantic), cool Intermediate Waters (cyan) sink in sub-polar regions (red arrows fading to white indicating warming with time), before spreading toward the equator under warmer Subtropical Waters (green), which in turn sink (red arrows fading to white indicate stronger warming of the intermediate and subtropical waters most recently in contact with the surface) and spread toward the equator under tropical waters, the warmest and lightest (orange) in all three oceans. Excess heat or cold entering at the ocean surface (top curvy red arrows) also mixes slowly downward (sub-surface squiggly red arrows).

FAQ 3.2, Figure 1: A smoothed time series of atmospheric CO₂ mole fraction (in ppm) at the atmospheric Mauna Loa Observatory (top red line), surface ocean partial pressure of CO₂ (pCO₂; middle blue line), and surface ocean pH (bottom green line) at Station ALOHA in the subtropical North Pacific north of Hawaii for the period from 1990–2011 (after Doney et al., 2009; data from Dore et al., 2009). The results indicate that the surface ocean pCO₂ trend is generally consistent with the atmospheric increase but is more variable due to large-scale interannual variability of oceanic processes.

FAQ 3.3, Figure 1: Changes in sea surface salinity are related to the atmospheric patterns of Evaporation minus Precipitation (E-P) and trends in total precipitable water: a) Linear trend (1988–2010) in total precipitable water (water vapor integrated from Earth’s surface up through the entire atmosphere) (kg m^{-2} per decade) from satellite observations (Special Sensor Microwave Imager) (after Wentz et al., 2007) (blues wetter; yellows drier). b) The 1979–2005 climatological mean net E-P (cm yr^{-1}) from meteorological reanalysis (National Centers for Environmental Prediction/National Center for Atmospheric Research; Kalnay et al., 1996) (reds: net evaporation; blues: net precipitation). c) Trend (1950–2000) in surface salinity (PSS78 per 50years) (after Durack and Wijffels, 2010) (blues freshening; yellows-reds saltier). d) The climatological-mean surface salinity (PSS78) (blues <35; yellows-reds >35).

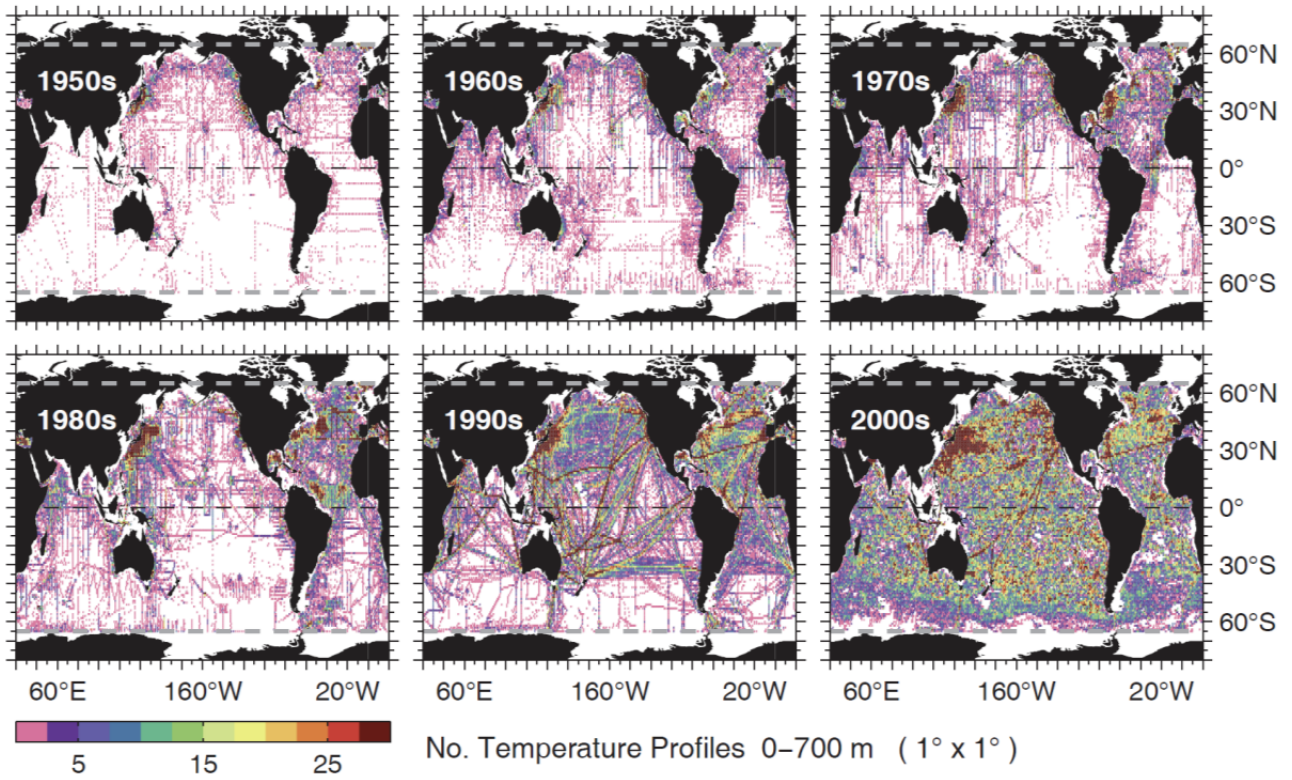

Figure 3.A.1: Number of temperature profiles extending to 700 m depth in each 1° × 1° square, by decade, between 65°N and 65°S.

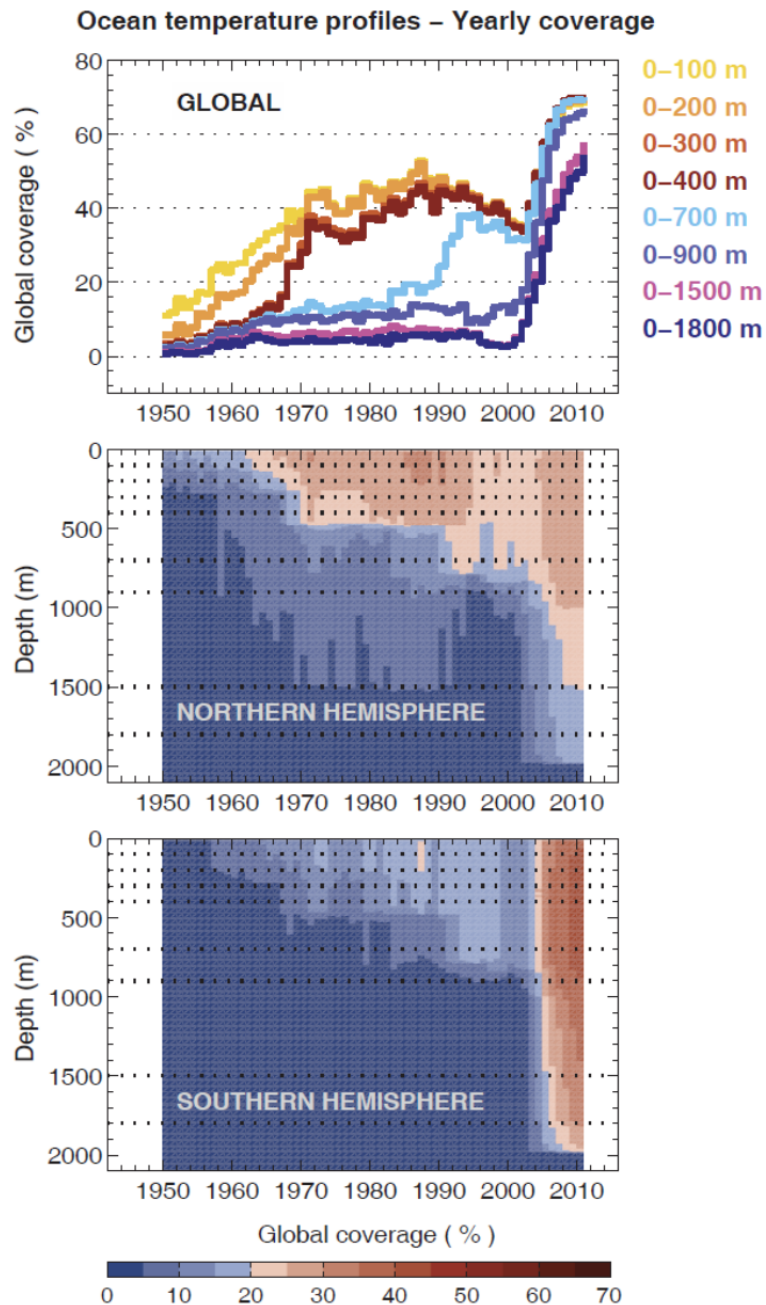

Figure 3.A.2: (top) Percentage of global coverage of ocean temperature profiles as a function of depth in one degree latitude by one degree longitude by one-year bins (top panel) shown versus time. Different colors indicate profiles to different depths (middle panel). Percentage of global coverage as a function of depth and time, for the northern hemisphere. (bottom panel) As above, but for the southern hemisphere.

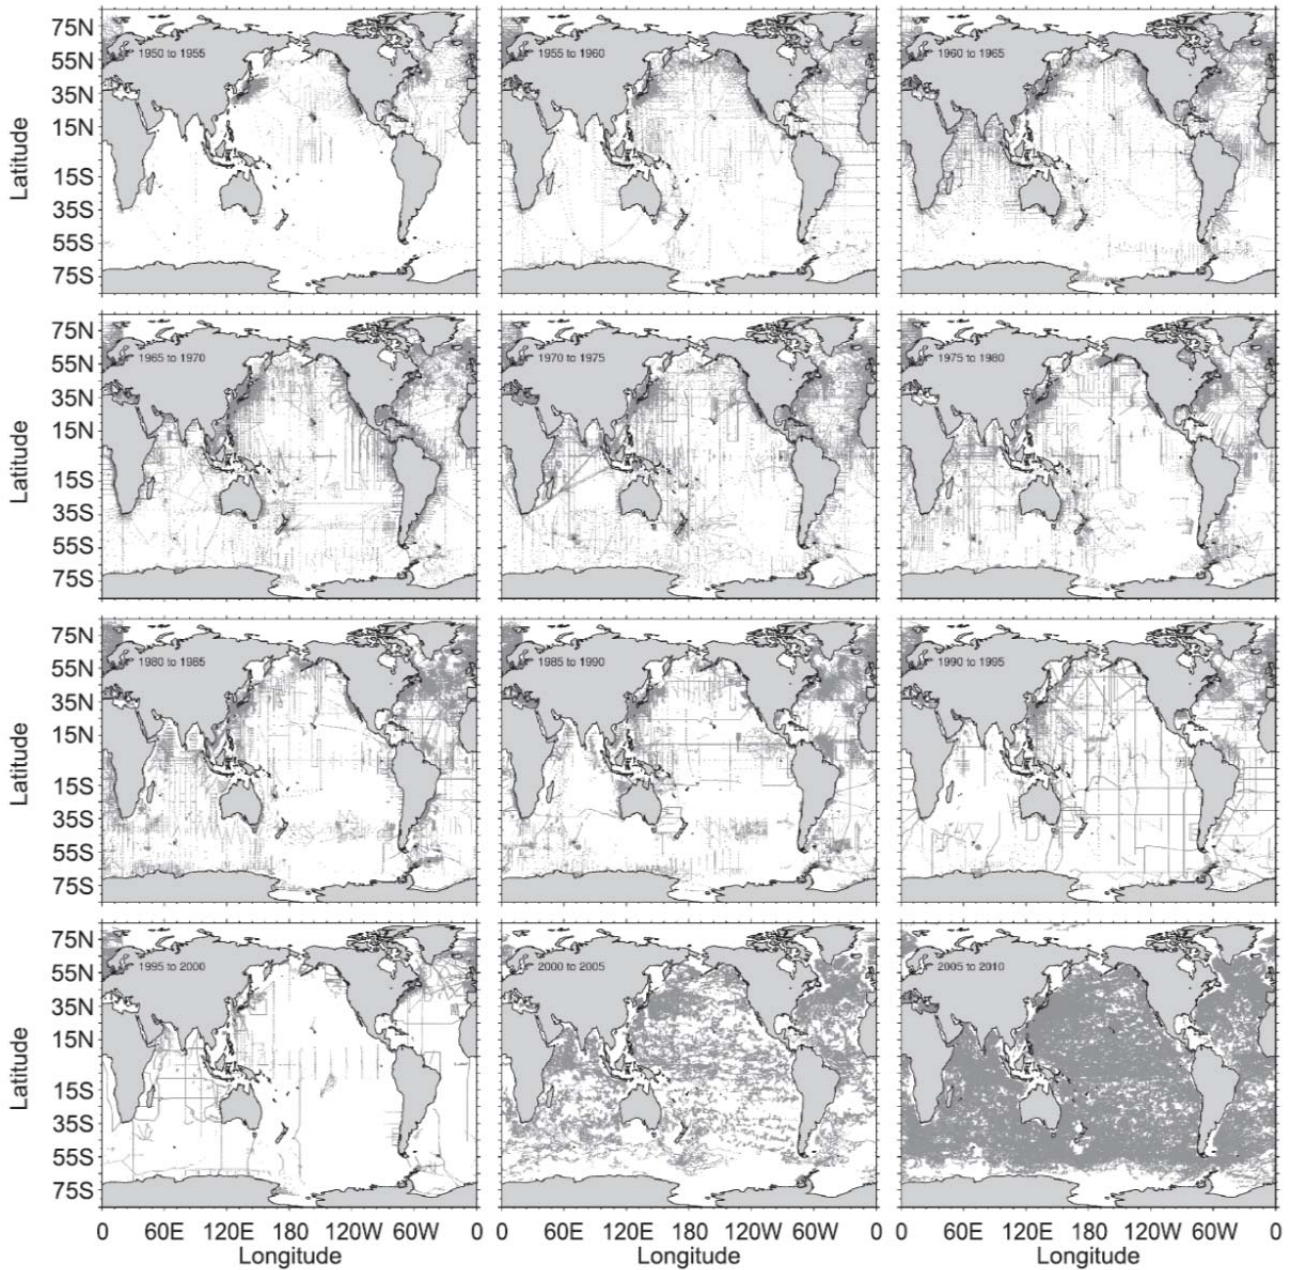

Figure 3.A.3: Hydrographic profile data used in the Durack and Wijffels (2010) study. Station locations for 5-year temporal bins from 1950–1955 (top left) to 2005–2010 (bottom right).

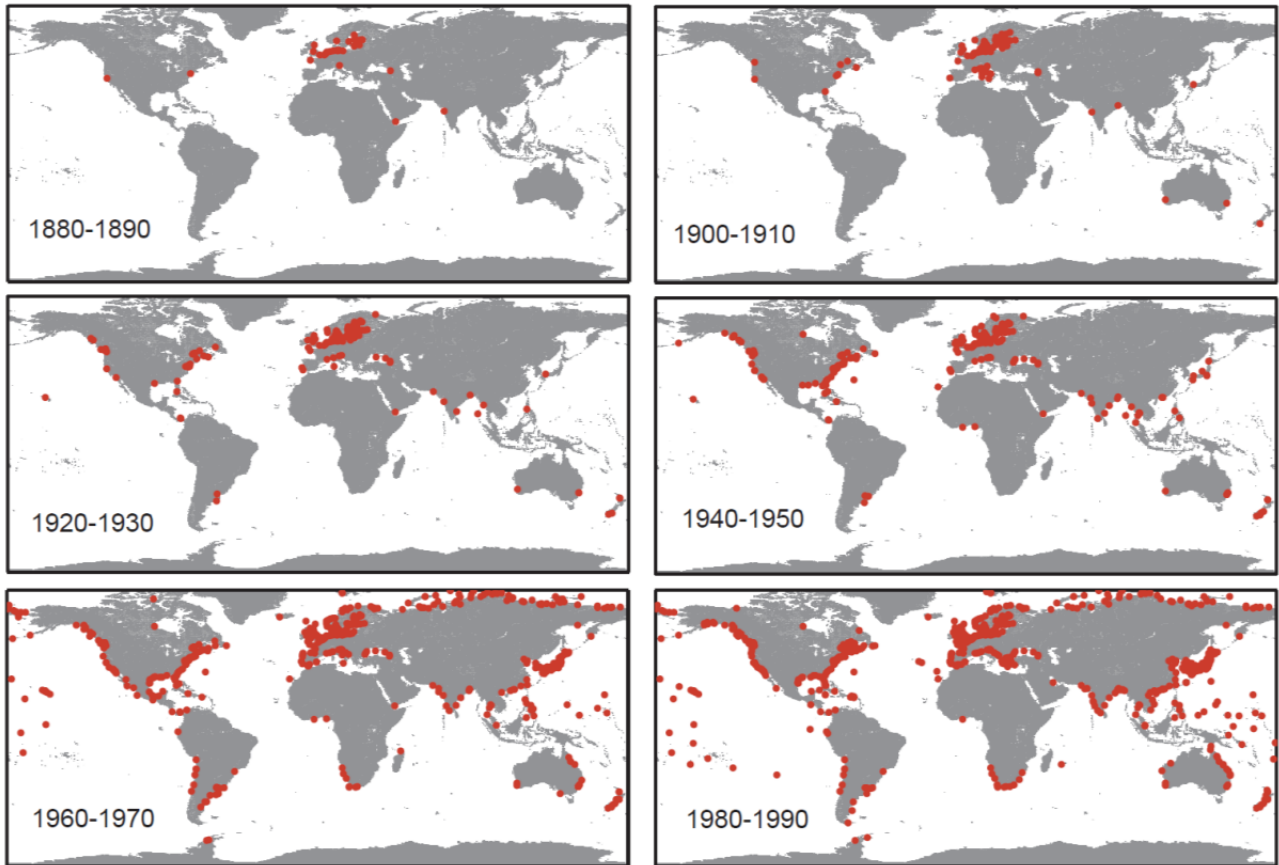

Figure 3.A.4: Location of tide gauges (red dots) that had at least one year of observations within the decade indicated.

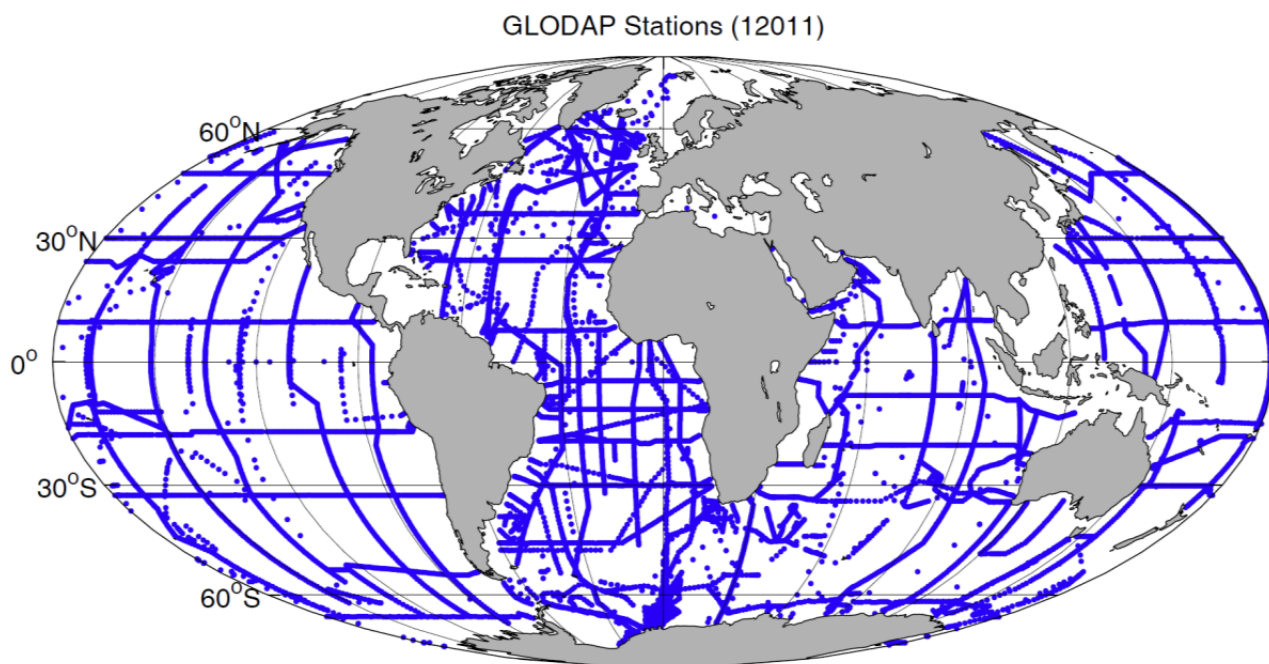

Figure 3.A.5: Location of profiles used to construct the Global Ocean Data Analysis Project (GLODAP) ocean carbon climatology.

Figure 3.A.6: Distribution of oxygen measurements at 300 dbar for the decades 1950 to 1960 (upper left) to 2000 to 2010 (lower right frame). (From Stramma et al., 2012). [Note that additional oxygen data have become available for the 2000–2010 period since that study was completed.]

Figures 75

Executive Summary

The cryosphere, comprising snow, river and lake ice, sea ice, glaciers, ice shelves and ice sheets, and frozen ground, plays a major role in the Earth's climate system through its impact on the surface energy budget, the water cycle, primary productivity, surface gas exchange and sea level. The cryosphere is thus a fundamental control on the physical, biological and social environment over a large part of the Earth's surface. Given that all its components are inherently sensitive to temperature change over a wide range of timescales, the cryosphere is a natural integrator of climate variability and provides some of the most visible signatures of climate change.

Since the AR4, observational technology has improved and key time-series of measurements have been lengthened, such that our identification and measurement of changes and trends in all components of the cryosphere has been substantially improved, and our understanding of the specific processes governing their responses has been refined. Since the AR4, observations show that there has been a continued net loss of ice from the cryosphere, although there are significant differences in the rate of loss between cryospheric components and regions. The major changes occurring to the cryosphere are as follows.

Sea Ice

Continuing the trends reported in AR4, the annual Arctic sea ice extent decreased over the period 1979–2012: the rate of this decrease was *very likely*¹ between 3.5 and 4.1% per decade. The average decrease in decadal extent of Arctic sea ice has been most rapid in summer and autumn (*high confidence*²), but the extent has decreased in every season, and in every successive decade since 1979 (*high confidence*). [4.2.2, Figure 4.2]

The extent of Arctic perennial and multiyear sea ice decreased between 1979 and 2012 (*very high confidence*). The perennial sea ice extent (sea ice area at summer minimum) decreased between 1979 and 2012 at $11.5 \pm 2.1\%$ per decade (*very likely*) and the multiyear ice decreased at a rate of $13.5 \pm 2.5\%$ per decade (*very likely*). [4.2.2, Figures 4.4, 4.6]

The average winter sea ice thickness within the Arctic Basin decreased between 1980 and 2008 (*high confidence*). The average decrease was *likely* between 1.3 and 2.3 m. *High confidence* in this assessment is based on observations from multiple sources: submarine, EM probes, and satellite altimetry, and is consistent with the decline in multiyear and perennial ice extent [4.2.2, Figure 4.5, Figure 4.6] Satellite measurements made in the period 2010–2012 show a decrease in sea ice volume compared to those made over the period 2003–2008 (*medium confidence*). There is *high confidence* that in the Arctic, where the sea ice thickness has decreased, the sea ice drift speed has increased. [4.2.2, Figure 4.6]

It is likely that the annual period of surface melt on Arctic perennial sea ice lengthened by 5.7 ± 0.9 days per decade over the period 1979–2012. Over this period, in the region between the East Siberian Sea and the western Beaufort Sea, the duration of ice-free conditions increased by nearly 2-months. [4.2.2, Figure 4.6]

It is *very likely* that the annual Antarctic sea ice extent increased at a rate of between 1.2 and 1.8% per decade between 1979 and 2012. There was a greater increase in sea ice area, due to a decrease in the percentage of open water within the ice pack. There is *high confidence* that there are strong regional

¹ In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

² In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

differences in this annual rate, with some regions increasing in extent/area and some decreasing [4.2.3, Figure 4.7]

Glaciers

Since AR4, almost all glaciers world-wide have continued to shrink as revealed by the time series of measured changes in glacier length, area, volume and mass (*very high confidence*). Measurements of glacier change have increased substantially in number since AR4. Most of the new datasets, along with a globally complete glacier inventory, have been derived from satellite remote sensing. [4.3.1, 4.3.3, Figures 4.9, 4.10, 4.11]

During the last decade, most ice was lost from glaciers in Alaska, the Canadian Arctic, the periphery of the Greenland ice sheet, the Southern Andes and the Asian Mountains (*very high confidence*). Together these regions account for more than 80% of the total ice loss. [4.3.3, Figure 4.11, Table 4.4]

Total mass loss from all glaciers in the world, excluding those on the periphery of the ice sheets, was *very likely* 226 ± 135 Gt yr⁻¹ (sea-level equivalent, 0.62 ± 0.37 mm yr⁻¹) in the period 1971–2009, 275 ± 135 Gt yr⁻¹ (0.76 ± 0.37 mm yr⁻¹) in the period 1993–2009, and 301 ± 135 Gt yr⁻¹ (0.83 ± 0.37 mm yr⁻¹) between 2005 and 2009. [4.3.3, Figure 4.12 and Table 4.5]

Current glacier extents are out of balance with current climatic conditions, indicating that glaciers will continue to shrink in the future even without further temperature increase (*high confidence*). [4.3.3]

Ice Sheets

The Greenland Ice Sheet has lost ice during the last two decades (*very high confidence*). Combinations of satellite and airborne remote sensing together with field data indicate with *high confidence* that the ice loss has occurred in several sectors and that large rates of mass loss have spread to wider regions than reported in AR4. [4.4.2, 4.4.3, Figures 4.13, 4.15, 4.17]

The rate of ice loss from the Greenland Ice Sheet has accelerated since 1992: the average rate has *very likely* increased from 34 [–6 to 74] Gt yr⁻¹ over the period 1992–2001 (sea-level equivalent, 0.09 [–0.02 to 0.20] mm yr⁻¹), to 215 [157 to 274] Gt yr⁻¹ over the period 2002–2011 (0.59 [0.43 to 0.76] mm yr⁻¹). [4.4.3, Figures 4.15, 4.17]

Ice loss from Greenland is partitioned in approximately similar amounts between surface melt and outlet glacier discharge (*medium confidence*), and that both components have increased (*high confidence*). The area subject to summer melt has increased over the last two decades (*high confidence*). [4.4.2]

The Antarctic Ice Sheet has been losing ice during the last two decades (*high confidence*). There is *very high confidence* that these losses are mainly from the northern Antarctic Peninsula and the Amundsen Sea sector of West Antarctica, and *high confidence* that they result from the acceleration of outlet glaciers. [4.4.2, 4.4.3, Figures 4.14, 4.16, 4.17]

The average rate of ice loss from Antarctica *likely* increased from 30 [–37 to 97] Gt yr⁻¹ (sea level equivalent, 0.08 [–0.10 to 0.27] mm yr⁻¹) over the period 1992–2001, to 147 [72 to 221] Gt yr⁻¹ over the period 2002–2011 (0.40 [0.20 to 0.61] mm yr⁻¹). [4.4.3, Figures 4.16, 4.17]

In parts of Antarctica, floating ice shelves are undergoing substantial changes (*high confidence*). There is *medium confidence* that ice shelves are thinning in the Amundsen Sea region of West Antarctica, and *low confidence* that this is due to high ocean heat flux. There is *high confidence* that ice shelves round the Antarctic Peninsula continue a long-term trend of retreat and partial collapse that began decades ago. [4.4.2, 4.4.5]

Snow Cover

Snow cover extent has decreased in the Northern Hemisphere, especially in spring (*very high confidence*). Satellite records indicate that over the period 1967–2012, annual mean snow cover extent decreased with statistical significance; the largest change, –53% [*very likely*, –40% to –66%], occurred in June. No months had statistically significant increases. Over the longer period, 1922–2012, data are only available for March and April, but these show a 7% [*very likely*, 4.5% to 9.5%] decline and a strong negative [–0.76] correlation with March–April 40°N–60°N land temperature. [4.5.2, 4.5.3]

Station observations of snow, nearly all of which are in the Northern Hemisphere, generally indicate decreases in spring, especially at warmer locations (*medium confidence*). Results depend on station elevation, period of record, and variable measured (e.g., snow depth or duration of snow season), but in almost every study surveyed, a majority of stations showed decreasing trends, and stations at lower elevation or higher average temperature were the most liable to show decreases. In the Southern Hemisphere, evidence is too limited to conclude whether changes have occurred. [4.5.2, 4.5.3, Figures 4.19, 4.20, 4.21]

Freshwater Ice

The limited evidence available for freshwater (lake and river) ice indicates that ice duration is decreasing and average seasonal ice cover shrinking (*low confidence*). For 75 Northern Hemisphere lakes, for which trends were available for 150-, 100-, and 30-year periods ending in 2005, the most rapid changes were in the most recent period (*medium confidence*), with freeze-up occurring later (1.6 days per decade) and breakup earlier (1.9 days per decade). In the North American Great Lakes, the average duration of ice cover declined 71% over the period 1973–2010. [4.6]

Frozen Ground

Permafrost temperatures have increased in most regions since the early 1980s (*high confidence*) although the rate of increase has varied regionally. The temperature increase for colder permafrost was generally greater than for warmer permafrost (*high confidence*). [4.7.2, Table 4.8, Figure 4.24]

Significant permafrost degradation has occurred in the Russian European North (*medium confidence*). There is *medium confidence*, that in this area, over the period 1975–2005, warm permafrost up to 15 m thick completely thawed, the southern limit of discontinuous permafrost moved north by up to 80 km, and the boundary of continuous permafrost moved north by up to 50 km. [4.7.2]

In situ measurements and satellite data show that surface subsidence associated with degradation of ice-rich permafrost, occurred at many locations over the past two to three decades (*medium confidence*). [4.7.4]

In many regions, the depth and extent of seasonally frozen ground has changed in recent decades (*high confidence*). In these areas, active layer thicknesses increased since the 1990s (*medium confidence*), although the magnitude of the increase varied from a few centimetres to tens of centimetres. In other areas, especially in northern North America, there were large inter-annual variations but few significant trends (*high confidence*). The thickness of the seasonally frozen ground in some non-permafrost parts of the Eurasian continent *likely* decreased, in places by more than 30 cm from 1930 to 2000 (*high confidence*) [4.7.4]

4.1 Introduction

The cryosphere is the collective term for the components of the Earth system that contain a substantial fraction of water in the frozen state (Table 4.1). The cryosphere comprises several components: snow, river and lake ice; sea ice; ice sheets, glaciers and ice caps; and frozen ground which exist, both on land and beneath the oceans (see Glossary, Figure 4.1). The lifespan of each component is very different. River and lake ice, for example, are transient features that generally do not survive from winter to summer; sea ice advances and retreats with the seasons but especially in the Arctic can survive to become multi-year ice, lasting several years. The East Antarctic ice sheet, on the other hand, is believed to have become relatively stable around 14 million years ago (Barrett, 2013). Nevertheless, all components of the cryosphere are inherently sensitive to changes in air temperature and precipitation, and hence to a changing climate (see Chapter 2).

[INSERT FIGURE 4.1 HERE]

Figure 4.1: The cryosphere in the Northern and Southern Hemispheres in polar projection. The map of the Northern Hemisphere shows the sea ice cover during minimum summer extent (13th September 2012). The yellow line is the average location of the ice edge (15% ice concentration) for the yearly minima from 1979 to 2012. Areas of continuous permafrost (see Glossary) are shown in dark pink, discontinuous permafrost in light pink. The green line along the southern border of the map shows the maximum snow extent while the black line across North America, Europe and Asia shows the contour for the 50% snow extent. The Greenland ice sheet (blue/grey) and locations of glaciers (small golden dots) are also shown. The map of the Southern Hemisphere shows approximately the maximum sea ice cover during an austral winter (13th September 2012). The yellow line shows the average ice edge (15% ice concentration) during maximum extent of the sea ice cover from 1979 to 2012. Some of the elements (e.g., some glaciers and snow) located at low latitudes are not visible in this projection (see Figure 4.8). The source of the data for sea ice, permafrost, snow and ice sheet are datasets held at the National Snow and Ice Data Center (NSIDC), University of Colorado, on behalf of the North American Atlas, Instituto Nacional de Estadística, Geografía e Informática (Mexico), Natural Resources Canada, U.S. Geological Survey, Government of Canada, Canada Centre for Remote Sensing and The Atlas of Canada. Glacier locations were derived from the multiple datasets compiled in the Randolph Glacier Inventory (Arendt et al., 2012).

Changes in the longer-lived components of the cryosphere (e.g., glaciers) are the result of an integrated response to climate, and the cryosphere is often referred to as a ‘natural thermometer’. But as our understanding of the complexity of this response has grown, it is increasingly clear that elements of the cryosphere should rather be considered as a ‘natural climate-meter’, responsive not only to temperature, but also to other climate variables (e.g., precipitation). However, it remains the case that the conspicuous and widespread nature of changes in the cryosphere (in particular; sea ice, glaciers and ice sheets) means these changes are frequently used emblems of the impact of changing climate. It is thus imperative that we understand the context of current change within the framework of past changes and natural variability.

The cryosphere is, however, not simply a passive indicator of climate change; changes in each component of the cryosphere have a significant and lasting impact on physical, biological and social systems. Ice sheets and glaciers exert a major control on global sea level (see Chapters 5 and 13), ice-loss from these systems may affect global ocean circulation and marine ecosystems, and the loss of glaciers near populated areas as well as changing seasonal snow cover may have direct impacts on water resources and tourism (see WGII Chapters 3 and 24). Similarly, reduced sea ice extent has altered, and in future may continue to alter, ocean circulation, ocean productivity and regional climate, and will have direct impacts on shipping and mineral and oil exploration (see WGII Chapter 28). Furthermore, decline in snow cover and sea ice will tend to amplify regional warming through snow and ice-albedo feedback effects (see Glossary, Chapter 9). In addition, changes in frozen ground (in particular, ice-rich permafrost) will damage some vulnerable Arctic infrastructure (see WGII, Chapter 28), and could substantially alter the carbon budget through the release of methane (see Chapter 6).

Since AR4, substantial progress has been made in most types of cryospheric observations. Satellite technologies now permit estimates of regional and temporal changes in the volume and mass of the ice sheets. The longer time-series now available enable more accurate assessments of trends and anomalies in sea ice cover and rapid identification of unusual events such as the dramatic decline of Arctic summer sea ice extent in 2007 and 2012. Similarly, Arctic sea ice thickness can now be estimated using satellite altimetry, allowing pan-Arctic measurements of changes in volume and mass. A globally complete glacier inventory

now includes nearly all glaciers (Arendt et al., 2012) (42% in AR4) and allows for much better estimates of the total ice volume and its past and future changes. Remote sensing measurements of regional glacier volume change are also now available widely and modelling of glacier mass change has improved considerably. Finally, fluctuations in the cryosphere in the distant and recent past have been mapped with increasing certainty, demonstrating the potential for rapid ice loss, compared to slow recovery, particularly when related to sea level rise.

This chapter describes the current state of the cryosphere and its individual components, with a focus on recent improvements in understanding of the observed variability, changes and trends. Projections of future cryospheric changes (e.g., Chapter 13) and potential drivers (Chapter 10) are discussed elsewhere. Earlier IPCC reports used cryospheric terms that have specific scientific meanings (see, Cogley et al., 2011), but have rather different meanings in everyday language. To avoid confusion, this chapter uses the term “glaciers” for what was previously termed, “glaciers and ice caps” (e.g., Lemke et al., 2007). For the two largest ice masses of continental size, those covering Greenland and Antarctica, we use the term “ice sheets”. For simplicity, we use units such as Gigatonnes (Gt, 10^9 tonnes, or 10^{12} kg). One Gt is approximately equal to one cubic kilometre of freshwater (1.1 km^3 of ice), and 362.5 Gt of ice removed from the land and immersed in the oceans will cause roughly 1 mm of global sea level rise (Cogley, 2012).

Table 4.1: Representative statistics for cryospheric components indicating their general significance.

Ice on Land	Percent of Global Land Surface ^j	Sea Level Equivalent ^k (metres)
Antarctic ice sheet ^a	8.3%	58.3
Greenland ice sheet ^b	1.2%	7.36
Glaciers ^c	0.5%	0.41
Terrestrial Permafrost ^d	9–12%	0.02–0.10 ^q
Seasonally frozen ground ^e	33%	Not applicable
Seasonal snow cover (seasonally variable) ^f	1.3% to 30.6%	0.001–0.01
Northern Hemisphere freshwater (lake and river) ice ^p	1.1%	Not applicable
Total^m	52.0% to 55.0%	~66.1
Ice in the Ocean	Percent of Global Ocean Area ^j	Volume ^l (10^3 km^3)
Antarctic ice shelves	0.45% ^g	~380
Antarctic sea ice, austral summer (spring) ⁿ	0.8% (5.2%)	3.4 (11.1)
Arctic sea ice, boreal autumn (winter/spring) ⁿ	1.7% (3.9%)	13.0 (16.5)
Sub-sea permafrost ^h	~0.8%	Not available
Total^o	5.3 to 7.3%	

Notes:

(a) Area of grounded ice sheet not including ice shelves is 12.295 Mkm^2 (Fretwell et al., 2013)

(b) Area of ice sheet and peripheral glaciers, 1.801 Mkm^2 (Kargel et al., 2012). SLE (Bamber et al., 2013).

(c) Calculated from glacier outlines (Arendt et al., 2012), includes glaciers around Greenland and Antarctica. For sources of SLE see Table 4.2

(d) Area of permafrost excluding permafrost beneath the ice sheets, $13.2\text{--}18.0 \text{ Mkm}^2$ (Gruber, 2012).

(e) Long-term average maximum of seasonally frozen ground is 48.1 Mkm^2 (Zhang et al., 2003); excludes Southern Hemisphere

(f) Northern Hemisphere only (Lemke et al., 2007)

(g) Area is 1.617 Mkm^2 (Griggs and Bamber, 2011).

(h) Few estimates of the area of sub-sea permafrost exist in the literature. The estimate shown, 2.8 Mkm^2 has significant uncertainty attached, was assembled from other publications by Gruber (2012).

(j) Assuming a global land area of 147.6 Mkm^2 , and ocean area of 362.5 Mkm^2

(k) See Glossary. Assuming an ice density of 917 kg m^{-3} , a seawater density of $1,028 \text{ kg m}^{-3}$, with seawater replacing ice currently below sea level

- (l) Antarctic austral autumn (spring) (Kurtz and Markus, 2012); and Arctic boreal autumn (winter) (Kwok et al., 2009). For the Arctic, volume includes only sea ice in the Arctic basin.
- (m) To allow for areas of permafrost and seasonally-frozen ground that are also covered by seasonal snow, total area excludes seasonal snow cover.
- (n) Maximum and minimum areas taken from this assessment, Sections 4.2.2 and 4.2.3
- (o) Summer and winter totals assessed separately.
- (p) Areas and volume of freshwater (lake and river ice) were derived from modelled estimates of maximum seasonal extent (Brooks et al., 2012).
- (q) Value indicates the full range of estimated excess water content of Northern Hemisphere permafrost (Zhang et al., 1999)

4.2 Sea Ice

4.2.1 Background

Sea ice (see Glossary) is an important component of the climate system. A sea ice cover on the ocean changes the surface albedo, insulates the ocean from heat loss, and provides a barrier to the exchange of momentum and gases such as water vapour and CO₂ between the ocean and atmosphere. Salt ejected by growing sea ice alters the density structure and modifies the circulation of the ocean. Regional climate changes affect the sea ice characteristics and those changes can feed back on the climate system, both regionally and globally. Sea ice is also a major component of polar ecosystems; plants and animals at all trophic levels find a habitat in, or are associated with, sea ice.

Most sea ice exists as pack ice, and wind and ocean currents drive the drift of individual pieces of ice (called floes). Divergence and shear in sea ice motion create areas of open water where, during colder months, new ice can quickly form and grow. On the other hand, convergent ice motion causes the ice cover to thicken by deformation. Two relatively thin floes colliding with each other can “raft”, stacking one on top of the other and thickening the ice. When thicker floes collide, thick ridges may be built from broken pieces, with a height above the surface (ridge sail) of 2 m or more, and a much greater thickness (~10 m) and width below the ocean surface (ridge keel).

Sea ice thickness also increases by basal freezing during winter months. But the thicker the ice becomes the more it insulates heat-loss from the ocean to the atmosphere and the slower the basal growth is. There is an equilibrium thickness for basal ice growth that is dependent on the surface energy balance and heat from the deep ocean below. Snow cover lying on the surface of sea ice provides additional insulation, and also alters the surface albedo and aerodynamic roughness. But also, and particularly in the Antarctic, a heavy snow load on thin sea ice can depress the ice surface and allow seawater to flood the snow. This saturated snow layer freezes quickly to form “snow ice” (see FAQ 4.2).

Because sea ice is formed from seawater it contains sea salt, mostly in small pockets of concentrated brine. The total salt content in newly formed sea ice is only 25–50% of that in the parent seawater, and the residual salt rejected as the sea ice forms alters ocean water density and stability. The salinity of the ice decreases as it ages, and particularly during the Arctic summer when melt water (including from melt ponds that form on the surface) drains through and flushes the ice. The salinity and porosity of sea ice affect its mechanical strength, its thermal properties and its electrical properties – the latter being very important for remote sensing.

Geographical constraints play a dominant but not an exclusive role in determining the quite different characteristics of sea ice in the Arctic and the Antarctic (see FAQ 4.2). This is one of the reasons why changes in sea ice extent and thickness are very different in the north and south. We also have much more information on Arctic sea ice thickness than we do on Antarctic sea ice thickness, and so discuss Arctic and Antarctic separately in this assessment.

4.2.2 Arctic Sea Ice

Regional sea ice observations, which span more than a century, have revealed significant inter-annual changes in sea ice coverage (Walsh and Chapman, 2001). Since the advent of satellite multichannel passive

microwave imaging systems in 1979, which now provide more than 34 years of continuous coverage, it has been possible to monitor the entire extent of sea ice with a temporal resolution less than a day. A number of procedures have been used to convert the observed microwave brightness temperature into sea ice concentration – the fractional area of the ocean covered by ice (Markus and Cavalieri, 2000; Comiso and Nishio, 2008) – and thence to derive sea ice extent and area. Sea ice extent is defined as the sum of ice covered areas with concentrations of at least 15%, while ice area is the product of the ice concentration and area of each data element within the ice extent. A brief description of the different techniques for deriving sea ice concentration is provided in the supplementary material. The trends in the sea ice concentration, ice extent and ice area, as inferred from data derived from the different techniques, are generally compatible. A comparison of derived ice extents from different sources are presented in the next section and in the supplementary material. Results presented in this assessment are based primarily on a single technique (Comiso and Nishio, 2008) but the use of data from other techniques would provide generally the same conclusions.

Arctic sea ice cover varies seasonally, with average ice extent varying between about 6×10^6 km² in the summer and about 15×10^6 km² in the winter (Comiso and Nishio, 2008 ; Cavalieri and Parkinson, 2012; Meier et al., 2012). The summer ice cover is confined to mainly the Arctic Ocean basin and the Canadian Arctic Archipelago, while winter sea ice reaches as far south as 44°N, into the peripheral seas. At the end of summer, the Arctic sea ice cover consists primarily of the previously thick, old and ridged ice types that survived the melt period. Interannual variability is largely determined by the extent of the ice cover in the peripheral seas in winter, and by the ice cover that survives the summer melt in the Arctic basin.

4.2.2.1 Total Arctic Sea Ice Extent and Concentration

Figure 4.2 (derived from passive microwave data) shows both the seasonality of the Arctic sea ice cover, and the large decadal changes that have occurred over the last 34 years. Typically, Arctic sea ice reaches its maximum seasonal extent in February or March while the minimum occurs in September at the end of summer-melt. Changes in decadal averages in Arctic ice extent are more pronounced in summer than in winter. The change in winter extent between 1979–1988 and 1989–1998 was negligible. Between 1989–1998 and 1999–2008, there was a decrease in winter extent of around 0.6×10^6 km². This can be contrasted to a decrease in ice extent at the end of the summer (September) of 0.5×10^6 km² between 1979–1988 and 1989–1998, followed by a further decrease of 1.2×10^6 km² between 1989–1998 and 1999–2008. Figure 4.2 also shows that the change in extent from 1979–1988 to 1989–1998 was statistically significant mainly in spring and summer while the change from 1989–1998 to 1999–2008 was statistically significant during winter and summer. The largest interannual changes occur during the end of summer when only the thick components of the winter ice cover survive the summer melt (Comiso et al., 2008; Comiso, 2012).

For comparison, the average extents during the 2009–2012 period are also presented: the extent during this period was considerably less than in earlier periods in all seasons, except spring. The summer minimum extent was at a record low in 2012 following an earlier record set in 2007 (Stroeve et al., 2007; Comiso et al., 2008). The minimum ice extent in 2012 was 3.44×10^6 km² while the low in 2007 was 4.22×10^6 km². For comparison, the record high value was 7.86×10^6 km² in 1980. The low extent in 2012 (which is 18.5% lower than in 2007) was probably caused in part by an unusually strong storm in the Central Arctic basin on 4–8 August 2012 (Parkinson and Comiso, 2013). The extents for 2007 and 2012 were almost the same from June until the storm period in 2012, after which the extent in 2012 started to trend considerably lower than in 2007. The error bars, which represent 1- σ of samples used to estimate each data point, are smallest in the first decade and get larger with subsequent decades indicating much higher interannual variability in recent years. The error bars are also comparable in summer and winter during the first decade but become progressively larger for summer compared to winter in subsequent decades. These results indicate that the largest interannual variability has occurred in the summer and in the recent decade.

Although relatively short as a climate record, the 34-year satellite record is long enough to allow determination of significant and consistent trends of the time series of monthly anomalies (i.e., difference between the monthly and the averages over the 34-year record) of ice extent, area and concentration. The trends in ice concentration for the winter, spring, summer and autumn for the period November 1978 to December 2012 are shown in Figure 4.2 (b, c, d and e). The seasonal trends for different regions, except the Bering Sea, are negative. Ice cover changes are relatively large in the eastern Arctic basin and most

peripheral seas in winter and spring, while changes are pronounced almost everywhere in the Arctic basin, except at $>82^{\circ}\text{N}$, in summer and autumn. In connection with a comprehensive observational research program during the International Polar Year 2007–2008, regional studies primarily on the Canadian side of the Arctic revealed very similar patterns of spatial and interannual variability of the sea ice cover (Derksen et al., 2012).

From the monthly anomaly data, the trend in sea ice extent in the Northern Hemisphere for the period from November 1978 to December 2012 is $-3.8 \pm 0.3\%$ per decade (*very likely*) (see FAQ 4.2). The error quoted is calculated from the standard deviation of the slope of the regression line. The baseline for the monthly anomalies is the average of all data for each month from November 1978 to December 2012. The trends for different regions vary greatly, ranging from $+7.3\%$ per decade in the Bering Sea to -13.8% per decade in the Gulf of St. Lawrence. This large spatial variability is associated with the complexity of the atmospheric and oceanic circulation system as manifested in the Arctic Oscillation (Thompson and Wallace, 1998). The trends also differ with season (Comiso and Nishio, 2008; Comiso et al., 2011). For the entire Northern Hemisphere, the trends in ice extent are -2.3 ± 0.5 , -1.8 ± 0.5 , -6.1 ± 0.8 , and $-7.0 \pm 1.5\%$ per decade (*very likely*) in winter, spring, summer and autumn, respectively. The corresponding trends in ice area are -2.8 ± 0.5 , -2.2 ± 0.5 , -7.2 ± 1.0 , and $-7.8 \pm 1.3\%$ per decade (*very likely*). Similar results were obtained by (Cavalieri and Parkinson, 2012) but cannot be compared directly since their data are for the period from 1979 to 2010 (see Supplementary Material). The trends for ice extent and ice area are comparable except in the summer and autumn when the trend in ice area is significantly more than that in ice extent. This is due in part to increasing open water areas within the pack that may be caused by more frequent storms and more divergence in the summer (Simmonds et al., 2008). The trends are larger in the summer and autumn mainly because of the rapid decline of the multiyear ice cover (Comiso, 2012) as discussed below. The trends in km^2/year were estimated as in Comiso and Nishio (2008) and Comiso (2012) but the percentage trends presented in this chapter were calculated differently. Here the percentage is calculated as a difference from the first data point on the trend line whereas the earlier estimations used the difference from the mean value. The new percentage trends are only slightly different from the previous ones and the conclusions about changes are the same.

[INSERT FIGURE 4.2 HERE]

Figure 4.2: (a) Plots of decadal averages of daily sea ice extent in the Arctic (1979 to 1988 in red, 1989 to 1998 in blue, 1999 to 2008 in gold) and a four-year average daily ice extent from 2009 to 2012 in black. Maps ice concentration trends (1979–2012) in (b) winter, (c) spring, (d) summer and (e) autumn (updated from Comiso, 2010).

4.2.2.2 Longer Records of Arctic Ice Extent

For climate analysis, the variability of the sea ice cover prior to the commencement of the satellite era in 1979 is also of interest. There are a number of pre-satellite records, some based on regional observations taken from ships or aerial reconnaissance (e.g., Walsh and Chapman, 2001; Polyakov et al., 2003) while others were based on terrestrial proxies (e.g., Fauria et al., 2010; Kinnard et al., 2011). The records constructed by Kinnard et al (2011) and Fauria et al. (2010) suggest that the decline of sea ice over the last few decades has been unprecedented over the past 1450 years. In a study of the marginal seas near the Russian coastline using ice extent data from 1900 to 2000, Polyakov et al. (2003) found a low frequency multidecadal oscillation near the Kara Sea that shifted to a dominant decadal oscillation in the Chukchi Sea.

A more comprehensive basin-wide record, compiled by Walsh and Chapman (2001), showed very little interannual variability until the last three to four decades. For the period 1901 to 1998, their results show a summer mode that includes an anomaly of the same sign over nearly the entire Arctic and which captures the sea-ice trend from recent satellite data. Figure 4.3 shows an updated record of the Walsh and Chapman data set with longer time coverage (1870 to 1978) that is more robust since it includes additional historical sea ice observations (e.g., from Danish meteorological stations). A comparison of this updated data set with that originally reported by Walsh and Chapman (2001) shows similar interannual variability that is dominated by a nearly constant extent of the winter (JFM) and autumn (OND) ice cover from 1870 to the 1950s. The absence of interannual variability during that period is due to the use of climatology to fill gaps, potentially masking the natural signal. Sea ice data from 1900 to 2011 as compiled by Met Office Hadley Centre are also plotted for comparison. In this data set, the 1979 to 2011 values were derived from various sources, including satellite data, as described by Rayner et al. (2003). Since the 1950s, more in situ data are available

and have been homogenized with the satellite record (Meier et al., 2012). These data show a consistent decline in the sea ice cover that is relatively moderate during the winter but more dramatic during the summer months. Satellite data from other sources are also plotted in Figure 4.3, including SBA (SMMR and SSM/I data using the Bootstrap Algorithm) as described by Comiso and Nishio (2008) and NT1 (NASA Team Algorithm using SMMR and SSM/I data) as described by Cavalieri et al. (1984) (see Supplementary Material). Data from AMSR-E using the Bootstrap Algorithm (ABA) and the revised team algorithm (NT2) are also presented. The error bars represent one standard deviation of the interannual variability during the satellite period. Because of the use of climatology to fill data gaps from 1870 to 1953, the error bars in the Walsh and Chapman data were set to twice that of the satellite period and 1.5 times higher for 1954 to 1978. The apparent reduction of the sea ice extent from 1978 to 1979 is in part due to the change from surface observations to satellite data. Generally, the temporal distributions from the various sources are consistent with some exceptions that may be attributed to possible errors in the data (e.g., Screen, 2011, Supplementary Material). Taking this into account, the various sources provide similar basic information and conclusions about the changing extent and variability of the Arctic sea ice cover.

[INSERT FIGURE 4.3 HERE]

Figure 4.3: Ice extent in the Arctic from 1870 to 2011. (a) Annual ice extent, and (b) seasonal ice extent using averages of mid-month values derived from in situ and other sources including observations from the Danish meteorological stations from 1870 to 1978 (updated from, Walsh and Chapman, 2001). Ice extent from a joint Hadley and NOAA project (called HADISST1_Ice) from 1900 to 2011 is also shown. The yearly and seasonal averages for the period from 1979 to 2011 are shown as derived from SMMR and SSM/I passive microwave data (called SBA and NT1) using procedures in Comiso and Nishio (2008), and Cavalieri et al. (1984), respectively; and from AMSR2 procedures (called ABA and NT2) from Comiso and Nishio (2008) and Markus and Cavalieri (2000). In (b), data from the different seasons are shown in different colours to illustrate variation between seasons, with SBA data from the procedure in Comiso and Nishio (2008) shown in black.

4.2.2.3 Multiyear/Seasonal Ice Coverage

The winter extent and area of the perennial and multiyear ice cover in the Central Arctic (i.e., excluding Greenland Sea multiyear ice) for 1979–2010 are shown in Figure 4.4. Perennial ice is that which survives the summer, and the ice extent at summer minimum has been used as a measure of its coverage (Comiso, 2002). Multiyear ice (as defined by World Meteorological Organization) is ice that has survived at least two summers. Generally, multiyear ice is less saline and has a distinct microwave signature that differs from the seasonal ice, and thus can be discriminated and monitored with satellite microwave radiometers (Johannessen et al., 1999; Zwally and Gloersen, 2008; Comiso, 2012).

Figure 4.4 shows similar interannual variability and large trends for both perennial and multiyear ice for the period 1979 to 2012. The extent of the perennial ice cover, which was about 7.9×10^6 km² in 1980, decreased to as low as 3.5×10^6 km² in 2012. Similarly, the multiyear ice extent decreased from about 6.2×10^6 km² in 1981 to about 2.5×10^6 km² in 2012. The trends in perennial ice extent and ice area were strongly negative at -11.5 ± 2.1 and -12.5 ± 2.1 % per decade (*very likely*) respectively. These values indicate an increased rate of decline from the -6.4 % and -8.5 % per decade, respectively, reported for the 1979 to 2000 period by Comiso (2002). The trends in multiyear ice extent and area are even more negative, at -13.5 ± 2.5 and -14.7 ± 3.0 % per decade (*very likely*), respectively, as updated for the period 1979 to 2012 (Comiso, 2012). The more negative trend in ice area than in ice extent indicates that the average ice concentration of multiyear ice in the Central Arctic has also been declining. The rate of decline in the extent and area of multiyear ice cover is consistent with the observed decline of old ice types from the analysis of ice drift and ice age by Maslanik et al. (2007), confirming that older and thicker ice types in the Arctic have been declining significantly. The more negative trend for the thicker multiyear ice area than that for the perennial ice area implies that the average thickness of the ice, and hence the ice volume, has also been declining.

Drastic changes in the multiyear ice coverage from QuikScat (satellite radar scatterometer) data, validated using high resolution Synthetic Aperture Radar data (Kwok, 2004; Nghiem et al., 2007), have also been reported. Some of these changes have been attributed to the near zero replenishment of the Arctic multiyear ice cover by ice that survives the summer (Kwok, 2007).

[INSERT FIGURE 4.4 HERE]

Figure 4.4: Annual perennial (blue) and multiyear (green) sea ice extent (a) and sea ice area (b) in the Central Arctic from 1979 to 2012 as derived from satellite passive microwave data. Perennial ice values are derived from summer ice minimum values, while the multiyear ice values are averages of those from December, January and February. The gold lines (after 2002) are from AMSR-E data (updated from Comiso, 2012).

4.2.2.4 Ice Thickness and Volume

For the Arctic, there are several techniques available for estimating the thickness distribution of sea ice. Combined data sets of draft and thickness from submarine sonars, satellite altimetry, and airborne electromagnetic sensing provide broadly consistent and strong evidence of decrease in Arctic sea ice thickness in recent years (Figure 4.6c).

Data collected by upward-looking sonar on submarines operating beneath the Arctic pack ice provided the first evidence of ‘basin-wide’ decreases in ice thickness (Wadhams, 1990). Sonar measurements are of average draft (the submerged portion of sea ice), which is converted to thickness by assuming an average density for the measured floe including its snow cover. With the then available submarine records, Rothrock et al. (1999) found that ice draft in the mid-1990s was less than that measured between 1958 and 1977 in each of six regions within the Arctic basin. The change was least (-0.9 m) in the Beaufort and Chukchi Seas and greatest (-1.7 m) in the Eurasian Basin. The decrease averaged about 42% of the average 1958 to 1977 thickness. This decrease matched the decline measured in the Eurasian Basin between 1976 and 1996 using UK submarine data (Wadhams and Davis, 2000), which was 43%.

A subsequent analysis of US Navy submarine ice draft (Rothrock et al., 2008) used much richer and more geographically extensive data from 34 cruises within a data release area that covered almost 38% of the area of the Arctic Ocean. These cruises were equally distributed in spring and autumn over a 25-year period between 1975 and 2000. Observational uncertainty associated with the ice draft from these is 0.5 m (Rothrock and Wensnahan, 2007). Multiple regression analysis was used to separate the interannual changes (Figure 4.6c), the annual cycle, and the spatial distribution of draft in the observations. Results of that analysis show that the annual mean ice thickness declined from a peak of 3.6 m in 1980 to 2.4 m in 2000, a decrease of 1.2 m. Over the period, the most rapid change was -0.08 m yr⁻¹ in 1990.

The most recent submarine record, Wadhams et al. (2011), found that tracks north of Greenland repeated between the winters of 2004 and 2007 showed a continuing shift towards less multiyear ice.

Satellite altimetry techniques are now capable of mapping sea ice freeboard to provide relatively comprehensive pictures of the distribution of Arctic sea ice thickness. Similar to the estimation of sea ice thickness from ice draft, satellite measured freeboard (the height of sea ice above the water surface) is converted to thickness, assuming an average density of ice and snow. The principal challenges to accurate thickness estimation using satellite altimetry are in the discrimination of ice and open water, and in estimating the thickness of the snow cover.

Since 1993, radar altimeters on the ESA, ERS and Envisat satellites have provided Arctic observations south of 81.5°N. With the limited latitudinal reach of these altimeters, however, it has been difficult to infer basin-wide changes in thickness. The ERS-1 estimates of ice thickness show a downward trend but, because of the high variability and short time-series (1993–2001), Laxon et al. (2003) concluded that the trend in a region of mixed seasonal and multiyear ice (i.e., below 81.5°N) cannot be considered as significant. Envisat observations showed a large decrease in thickness (0.25 m) following September 2007 when ice extent was the second lowest on record (Giles et al., 2008b). This was associated with the large retreat of the summer ice cover, with thinning regionally confined to the Beaufort and Chukchi Seas, but with no significant changes in the eastern Arctic. These results are consistent with those from the NASA ICESat laser altimeter (see comment on ICESat data in Section 4.4.2.1), which show thinning in the same regions between 2007 and 2008 (Kwok, 2009) (Figure 4.5). Large decreases in thickness due to the 2007 minimum in summer ice are clearly seen in both the radar and laser altimeter thickness estimates.

The coverage of the laser altimeter on ICESat (which ceased operation in 2009) extended to 86°N and provided a more complete spatial pattern of the thickness distribution in the Arctic Basin (Figure 4.6c). Thickness estimates are consistently within 0.5 m of sonar measurements from near-coincident submarine

tracks and profiles from sonar moorings in the Chukchi and Beaufort seas (Kwok, 2009). Ten ICESat campaigns between autumn 2003 and spring 2008 showed seasonal differences in thickness, and thinning and volume losses of the Arctic Ocean ice cover (Kwok, 2009). Over these campaigns, the multiyear sea ice thickness in spring declined by ~ 0.6 m (Figure 4.5), while the average thickness of the first-year ice (~ 2 m) had a negligible trend. The average sea ice volume inside the Arctic Basin in spring (Feb/Mar) was $\sim 14,000$ km³. Between 2004 and 2008, the total multiyear ice volume in spring (Feb/Mar) experienced a net loss of 6300 km³ ($>40\%$). Residual differences between sonar mooring and satellite thicknesses suggest basin-scale volume uncertainties of approximately 700 km³. The rate of volume loss (-1237 km³ yr⁻¹) during autumn (Oct/Nov), while highlighting the large changes during the short ICESat record compares with a more moderate loss rate (-280 ± 100 km³ yr⁻¹) over a 31-year period (1979–2010) estimated from a sea ice reanalysis study using the Pan-Arctic Ice-Ocean Modelling and Assimilation system (Schweiger et al., 2011).

The CryoSat-2 radar altimeter (launched in 2010), which provides coverage up to 89°N, has provided new thickness and volume estimates of Arctic Ocean sea ice (Laxon et al., 2013). These show that the ice volume inside the Arctic Basin decreased by a total of 4291 km³ in autumn (October/November) and 1479 km³ in winter (February/March) between the ICESat (2003–2008) and CryoSat-2 (2010–2012) periods. Based on ice thickness estimates from sonar moorings, an inter-satellite bias between ICESat and CryoSat-2 of 700 km³ can be expected. This is much less than the change in volume between two periods.

[INSERT FIGURE 4.5 HERE]

Figure 4.5: The distribution of winter sea ice thickness in the Arctic and the trends in average, first-year (FY) and multiyear (MY) ice thickness derived from ICESat data between 2004 and 2008 (Kwok, 2009).

Airborne electro-magnetic (EM) sounding measures the distance between an EM instrument near the surface or on an aircraft and the ice/water interface, and provides another method to measure ice thickness. Uncertainties in these thickness estimates are 0.1 m over level ice. Comparison with drill-hole measurements over a mix of level and ridged ice found differences of 0.17 m (Haas et al., 2011).

Repeat EM surveys in the Arctic, though restricted in time and space, have provided a regional view of the changing ice cover. From repeat ground-based and helicopter-borne EM surveys, Haas et al. (2008) found significant thinning in the region of the Transpolar Drift (an average wind-driven drift pattern that transports sea ice from the Siberian coast of Russia across the Arctic basin to Fram Strait). Between 1991 and 2004, the modal ice thickness decreased from 2.5 m to 2.2 m, with a larger decline to 0.9 m in 2007. Mean ice thicknesses also decreased strongly. This thinning was associated with reduction of the age of the ice, and replacement of second-year ice by first-year ice in 2007 (following the large decline in summer ice extent in 2007) as seen in satellite observations. Ice thickness estimates from EM surveys near the North Pole can be compared to submarine estimates (Figure 4.6c). Airborne EM measurements from the Lincoln Sea between 83°N and 84°N since 2004 (Haas et al., 2010) showed some of the thickest ice in the Arctic, with mean and modal thicknesses of more than 4.5 m and 4 m, respectively. Since 2008, the modal thickness in this region has declined to 3.5 m, which is most likely related to the narrowing of the remaining band of old ice along the northern coast of Canada.

4.2.2.5 Arctic Sea Ice Drift

Ice motion influences the distribution of sea ice thickness in the Arctic basin: locally, through deformation and creation of open water areas; regionally, through advection of ice from one area to another; and basin-wide, through export of ice from polar seas to lower latitudes where it melts. The drift and deformation of sea ice is primarily forced by winds and surface currents, but depends also on ice strength, top and bottom surface roughness, and ice concentration. On time scales of days to weeks, winds are responsible for most of the variance in sea ice motion.

Drifting buoys have been used to measure Arctic sea ice motion since 1979. From the record of buoy drift archived by the International Arctic Buoy Programme, Rampal et al. (2009) found an increase in average drift speed between 1978 and 2007 of $17 \pm 4.5\%$ per decade in winter and $8.5 \pm 2.0\%$ per decade in summer. Using daily satellite ice motion fields, which provide a basin-wide picture of the ice drift, Spreen et al. (2011) found that, between 1992 and 2008, the spatially averaged winter ice drift speed increased by $10.6 \pm$

0.9% per decade, but varied regionally between -4 and $+16\%$ per decade (Figure 4.6e). Increases in drift speed are seen over much of the Arctic except in areas with thicker ice (Figure 4.6b, e.g., north of Greenland and the Canadian Archipelago). The largest increases occurred during the second half of the period (2001–2009), coinciding with the years of rapid ice thinning discussed above. Both Rampal et al. (2009) and Spreen et al. (2011) suggest that, since atmospheric reanalyses do not show stronger winds, the positive trend in drift speed is probably due to a weaker and thinner ice cover, especially during the period after 2003.

In addition to freezing and melting, sea ice export through Fram Strait is a major component of the Arctic Ocean ice mass balance. Approximately 10% of the area of Arctic Ocean ice is exported annually. Over a 32-year satellite record (1979–2010), the mean annual outflow of ice area through Fram Strait was $699 \pm 112 \times 10^3 \text{ km}^2$ with a peak in 1994/1995 (updated from , Kwok, 2009), but with no significant decadal trend. Decadal trends in ice volume export – a more definitive measure of change – is far less certain due to the lack of an extended record of the thickness of sea ice exported through Fram Strait. Comparison of volume outflow using ICESat thickness estimates (Spreen et al., 2009) with earlier estimates by Kwok and Rothrock (1999) and Vinje (2001) using thicknesses from moored upward looking sonars shows no discernible change.

Between 2005 and 2008, more than a third of the thicker and older sea ice loss occurred by transport of thick, multiyear ice, typically found west of the Canadian Archipelago, into the southern Beaufort Sea where it melted in summer (Kwok and Cunningham, 2010). Uncertainties remain in the relative contributions of in-basin melt and export to observed changes in Arctic ice volume loss, and it has also been shown that export of thicker ice through Nares Strait could account for a small fraction of the loss (Kwok, 2005).

4.2.2.6 *Timing of Sea Ice Advance, Retreat and Ice Season Duration; Length of Melt Season*

Importantly from both physical and biological perspectives, strong regional changes have occurred in the seasonality of sea ice in both polar regions (Massom and Stammerjohn, 2010; Stammerjohn et al., 2012). However, there are distinct regional differences in when seasonally the change is strongest (Stammerjohn et al., 2012).

Seasonality collectively describes the annual time of sea ice advance and retreat, and its duration (the time between day of advance and retreat). Daily satellite ice-concentration records (1979–present) are used to determine the day to which sea ice advanced, and the day from which it retreated, for each satellite pixel location. Maps of the timing of sea ice advance, retreat and duration are derived from these data (see, Parkinson, 2002; Stammerjohn et al., 2008, for detailed methods).

Most regions in the Arctic show trends towards shorter ice season duration. One of the most rapidly changing areas (showing greater than 2 days/year change) extends from the East Siberian Sea to the western Beaufort Sea. Here, between 1979 and 2011, sea ice advance occurred 41 ± 6 days later (or 1.3 ± 0.2 days/year), sea ice retreat 49 ± 7 days earlier (-1.5 ± 0.2 days/year), and duration became 90 ± 16 days shorter (-2.8 ± 0.5 days/year) (Stammerjohn et al., 2012). There has been a 3-month lengthening of the summer ice-free season which places Arctic summer sea ice extent loss into a seasonal perspective and underscores impacts to the marine ecosystem (e.g., Grebmeier et al., 2010).

The timing of surface melt onset in spring, and freeze-up in autumn, can be derived from satellite microwave data as the emissivity of the surface changes significantly with snow melt (Smith, 1998; Drobot and Anderson, 2001; Belchansky et al., 2004). The amount of solar energy absorbed by the ice cover increases with the length of the melt season. Longer melt seasons with lower albedo surfaces (wet snow, melt ponds, and open water) increase absorption of incoming shortwave radiation and ice melt (Perovich et al., 2007). Hudson (2011) estimates that the observed reduction in Arctic sea ice has contributed approximately 0.1 W m^{-2} of additional global radiative forcing, and that an ice-free summer Arctic Ocean will result in a forcing of about 0.3 W m^{-2} . The satellite record (Markus et al., 2009) shows a trend toward earlier melt and later freeze-up nearly everywhere in the Arctic (Figure 4.6e). Over the last 30 years, the mean melt season over the Arctic ice cover has increased at a rate of 5.7 ± 0.9 days/decade. The largest and most significant trends (at the 99% level) of >10 days per decade are seen in the coastal margins and peripheral seas: Hudson Bay, the East Greenland Sea, the Laptev/East Siberian seas, and the Chukchi/Beaufort seas.

4.2.2.7 *Arctic Polynyas*

High sea ice production in coastal polynyas (anomalous regions of open water or low ice concentration) over the continental shelves of the Arctic Ocean is responsible for the formation of cold saline water, which contributes to the maintenance of the Arctic Ocean halocline (see Glossary). A new passive microwave algorithm has been used to estimate thin sea ice thicknesses (<0.15 m) in the Arctic Ocean (Tamura and Ohshima, 2011), providing the first circumpolar mapping of sea ice production in coastal polynyas. High sea ice production is confined to the most persistent Arctic coastal polynyas, with the highest ice production rate being in the North Water Polynya. The mean annual sea ice production in the 10 major Arctic polynyas is estimated to be $2942 \pm 373 \text{ km}^3$ and decreased by 462 km^3 between 1992 and 2007 (Tamura and Ohshima, 2011).

4.2.2.8 *Arctic Land-Fast Ice*

Shore- or land-fast ice is sea ice attached to the coast. Land-fast ice along the Arctic coast is usually grounded in shallow water, with the seaward edge typically around the 20–30 m isobath (Mahoney et al., 2007). In fjords and confined bays, land-fast ice extends into deeper water.

There are no reliable estimates of the total area or interannual variability of land-fast ice in the Arctic. However both significant and non-significant trends have been observed regionally. Long-term monitoring near Hopen, Svalbard, revealed thinning of land-fast ice in the Barents Sea region by 11 cm per decade between 1966 and 2007 (Gerland et al., 2008). Between 1936 and 2000, the trends in land-fast ice thickness (in May) at four Siberian sites (Kara Sea, Laptev Sea, East Siberian Sea, Chukchi Sea) are insignificant (Polyakov et al., 2003). A more recent composite time series of land-fast ice thickness between the mid 1960s and early 2000s from 15 stations along the Siberian coast revealed an average rate of thinning of 0.33 cm yr^{-1} (Polyakov et al., 2010). End-of-winter ice thickness for three stations in the Canadian Arctic reveal a small downward trend at Eureka, a small positive trend at Resolute Bay, and a negligible trend at Cambridge Bay (updated from, Brown and Côté, 1992; Melling, 2012), but these trends are small and not statistically significant. Even though the trend in the land-fast ice extent near Barrow, Alaska has not been significant (Mahoney et al., 2007), relatively recent observations by Mahoney et al. (2007) and Druckenmiller et al. (2009) found longer ice-free seasons and thinner land-fast ice compared to earlier records (Weeks and Gow, 1978; Barry et al., 1979). As freeze-up happens later, the growth season shortens and the thinner ice breaks up and melts earlier.

4.2.2.9 *Decadal Trends in Arctic Sea Ice*

The average decadal extent of Arctic sea ice has decreased in every season and in every successive decade since satellite observations commenced. The overall trend in extent over the period 1979–2010 has been -3.8% per decade (-0.47 million square kilometres per decade; Figure 4.6a), with larger changes occurring in summer and autumn, and the largest changes of all to the perennial ice (the summer minimum extent; -11.5% per decade) and multiyear ice (more than 2 years old; -13.5% per decade; Figure 4.6b and Figure 4.4). The rate of decrease in ice area has been greater than that in extent because the ice concentration has also decreased (Figure 4.6a).

The decrease in perennial and multiyear ice coverage has resulted in a strong decrease in ice thickness, and hence in ice volume. Declassified submarine sonar measurements, covering $\sim 38\%$ of the Arctic Ocean, indicate an overall mean winter thickness of 3.64 m in 1980, which decreased by 1.75 m to 1.89 m during 2009. Between 1975 and 2000, the steepest rate of decrease was -0.08 m yr^{-1} in 1990 compared to a slightly higher winter/summer rate of $-0.10/-0.20 \text{ m yr}^{-1}$ in the five-year ICESat record (2003–2008). This combined analysis (Figure 4.6b) shows a long-term trend of sea ice thinning that spans five decades. Satellite measurements made in the period 2010–2012 show a decrease in basin-scale sea ice volume compared to those made over the period 2003–2008. The Arctic sea ice is becoming increasingly seasonal with thinner ice, and it will take several years for any recovery.

The decreases in both concentration and thickness reduces sea ice strength reducing its resistance to wind forcing, and drift speed has increased (Figure 4.6e) (Rampal et al., 2009; Spreen et al., 2011). Other significant changes to the Arctic Ocean sea ice include lengthening in the duration of the surface melt on

perennial ice of 6 days per decade (Figure 4.6d) and a nearly 3-month lengthening of the ice-free season in the region from the East Siberian Sea to the western Beaufort Sea.

[INSERT FIGURE 4.6 HERE]

Figure 4.6: Summary of linear decadal trends (red lines) and pattern of changes in: (a) Anomalies in Arctic sea ice extent from satellite passive microwave observations (Comiso and Nishio, 2008, updated to include 2012). Uncertainties are discussed in the text. (b) Multiyear sea ice coverage on January 1st from analysis of the QuikSCAT time series (Kwok, 2009); grey band shows uncertainty in the retrieval. (c) Sea ice thickness from submarine (blue), satellites (black) (Kwok and Rothrock, 2009), and in-situ/EM surveys (circles) (Haas et al., 2008); trend in submarine ice thickness is from multiple regression of available observations within the data release area (Rothrock et al., 2008). Error bars show uncertainties in observations. (d) Anomalies in buoy (Rampal et al., 2009) and satellite-derived sea ice drift speed (Spren et al., 2011). (e) Length of melt season (updated from, Markus et al., 2009); grey band shows the basin-wide variability.

4.2.3 Antarctic Sea Ice

The Antarctic sea ice cover is largely seasonal, with average extent varying from a minimum of about 3×10^6 km² in February to a maximum of about 18×10^6 km² in September (Zwally et al., 2002a; Comiso et al., 2011). The relatively small fraction of Antarctic sea ice that survives the summer is found mostly in the Weddell Sea, but with some perennial ice also surviving on the western side of the Antarctic Peninsula and in small patches around the coast. As well as being mostly first-year ice, Antarctic sea ice is also on average thinner, warmer, more saline and more mobile than Arctic ice (Wadhams and Comiso, 1992). These characteristics, which reduce the capabilities of some remote sensing techniques, together with its more distant location from inhabited continents, result in far less being known about the properties of Antarctic sea ice than of that in the Arctic.

4.2.3.1 Total Antarctic Sea Ice Extent and Concentration

Figure 4.7a shows the seasonal variability of Antarctic sea ice extent using 34 years of satellite passive microwave data updated from Comiso and Nishio (2008). In contrast to the Arctic, decadal monthly averages almost overlap with each other, and the seasonal variability of the total Antarctic sea ice cover has not changed much over the period. In winter, the values for the 1999–2008 decade were slightly higher than those of the other decades; while in autumn, the values for 1989–1998 and 1999–2008 decades were higher than those of 1979–1988. There was more seasonal variability in the period 2009–2012 than for earlier decadal periods, with relatively high values in late autumn, winter and spring.

Trend maps for winter, spring, summer and autumn extent are presented in Figure 4.7 (b, c, d, and e respectively). The seasonal trends are significant mainly near the ice edge, with the values alternating between positive and negative around Antarctica. Such an alternating pattern is similar to that described previously as the Antarctic Circumpolar Wave (ACW) (White and Peterson, 1996) but the ACW may not be associated with the trends since the trends have been strongly positive in the Ross Sea and negative in the Bellingshausen/Amundsen Seas but with almost no trend in the other regions, Comiso et al. (2011). In the winter, negative trends are evident at the tip of the Antarctic Peninsula and the western part of the Weddell Sea, while positive trends are prevalent in the Ross sea. The patterns in spring are very similar to those of winter while in summer and autumn, negative trends are mainly confined to the Bellingshausen/Amundsen Seas, while positive trends are dominant in the Ross Sea and the Weddell Sea.

The regression trend in the monthly anomalies of Antarctic sea ice extent from November 1978 to December 2012 is slightly positive, at $1.5 \pm 0.3\%$ per decade (*very likely*) (see FAQ 4.2) as updated from Comiso and Nishio (2008). The seasonal trends in ice extent are 1.2 ± 0.5 , 1.0 ± 0.5 , 2.5 ± 2.0 , and $3.0 \pm 2.0\%$ per decade (*very likely*) in winter, spring, summer and autumn, respectively, as updated from Comiso et al. (2011). The corresponding trends in ice area (also updated) are 1.9 ± 0.7 , 1.6 ± 0.5 , 3.0 ± 2.1 , and $4.4 \pm 2.3\%$ per decade (*very likely*). The values are all positive with the largest trends occurring in the autumn. The trends are consistently higher for ice area than ice extent, indicating less open water (possibly due to less storms and divergence) within the pack in later years. Trends reported by Parkinson and Cavalieri (2012) using data from 1978 to 2010 are slightly different, in part because they cover a different time period (see, Supplementary Material). The overall inter-annual trends for various sectors around Antarctica are given in

FAQ 4.2, and show large regional variability. Changes in ice drift and wind patterns as reported by Holland and Kwok (2012) may be related to this phenomenon.

[INSERT FIGURE 4.7 HERE]

Figure 4.7: (a) Plots of decadal averages of daily sea ice extent in the Antarctic (1979 to 1988 in red, 1989 to 1998 in blue, 1999 to 2008 in gold) and a four-year average daily ice extent from 2009 to 2012 in black. Maps of ice concentration trends (1979–2012) in (b) winter, (c) spring, (d) summer and (e) autumn (updated from Comiso, 2010).

4.2.3.2 *Antarctic Sea Ice Thickness and Volume*

Since AR4, some advances have been made in determining the thickness of Antarctic sea ice, particularly in the use of ship-based observations and satellite altimetry. However there is still no information on large-scale Antarctic ice thickness change. Worby et al. (2008) compiled 25 years of ship-based data from 83 Antarctic voyages on which routine observations of sea ice and snow properties were made. Their compilation included a gridded data set that reflects the regional differences in sea ice thickness. A subset of these ship observations, and ice charts, was used by DeLiberty et al. (2011) to estimate the annual cycle of sea ice thickness and volume in the Ross Sea, and to investigate the relationship between ice thickness and extent. They found that maximum sea ice volume was reached later than maximum extent. While ice is advected to the northern edge and melts, the interior of the sea ice zone is supplied with ice from higher latitudes and continues to thicken by thermodynamic growth and deformation. Satellite retrievals of sea ice freeboard and thickness in the Antarctic (Mahoney et al., 2007; Zwally et al., 2008; Xie et al., 2011) are under development but progress is limited by knowledge of snow thickness and the paucity of suitable validation data sets. A recent analysis of the ICESat record by Kurtz and Markus (2012), assuming zero ice freeboard, found negligible trends in ice thickness over the 5-year record.

4.2.3.3 *Antarctic Sea Ice Drift*

Using a 19-year dataset (1992–2010) of satellite-tracked sea ice motion, Holland and Kwok (2012) found large and statistically significant decadal trends in Antarctic ice drift that in most sectors are caused by changes in local winds. These trends suggest acceleration of the wind-driven Ross Gyre and deceleration of the Weddell Gyre. The changes in meridional ice transport affect the freshwater budget near the Antarctic coast. This is consistent with the increase of $30,000 \text{ km}^2 \text{ yr}^{-1}$ in the net area export of sea ice from the Ross Sea shelf coastal polynya region between 1992 and 2008 (Comiso et al., 2011). Assuming an annual average thickness of 0.6 m, Comiso et al. (2011) estimated a volume export of $20 \text{ km}^3 \text{ yr}^{-1}$ which is similar to the rate of production in the Ross Sea coastal polynya region for the same period discussed in Section 4.2.3.5.

4.2.3.4 *Timing of Sea Ice Advance, Retreat and Ice Season Duration*

In the Antarctic there are regionally different patterns of strong change in ice duration (>2 days/year). In the northeast and west Antarctic Peninsula and southern Bellingshausen Sea region, later ice advance ($+61 \pm 15$ days); earlier retreat (-39 ± 13 days); and shorter duration ($+100 \pm 31$ days, a trend of -3.1 ± 1.0 days/year) occurred over the period 1979/1980–2010/2011 (Stammerjohn et al., 2012). These changes have strong impacts on the marine ecosystem (Montes-Hugo et al., 2009; Ducklow et al., 2011). The opposite is true in the adjacent western Ross Sea, where substantial lengthening of the ice season of 79 ± 12 days has occurred ($+2.5 \pm 0.4$ days/year) due to earlier advance ($+42 \pm 8$ days) and later retreat (-37 ± 8 days). Patterns of change in the relatively narrow East Antarctic sector are generally of a lower magnitude and zonally complex, but in certain regions involve changes in the timing of sea ice advance and retreat of the order of ± 1 – 2 days/year (for the period 1979–2009) (Massom et al., 2013).

4.2.3.5 *Antarctic Polynyas*

Polynyas are commonly found along the coast of Antarctica. There are two different processes that cause a polynya. Warm water upwelling keeps the surface water near the freezing point and reduces ice production (sensible heat polynya), and wind or ocean currents move ice away and increase further ice production (latent heat polynya).

An increase in the extent of coastal polynyas in the Ross Sea caused increased ice production (latent heat effect) that is primarily responsible for the positive trend in ice extent in the Antarctic (Comiso et al., 2011). Drucker et al. (2011) show that in the Ross Sea, the net ice export equals the annual ice production in the Ross Sea polynya (approximately 400 km³ in 1992), and that ice production increased by 20 km³ per year from 1992 to 2008. However the ice production in the Weddell Sea, which is three times less, has had no statistically significant trend over the same period. Variability in the ice cover in this region is linked to changes in the Southern Annular Mode (SAM). Between 1974 and 1976, the large Weddell Sea Polynya, which is a sensible heat polynya, was created by the injection of relatively warm deep water into the surface layer due to sustained deep-ocean convection (sensible heat effect) during negative SAM, but since the late-1970s the SAM has been mainly positive, resulting in warmer and wetter condition forestalling any reoccurrence of the Weddell Sea Polynya (Gordon et al., 2007).

4.2.3.6 *Antarctic Land-Fast Ice*

Land-fast ice forms around the coast of Antarctica, typically in narrow coastal bands of varying width up to 150 km from the coast and in water depths of up to 400–500 m. Around East Antarctica, it comprises generally between 5% (winter) and 35% (summer) of the overall sea ice area (Fraser et al., 2012), and a greater fraction of ice volume (Giles et al., 2008a).

Variability in the distribution and extent of land-fast ice is sensitive to processes of ice formation and to processes such as ocean swell and waves, and strong wind events that cause the ice to break-up. Historical records of Antarctic land-fast ice extent, such as that of Kozlovsky et al. (1977) covering 0° to 160°E, were limited by sparse and sporadic sampling. Recently, using cloud-free MODIS composite images, Fraser et al. (2012) derive a high resolution time series of land-fast sea ice extent along the East Antarctic coast, showing a statistically-significant increase ($1.43 \pm 0.30\% \text{ yr}^{-1}$) between March 2000 and December 2008. There is a strong increase in the Indian Ocean sector (20°E to 90°E, $4.07 \pm 0.42\% \text{ yr}^{-1}$), and a non-significant decrease in the sector from 90°E to 160°E ($-0.40 \pm 0.37\% \text{ yr}^{-1}$). An apparent shift from a negative to a positive trend was noted in the Indian Ocean sector from 2004, which coincided with greater interannual variability. Although significant changes are observed, this record is only 9 years in length.

4.2.3.7 *Decadal Trends in Antarctic Sea Ice*

For the Antarctic, any changes in many sea ice characteristics are unknown. There has been a small but significant increase in total ice extent of 1.5% per decade between 1979 and 2012, and a greater increase in ice area, indicating an increase in concentration. But there are strong regional differences within this total, with some regions increasing in extent/area and some decreasing. There are also contrasting regions around the Antarctic where the ice-free season has lengthened, and others where it has decreased over the satellite period. There are still inadequate data to make any assessment of changes to Antarctic sea ice thickness and volume.

4.3 **Glaciers**

This section considers all perennial surface land ice masses (defined in 4.1 and Glossary) outside of the Antarctic and Greenland ice sheets. Glaciers occur where climate conditions and topographic characteristics allow snow to accumulate over several years and to transform gradually into firn (snow that persists for at least one year) and finally to ice. Under the force of gravity, this ice flows downwards to elevations with higher temperatures where various processes of ablation (loss of snow and ice) dominate over accumulation (gain of snow and ice). The sum of all accumulation and ablation processes determines the mass balance of a glacier. Accumulation is in most regions mainly due to solid precipitation (in general snow), but also results from refreezing of liquid water, especially in polar regions or at high altitudes where firn remains below melting temperature. Ablation is, in most regions, mainly due to surface melting with subsequent runoff, but loss of ice by calving (on land or in water; see Glossary) or sublimation (important in dry regions) can also dominate. Re-distribution of snow by wind and avalanches can contribute to both accumulation and ablation. The energy and mass fluxes governing the surface mass balance are directly linked to atmospheric conditions and are modified by topography (e.g., due to shading). Glaciers are sensitive climate indicators because they adjust their size in response to changes in climate (e.g., temperature and precipitation) (FAQ 4.1). Glaciers are also important seasonal to long-term hydrologic reservoirs (Chapter 3, Section 3.4.4) on a regional scale

and a major contributor to sea-level rise on a global scale (see Section 4.3.3.4, Chapter 13). In the following, we report global glacier coverage (Section 4.3.1), how changes in length, area, volume and mass are determined (Section 4.3.2), and the observed changes in these parameters through time (Section 4.3.3).

4.3.1 Current Area and Volume of Glaciers

The total area covered by glaciers was only roughly known in AR4, resulting in large uncertainties for all related calculations (e.g., overall glacier volume or mass changes). Since AR4, the formerly used world glacier inventory (WGMS, 1989) was gradually extended by Cogley (2009a) and Radić and Hock (2010); and for AR5, a new globally-complete dataset of glacier outlines (Randolph Glacier Inventory, RGI) was compiled from a wide range of data sources from the 1950s to 2010 and having varying levels of detail and quality (Arendt et al., 2012). Regional glacier-covered areas for 19 regions were extracted from the RGI and supplemented with the percentage of the area covered by glaciers terminating in tidewater (Figure 4.8 and Table 4.2). The area covered by glaciers that are in contact with freshwater lakes is only locally available. The separation of so-called peripheral glaciers from the ice sheets in Greenland and Antarctica is not easy. A new detailed inventory of the glaciers in Greenland (Rastner et al., 2012) allows for estimation of their area, volume, and mass balance separately from those of the ice sheets. This separation is still incomplete for Antarctica, and values discussed here (Figures 4.1, 4.8–4.11, Tables 4.2 and 4.4) refer to the glaciers on the islands in the Antarctic and Subantarctic (Bliss et al., 2013) but exclude glaciers on the mainland of Antarctica that are separate from the ice sheet. Regionally-variable accuracy of the glacier outlines leads to poorly-quantified uncertainties. These uncertainties, along with the regional variation in the minimum size of glaciers included in the inventory, and the subdivision of contiguous ice masses, also makes the total number of glaciers uncertain; the current best estimate is around 170,000 covering a total area of about 730,000 km². More than 80% of the glacier area is in Antarctica and the Subantarctic [region 19], the Canadian Arctic [2 and 3], High Mountain Asia [13, 14, 15], Alaska [1], and Greenland [17] (Table 4.2).

From the glacier areas in the new inventory, total glacier volumes and masses have been determined by applying both simple scaling relations and ice-dynamical considerations (Table 4.2, and references therein), however, both methods are calibrated with only a few hundred glacier thickness measurements. This small sample means that uncertainties are large and difficult to quantify. The range of values as derived from four global-scale studies for each of the 19 RGI regions is given in Table 4.2, suggesting a global glacier mass that is *likely* between 114,000 and 192,000 Gt (314–529 mm SLE). The numbers and areas of glaciers reported in Table 4.2 are directly taken from RGI 2.0 (Arendt et al., 2012) with updates for the Low Latitudes [16] and the Southern Andes [17]

Table 4.2: The 19 regions used throughout this chapter and their respective glacier numbers and area (absolute and in percent) from derived from the RGI 2.0 (Arendt et al., 2012), tidewater fraction from Gardner et al. (2013). The minimum and maximum values of glacier mass are the minimum and maximum of the estimates given in four studies: Grinsted (2013), Huss and Farinotti (2012), Marzeion et al. (2012), and Radić et al. (2013). The mean sea-level equivalent (SLE) of the mean glacier mass is the mean of estimates from the same four studies, using an ocean area of 362.5×10^6 km² for conversion. All values were derived with globally consistent methods; deviations from more precise national datasets are thus possible.

Region	Region Name	Number of Glaciers	Area (10 ³ km ²)	Percent of total area (%)	Tidewater fraction (%)	Mass (min.) (Gt)	Mass (max.) (Gt)	Mean SLE (mm)
1	Alaska	23112	89267	12.3	13.0	16168	28021	54.7

Notes:

(a) For regions 10, 16 and 17 the number and area of glaciers are corrected to allow for over-inclusion of seasonal snow in the glacierized extent of RGI 2.0 and for improved outlines (region 10) compared to RGI 2.0 (updated from, Arendt et al., 2012).

[INSERT FIGURE 4.8 HERE]

Figure 4.8: Global distribution of glaciers (yellow, area increased for visibility) and area covered (diameter of the circle), sub-divided into the 19 RGI regions (white number) referenced in Table 4.2. The area percentage covered by tidewater (TW) glaciers in each region is shown in green. Data from Arendt et al. (2012) and Gardner et al. (2013).

4.3.2 Methods to Measure Changes in Glacier Length, Area and Volume/Mass

To measure changes in glacier length, area, mass and volume, a wide range of observational techniques has been developed. Each technique has individual benefits over specific spatial and temporal scales; their main characteristics are summarized in Table 4.3. Monitoring programs include complex climate-related observations at a few glaciers, index measurements of mass balance and annual length changes for some hundreds of glaciers, and repeat geodetic estimates of area and volume changes at regional scales using remote sensing methods (e.g., Haeberli et al., 2007). While in situ measurements of glacier changes are biased towards glaciers that are easily accessible, comparatively small and simple to interpret; a large proportion of all glaciers in the world is debris-covered or tidewater-calving (see Table 4.2) and changes of such glaciers are more difficult to interpret in climatic terms (Yde and Pasche, 2010). In addition, many of the remote-sensing based assessments do not discriminate these types.

4.3.2.1 Length Change Measurements

For the approximately 500 glaciers worldwide that are regularly observed, front variations (commonly called length changes) are usually obtained through annual measurements of the glacier terminus position. Globally coordinated observations were started in 1894, providing one of the longest available time series of environmental change (WGMS, 2008). More recently, particularly in regions that are difficult to access, aerial photography and satellite imaging have been used to determine glacier length changes. For selected glaciers globally, historic terminus positions have been reconstructed from maps, photographs, satellite imagery, paintings and dated moraines, and other sources (e.g., Masiokas et al., 2009; Lopez et al., 2010; Nussbaumer et al., 2011; Davies and Glasser, 2012; Leclercq and Oerlemans, 2012; Rabatel et al., 2013). Early reconstructions are sparsely distributed in both space and time, generally at intervals of decades. The terminus fluctuations of some individual glaciers have been reconstructed more than 3000 years back in time (Holzhauser et al., 2005), with a much larger number of records going back to the 16th or 17th centuries (Zemp et al., 2011, and references therein). The reconstructed glacier length records are globally well distributed and were used, for example, to determine the contribution of glaciers to global sea-level rise (Leclercq et al., 2011) (Section 4.3.3.4), and for an independent temperature reconstruction at a hemispheric scale (Leclercq and Oerlemans, 2012).

4.3.2.2 Area Change Measurements

Glacier area changes are reported in increasing number and coverage based on repeat satellite imagery (WGMS, 2008). While satellite based observations are only available for the past four decades, studies using

air photographs, old maps as well as mapped and dated moraines and trim lines show glacier areas back to the end of the so-called Little Ice Age (LIA, see Glossary) about 150 years ago (cf. Figure 6 in, Rabatel et al., 2008) and beyond (e.g., Citterio et al., 2009; Davies and Glasser, 2012). The observed area changes depend (in most regions) on glacier size (with smaller glaciers shrinking at faster percentage rates) and tend to vary greatly within any one mountain range. Moreover the time spans of the measurements of change vary from study to study, and regional or global-scale estimates are therefore difficult to generate. The focus here is, thus, on the comparison of mean annual relative area changes averaged over entire mountain regions.

4.3.2.3 Volume and Mass Change Measurements

Several methods are in use for measuring mass changes of glaciers. Traditionally, the annual surface mass balance is derived from repeated snow density and snow/ice stake readings on individual glaciers. Estimates over larger regions are obtained by extrapolating from the measured glaciers. This labour intensive method is generally restricted to a limited number of accessible glaciers, which are unevenly distributed over glacier regions and types. Annual measurements began in the 1940s on a few glaciers, with slightly more than 100 since the 1980s—and only 37 glaciers have been measured without interruption for more than 40 years (Zemp et al., 2011). Potential mass loss from calving or from basal ablation is not included. At present, it is not possible to quantify all sources of uncertainty in mass budgets extrapolated from measurements of individual glaciers (Cogley, 2009b).

A second method determines the volume change of all glaciers in a region by measurement of surface-elevation changes (Section 4.3.3.3 and Figure 4.11). The information is derived by subtracting digital terrain models, including those from repeat airborne or satellite altimetry (particularly suitable for larger and flatter ice surfaces). The conversion from volume to mass change can cause a major uncertainty, in particular over short periods, as density information is required, but is generally only available from field measurements (Gardner et al., 2013, and references therein).

Since 2003, a third method used to estimate overall mass change is through measurement of the changing gravity field from satellites (GRACE mission). The coarse spatial resolution (about 300 km) and the difficulties of separating different mass change signals such as hydrological storage and glacial isostatic adjustment, limit this method to regions with large continuous ice extent (Gardner et al., 2013).

A fourth method calculates the mass balance of individual glaciers, or a glacier region, with models which either convert particular glacier variables such as length changes or the altitude of the equilibrium line (see Glossary) (e.g., Rabatel et al., 2005; Luethi et al., 2010; Leclercq et al., 2011) into mass changes, or use time series of atmospheric temperature and other meteorological variables to simulate glacier mass balances at different levels of complexity (e.g., Hock et al., 2009; Machguth et al., 2009; Marzeion et al., 2012; Hirabayashi et al., 2013). The models improve fidelity and physical completeness, and add value to the scarce direct measurements.

A fifth method determines glacier mass changes as residuals of the water balance for hydrological basins rather than for glacier regions. Results from all but this last method are used in the following regional and global assessment of glacier mass changes (Sections 4.3.3.3 and 4.3.3.4).

Table 4.3: Overview of methods used to determine changes in glacier length, area and volume along with some typical characteristics. The techniques are not exclusive. The last three columns provide only indicative values.

Parameter	Method	Technique	Typical accuracy	Number of Glaciers	Repeat Interval	Earliest Data
Length change	Various	Reconstruction	10 m	dozens	decadal - centuries	Holocene
	Field	in-situ measurement	1 m	hundreds	annual	19th century
	Remote Sensing	Photogrammetric survey	two image pixels (depending on resolution)	hundreds	annual	20th century
Area change	Maps	Cartographic	5% of the area	hundreds	decadal	19th century
	Remote	Image processing	5% of the area	thousands	sub-	20th century

	sensing				decadal	
Volume change	Remote sensing	Laser and radar profiling	0.1 m	hundreds	annual	21st century
	Remote sensing	DEM differencing	0.5 m	thousands	decadal	20th century
Mass change	Field	Direct mass balance measurement	0.2 m	> 450 annually	seasonal	20th century
	Remote sensing	Gravimetry (GRACE)	dependent on the region	Global	seasonal	21st century

4.3.3 Observed Changes in Glacier Length, Area and Mass

4.3.3.1 Length Changes

Despite their variability due to different response times and local conditions (see FAQ 4.1), the annually measured glacier terminus fluctuations from about 500 glaciers worldwide reveal a largely homogeneous trend of retreat (WGMS, 2008). In Figure 4.9, a selection of the available long-term records of field measurements is shown for 11 out of the 19 RGI regions. Cumulative values of retreat for large, land-terminating valley glaciers typically reach several kilometres over the 120-year period of observation. For mid-latitude mountain and valley glaciers, typical retreat rates are of the order of 5 to 20 m yr⁻¹. Rates of up to 100 m yr⁻¹ (or even more) are seen to occur under special conditions, such as the complete loss of a tongue on a steep slope, FAQ4.1, Figure 1c, or the disintegration of a very flat tongue. A non-calving valley glacier in Chile had reported mean annual retreat rates of 125 m from 1961 to 2011 (Rivera et al., 2012). The general tendency of retreat in the 20th century was interrupted in several regions (e.g., regions [2], [8], [11], [17]) by phases of stability lasting one or two decades, or even advance, for example in the 1920s, 1970s and 1990s (regionally variable). In regions for which long-term field measurements of several glaciers of different sizes are available, the terminus fluctuations typically show a pattern with the largest (flatter) glaciers tending to retreat continuously and by large cumulative distances, medium-sized (steeper) glaciers showing decadal fluctuations, and smaller glaciers showing high variability superimposed on smaller cumulative retreats (Figure 4.9).

The exceptional terminus advances of a few individual glaciers in Scandinavia and New Zealand in the 1990s may be related to locally-specific climatic conditions such as increased winter precipitation (Nesje et al., 2000; Chinn et al., 2005; Lemke et al., 2007). In other regions, such as Iceland, the Karakoram and Svalbard, observed advances were related to dynamical instabilities (surging) of glaciers (e.g., Murray et al., 2003; Quincey et al., 2011; Bolch et al., 2012; Björnsson et al., 2013). Glaciers with calving instabilities can retreat exceptionally rapidly (Pfeffer, 2007), while those with heavily debris-covered tongues are often close to stationary (Scherler et al., 2011). More regionally, focused studies of length change over different time periods (e.g., Citterio et al., 2009; Masiokas et al., 2009; Lopez et al., 2010; Bolch et al., 2012) justify *high confidence* about the trend of glacier length variations shown in Figure 4.9.

[INSERT FIGURE 4.9 HERE]

Figure 4.9: Selection of long-term cumulative glacier length changes as compiled from in situ measurements (WGMS, 2008), reconstructed data points added to measured time series (region 5) from Leclercq et al. (2012), and additional time series from reconstructions (regions 1, 2, 7, 10, 12, 16, 17, and 18) from Leclercq and Oerlemans (2012). Independent of their (highly variable) temporal density, all measurement points are connected by straight lines. The glacier Mulajokull (region 6) is of surge type and some of the glaciers showing strong retreat either terminate (Gueissfeldt and Upsala in region 17) or terminated (Engabreen and Nigardsbreen in region 8) in lakes. For region 11, many more time series are available (see, WGMS, 2008), but are not shown for graphical reasons.

4.3.3.2 Area Changes

From the large number of published studies on glacier area changes in all parts of the world since AR4 (see Table 4.SM.1) a selection with examples from 16 out of the 19 RGI regions is shown in Figure 4.10. The studies reveal that: (1) total glacier area has decreased in all regions, (2) the rates of change cover a similar range of values in all regions, (3) there is considerable variability of the rates of change within each region,

(4) highest loss rates are found in regions [2], [11], and [16], and (5) the rates of loss have a tendency to be higher over more recent time periods. The last point (5) requires studies comparing the same sample of glaciers over multiple similar time periods. For 14 out of 19 regions listed in Table 4.SM.1 (see Supplementary Material) with such an analysis, higher loss rates were found for the more recent period.

While points (1) and (2) give *high confidence* in the global-scale shrinkage in glacier area, (3) points to a considerable regional to local-scale scatter of observed change rates. The shorter the period of investigation and the smaller the sample of glaciers analysed, the more variable are the rates of change reported for a specific region (Table 4.SM.1). In many regions of the world, rates of area loss have increased (Table 4.SM.1), confirming that glaciers are still too large for the current climate and will continue to shrink (see FAQ4.1 and Section 4.3.3.3).

Several studies have reported the disappearance of glaciers, among others in Arctic Canada (Thomson et al., 2011), the Rocky Mountains (Bolch et al., 2010; Tennant et al., 2012) and North Cascades (Pelto, 2006), Patagonia (Bown et al., 2008; Davies and Glasser, 2012), several tropical mountain ranges (Coudrain et al., 2005; Klein and Kincaid, 2006; Cullen et al., 2013), the European Alps (Citterio et al., 2007; Knoll and Kerschner, 2009; Diolaiuti et al., 2012), the Tien Shan (Hagg et al., 2012), the Terskey Alatau (Kutuzov and Shahgedanova, 2009) in Asia, and on James Ross island in Antarctica (Carrivick et al., 2012). In total, the disappearance of more than 600 glaciers has been reported, but the real number is certainly higher. Also some of the glaciers, whose annual mass balance has been measured over several years or even decades, have disappeared or started to disintegrate (Ramirez et al., 2001; Carturan and Seppi, 2007; Thibert et al., 2008). Though the number of glaciers that have disappeared is difficult to compare directly (e.g., the time periods analysed or the criteria applied to say a glacier has disappeared differ), these glaciers that have disappeared provide *robust evidence* that the ELA (see Glossary) has risen above the highest peaks in many mountain ranges (see FAQ4.1).

[INSERT FIGURE 4.10 HERE]

Figure 4.10: Mean annual relative area-loss rates for 16 out of the 19 RGI regions of Figure 4.8. Each line shows a measurement of the rate of percentage change in area over a mountain range from a specific publication (for sources see Table 4.SM.1), the length of the line shows the period used for averaging.

4.3.3.3 Regional Scale Glacier Volume and Mass Changes

In AR4, global and regional scale glacier mass changes were extrapolated from in situ measurements of mass balance on individual glaciers (Kaser et al., 2006; Lemke et al., 2007). In some regions, like Alaska, Patagonia and the Russian Arctic, very few if any such records were available. Since AR4, geodetically-derived ice volume changes have been assimilated (Cogley, 2009b), providing more consistent regional coverage and better representation of the proportion of calving glaciers. In addition, the new complete RGI inventory of glacier-covered areas (Arendt et al., 2012) has improved knowledge about regional and global glacier volume and mass changes.

Figure 4.11 shows a compilation of available mean mass-balance rates for 1960–2010 for each of the 19 RGI regions. Where error estimates are reported, the 90% confidence bounds are shown. Most results shown are calculated using a single method, some merge multiple methods; those from Gardner et al. (2013) are consensus estimates for 2003–2009 obtained by selecting the most reliable results of different observation methods, after region-by-region reanalysis and comparison.

[INSERT FIGURE 4.11 HERE]

Figure 4.11: Regional glacier mass budgets in units of $\text{kg m}^{-2} \text{yr}^{-1}$ for the world's 19 glacierized regions (Figure 4.8 and Table 4.2). Estimates are from modelling with climate data (blue: Hock et al., 2009; Marzeion et al., 2012), repeat gravimetry (green: Chen et al., 2007; Luthcke et al., 2008; Peltier, 2009; Matsuo and Heki, 2010; Wu et al., 2010; Gardner et al., 2011; Ivins et al., 2011; Schrama and Wouters, 2011; Jacob et al., 2012, updated for RGI regions), repeat volume area scaling (magenta: Glazovsky and Macheret, 2006), interpolation of local glacier records (black: Cogley, 2009a; Huss, 2012), or airborne and/or satellite repeat topographic mapping (orange: Arendt et al., 2002; Rignot et al., 2003; Abdalati et al., 2004; Schiefer et al., 2007; Paul and Haeberli, 2008; Berthier et al., 2010; Moholdt et al., 2010; Nuth et al., 2010; Gardner et al., 2011; Gardner et al., 2012; Moholdt et al., 2012; Willis et al., 2012; Björnsson et al., 2013; Bolch et al., 2013). Mass-budget estimates are included only for study domains that cover ~50% or more of the total regional glacier area. Mass-budget estimates include 90% confidence envelopes (not available from all studies).

Conversions from specific mass budget in kg m^{-2} to mm SLE are given for each region. Gravimetric estimates are often not accompanied by estimates of glacierized area (required for conversion from Gt yr^{-1} to $\text{kg m}^{-2} \text{yr}^{-1}$); in such cases the RGI regional glacier areas were used.

Despite the great progress made since AR4, uncertainties inherent to specific methods, and arising from the differences between methods (cf. Chapter 2, Box 2.1), remain large, and *confidence* about the absolute value of mass loss is *medium* at both regional and global scales (Figure 4.11). The highest density of measurement and best time resolution are available for Scandinavia [8] and Central Europe [11]. Least coverage and some of the highest uncertainties are in the Arctic [3, 4, 5, 9] and the Antarctic and Subantarctic [19].

Gardner et al. (2013) discussed inconsistencies among, and differences between, methods and their respective results for 2003–2009. They found that results from the GRACE gravimetric mission agree well with results from ICESat laser altimetry in regions of extensive ice cover (see comment on ICESat data in Section 4.4.2.1), but show much more variable and uncertain mass loss in regions with small or scattered ice cover such as Western Canada/US [2] and the Tibetan Plateau (e.g., Yao et al., 2012, and references therein). Based on ICESat measurements, Gardner et al. (2013) also found that glaciers with in-situ measurements tend to be located in sub-regions that are thinning more rapidly than the region as a whole. Thus extrapolation from in-situ measurements has a negative bias in regions with sparse measurements. Based on this analysis, Gardner et al. (2013) excluded GRACE results for regions with small or scattered glacier coverage and excluded results based on extrapolation of local records for remote, sparsely sampled regions.

The 2003–2009 regionally differentiated results are given in Table 4.4. There is *very high confidence* that, between 2003 and 2009, most mass loss was from glaciers in the Canadian Arctic [3–4], Alaska [1], Greenland [5], the Southern Andes [17] and the Asian Mountains [13–15], which together account for more than 80% ($>200 \text{ Gt yr}^{-1}$) of the global ice loss.

Table 4.4: Regional mass change rates in units of $\text{kg m}^{-2} \text{yr}^{-1}$ and Gt yr^{-1} for the period 2003 to 2009 from Gardner et al. (2013). Central Asia [13], South Asia West [14], and South Asia East [15] are merged into a single region. For the division of regions see Figure 4.8.

No.	Region Name	($\text{kg m}^{-2} \text{yr}^{-1}$)	(Gt yr^{-1})
1	Alaska	-570 ± 200	-50 ± 17
2	Western Canada and US	-930 ± 230	-14 ± 3
3	Arctic Canada North	-310 ± 40	-33 ± 4
4	Arctic Canada South	-660 ± 110	-27 ± 4
5	Greenland Periphery	-420 ± 70	-38 ± 7
6	Iceland	-910 ± 150	-10 ± 2
7	Svalbard	-130 ± 60	-5 ± 2
8	Scandinavia	-610 ± 140	-2 ± 0
9	Russian Arctic	-210 ± 80	-11 ± 4
10	North Asia	-630 ± 310	-2 ± 1
11	Central Europe	-1060 ± 170	-2 ± 0
12	Caucasus and Middle East	-900 ± 160	-1 ± 0
13–15	High Mountain Asia	-220 ± 100	-26 ± 12
16	Low Latitudes	-1080 ± 360	-4 ± 1
17	Southern Andes	-990 ± 360	-29 ± 10
18	New Zealand	-320 ± 780	0 ± 1
19	Antarctic and Subantarctic	-50 ± 70	-6 ± 10
	Total	-350 ± 40	-259 ± 28

Despite the considerable scatter, Figure 4.11 shows mass losses in all 19 regions over the past five decades that, together with their consistency with length (Section 4.3.3.1) and area changes (Section 4.3.3.2), provide *robust evidence* and *very high confidence* in global glacier shrinkage. In many regions, ice loss has *likely*

increased during the last two decades, with slightly smaller losses in some regions during the most recent years, since around 2005. In Central Europe [11], the increase of loss rates was earliest and strongest. In the Russian Arctic [9] and in the Antarctic and Subantarctic [19], the signal is highly uncertain and trends are least clear. Gardner et al. (2013) present values close to balance for the Antarctic and Subantarctic [19] that result from complex regional patterns; for example, with losses on Antarctic Peninsula islands and gains on Ellsworth Land islands. The picture is also heterogeneous in High Mountain Asia [13–15] (e.g., Bolch et al., 2012; Yao et al., 2012), where glaciers in the Himalaya and the Hindu Kush have been losing mass (Kääb et al., 2012) while those in the Karakoram are close to balance (Gardelle et al., 2012).

Several studies of recent glacier velocity change (Heid and Kääb, 2011; Azam et al., 2012) and of the world-wide present-day sizes of accumulation areas (Bahr et al., 2009) indicate that the world's glaciers are out of balance with the present climate and thus committed to losing considerable mass in the future, even without further changes in climate. Increasing ice temperatures recorded at high elevation sites in the tropical Andes (Gilbert et al., 2010) and in the European Alps (Col du Dome on Mt. Mont Blanc and Monte Rosa) (Vincent et al., 2007; Hoelzle et al., 2011), as well as the on-going thinning of the cold surface layer on Storglaciären in northern Sweden (Gusmeroli et al., 2012), support this conclusion and give it *high confidence*.

4.3.3.4 Global Scale Glacier Mass Changes – The Contribution to Sea Level

Global time series are required to assess the continuing contribution of glacier mass changes to sea level (See Chapter 13, Section 13.4.2, for discussion of the small proportion of ice loss from glaciers that does not contribute to sea-level rise). A series of recent studies, some updated to RGI areas for this report by their respective authors, provides *very high confidence* in a considerable and continuous mass loss, despite only *medium agreement* on the specific rates (Figure 4.12, Table 4.5). Cogley (updated from, 2009b) compiled 4,817 directly measured annual mass budgets, and 983 volume change measurements by extending the dataset of WGMS (2009, and earlier issues). Global 5-year averages for 1961–2010, with uncertainties, were estimated from these using an inverse-distance-weighted interpolation. Newly available volume change measurements increased the proportion of observations from calving glaciers from 3% to 16% compared to earlier estimates reported by Lemke et al. (2007). This proportion is more realistic, but may still underestimate the relative importance of calving glaciers (Figure 4.8, Chapter 4, Section 4.3.3.3).

Leclercq et al. (updated from, 2011) used length variations from 382 glaciers worldwide as a proxy for glacier mass loss since 1800. The length/mass change conversion was calibrated against mass balance observations for 1950–2005 from Cogley (2009b), and provide one estimate based on the arithmetic mean and another based on area-weighted extrapolation of regional averages. Uncertainty was estimated from upper and lower bounds of the calibration parameter assumptions, and cumulatively propagated backward in time. For the 19th century, the information was constrained by a limited number of observations, particularly in extensively glacierized regions that contribute most to the global mass budget.

Two global-scale time series are obtained from mass-balance modelling based on temperature and precipitation data (Marzeion et al., 2012; Hirabayashi et al., 2013). Glacier size adjustments are simulated by using area-volume power-law relations as proposed by Bahr et al. (1997) for the approximately 180,000 individual glaciers delineated in the RGI. Marzeion et al. (2012) derive mass balances for 1902–2009 from monthly mean temperature and precipitation obtained from Mitchell and Jones (2005). The model is calibrated against measured time series and validated against independent measurements. Uncertainty estimates are obtained from comprehensive error propagation, first accumulated temporally for each glacier, and then regionally and globally. The model does not account for the subsurface mass balance or calving, but reproduces geodetically measured volume changes for land-based glaciers within the uncertainties; however it underestimates volume loss slightly for calving glaciers. Hirabayashi et al. (2013) force an extended positive degree-day model with data from an observation-based global set of daily precipitation and near-surface temperature as updated from earlier work (Hirabayashi et al., 2008). Annual mass balance is provided for 1948–2005 with a constant root mean square error of $500 \text{ km}^3 \text{ yr}^{-1}$, estimated from comparison of modelled with measured mass balances.

For Antarctica and the Subantarctic [region 19] observational information is limited and difficult to incorporate into this assessment. For some studies the time spans do not match (e.g., Gardner et al., 2013 give only mean mass change for 2003–2009). Some estimates have been made simply by extrapolating the

global mean to region 19 (Cogley, 2009a; Marzeion et al., 2012). One, 1961 to 2004 mean glacier mass loss estimate based on an ERA-40 driven simulation (Hock et al., 2009), is for a glacier area differing from the RGI region 19. For these reasons, the region, Antarctica and the Subantarctic [19] is excluded from this global glacier mass change assessment. The contribution of region 19 to sea level is assumed to be within the uncertainty bounds of the Antarctic Ice Sheet assessment (Section 4.4.2). While Hirabayashi et al. (2013) exclude the Antarctic and Greenland from their simulations and Leclercq et al (2011) implicitly include Greenland, both Cogley (2009a) and Marzeion et al. (2012) explicitly estimate mass changes in Greenland. In Figure 4.12, cumulative mass changes and corresponding rates are shown for global glaciers excluding regions 5 and 19 (bold lines), and also for global glaciers excluding only region 19 (thin lines). The cumulative curves are normalized such that their 1986–2005 averages are all zero.

The arithmetic-mean estimate of Leclercq et al. (2011) indicates continuous mass loss from glaciers after about 1850 (Figure 4.12, panel a, top). During the 1920s their area-weighted extrapolation reaches considerably higher rates (Figure 4.12, panel a, bottom) than the other estimates, but reasons remain unclear. After 1950, mass loss rates including Greenland are all within the uncertainty bounds of those that exclude Greenland, except for the 2001–2005 period when the Greenland contribution was slightly outside the uncertainty bounds for both the Cogley and the Marzeion et al. estimates. Most notable is the rapid loss from Greenland glaciers in the Marzeion et al. simulations during the 1930s. Other studies support rapid Greenland mass loss around this time (Zeeberg and Forman, 2001; Yde and Knudsen, 2007, and references therein; Bjørk et al., 2012; Zdanowicz et al., 2012), however the neighbouring regions in the Canadian Arctic (south and north) and Iceland have mass loss anomalies an order of magnitude lower than predicted for Greenland in the same simulation. This discrepancy may be an artefact of the uncertainties in the forcing and methods of Marzeion et al. that are considerably larger in the first than in the second half of the 20th century, so that the rates may well be overestimated. The Marzeion et al. rates are also considerably greater in the 1950s and 1960s than in the other studies; during this period, the most rapid losses are in Arctic Canada and the Russian Arctic (Marzeion et al., 2012).

Overall, there is *very high confidence* that globally, the mass loss from glaciers has increased since the 1960s, and this is evident in regional-scale estimates (Figure 4.11). For 2003–2009, Gardner et al. (2013) indicate that some regional (Section 4.3.3.3, Figure 4.11) and also the global time series may overestimate mass loss (Figure 4.12, b, bottom). That glaciers with measured mass balances are concentrated in sub-regions with higher mass losses definitely biases the estimates of Cogley (2009a) (Section 4.3.3.3), but this explanation cannot hold for the Marzeion et al. (2012) time series, for which mass changes are simulated separately for every single glacier in the inventory. It also remains unclear whether the 2003–2009 inconsistency identified by Gardner et al. (2013) applies to earlier times, and if so how it should be reconciled. Neither the evidence nor our level of understanding warrants any simple correction of the longer time series at present.

[INSERT FIGURE 4.12 HERE]

Figure 4.12: Global cumulative (top graphs) and annual (lower graphs) glacier mass change for (a) 1801–2010 and (b) 1961–2010. The cumulative estimates are all set to zero mean over 1986–2005. Estimates are based on glacier length variations (updated from, Leclercq et al., 2011), from area-weighted extrapolations of individual directly and geodetically measured glacier mass budgets (updated from, Cogley, 2009b), and from modelling with atmospheric variables as input (Marzeion et al., 2012; Hirabayashi et al., 2013). Uncertainties are based on comprehensive error analyses in Cogley (2009b) and Marzeion et al. (2012) and on assumptions about the representativeness of the sampled glaciers in Leclercq et al. (2011). Hirabayashi et al (2013) give a bulk error estimate only. For clarity in the bottom panels, uncertainties are only shown for the Cogley and Marzeion curves excluding Greenland (GL). The blue bars (panel a, top) show the number of measured single-glacier mass balances per pentad in the updated Cogley (2009b) time series. The mean 2003–2009 estimate of Gardner et al. (2013) is added to the bottom panel b.

Table 4.5: Average annual rates of global mass change in Gt yr^{-1} and in sea-level equivalents (mm SLE yr^{-1}) for different time periods (Chapter 13) for (a) glaciers around the Greenland Ice Sheet (region 5 as defined by, Rastner et al., 2012), and (b) all glaciers globally, excluding peripheral glaciers around the Antarctic and Greenland ice sheets (see discussion in Section 4.4.2). The values are derived by averaging the results from the references listed and uncertainty ranges give 90% confidence level. The uncertainty calculated for 1971–2009 is also applied for the sub-periods 1993–2009 and 2005–2009. The global values for 2003–2009 from Gardner et al. (2013) are within this likelihood range (italics).

	Reference	a) Greenland glaciers (region 5)		b) All glaciers excluding ice sheet peripheries	
		Gt yr ⁻¹	mm SLE yr ⁻¹	Gt yr ⁻¹	mm SLE yr ⁻¹
1901–1990	Marzeion et al. (2012); Leclercq et al. (2011), updated*	-54 ± 16	0.15 ± 0.05	-197 ± 24	0.54 ± 0.07
1971–2009	Cogley (2009a); Marzeion et al. (2012)	-21 ± 10	0.06 ± 0.03	-226 ± 135	0.62 ± 0.37
1993–2009	Cogley (2009a); Marzeion et al. (2012)	-37 ± 10	0.10 ± 0.03	-275 ± 135	0.76 ± 0.37

Notes:

*isolation of (a) from (b) made by applying the respective annual ratios in Marzeion et al. (2012)

Table 4.5 summarizes global-scale glacier mass losses for different periods relevant to discussions on sea level change (Chapter 13) and the global energy budget (Chapter 3). Values are given separately for the Greenland glaciers alone [region 5] and for all glaciers excluding those in regions 5 and 19, which are included in the assessment of ice sheets (Section 4.4.2). For the more recent periods, the time series of Cogley (2009a) and Marzeion et al. (2012) are combined, while for 1901–1990 the Leclercq et al. (2011) series were separated by area-weighting and combined with the Marzeion et al. 2012 values. Each rate in Table 4.5 is thus the arithmetic mean of two series, with a confidence bound calculated from their difference, and assessed to represent the 90% likelihood range. Because differences between the two time-series vary considerably, the average confidence bound of 1971–2009 is also applied uniformly to the two sub-periods 1993–2009 and 2005–2009. The 2003 to 2009 estimate of Gardner et al. (2013) is lower than the Cogley and Marzeion averages but those for all glaciers excluding regions 5 and 19 are within the 2005–2009 90% confidence bound. The 1991–2009 assessment is shown as a cumulative time series in Section 4.8 (see, Figure 4.25). Earlier studies of the long-term contribution of glaciers to sea level change (Meier, 1984; Zuo and Oerlemans, 1997; Gregory and Oerlemans, 1998; Kaser et al., 2006; Lemke et al., 2007; Oerlemans et al., 2007; Hock et al., 2009, with removal of Antarctic glacier contribution) all give smaller estimates than those assessed here.

[START BOX 4.1 HERE]

Box 4.1: Interactions of Snow within the Cryosphere

Snow is just one component of the cryosphere, but snow also sustains ice sheets and glaciers, and has strong interactions with all the other cryospheric components, except sub-sea permafrost. For example, snow can affect the rate of sea-ice production, and can alter frozen ground through its insulating effect. Snowfall and the persistence of snow cover are strongly dependent on atmospheric temperature and precipitation, and are thus likely to change in complex ways in a changing climate (e.g. Brown and Mote, 2009).

For Earth's climate in general, and more specifically, the cryospheric components on which snow falls, the two most important physical properties of snow are its high albedo (reflectivity of solar radiation) and its low thermal conductivity, which results because its high air-content makes it an excellent thermal insulator. Both factors substantially alter the flux of energy between the atmosphere and the material beneath the snow cover. Snow also has a major impact on the total energy balance of the Earth's surface because large regions in the northern hemisphere are seasonally covered by snow (e.g., Barry and Gran, 2011). When seasonal snow is melting, snow is also an important fresh water resource.

The high albedo of snow has a strong impact on the radiative energy balance of all surfaces on which it lies, most of which (including glaciers and sea ice) are much less reflective. For example, the albedo of bare glacier or sea ice is typically only 20–30%, and hence 70–80% of solar radiation is absorbed at the surface. For ice at the melting point, this energy melts the ice. With a fresh snow cover over ice, the albedo changes to 80% or even higher and melting is greatly reduced (e.g., Oerlemans, 2001). The effect is similar for other land surfaces – bare soil, frozen ground, low-lying vegetation – but here the thermal properties of the snow cover also play an important role by insulating the ground from changes in ambient air temperature.

While an insulating snow cover can reduce the growth of sea ice, a heavy snow load, particularly in the Antarctic, often depresses the sea ice surface below sea level and this leads to faster transformation of snow

to ice (see FAQ 4.2). Even without flooding, the basal snow layer on Antarctic sea ice tends to be moist and saline because brine is wicked up through the snow cover. In regions of heavily ridged and deformed sea ice, snow redistributed by wind, smoothes the ice surface, reducing the drag of the air on the ice and thus slowing ice drift, and reducing heat exchange (Massom et al., 2001).

For frozen ground, the insulation characteristics of snow cover are particularly important. If the air above is colder than the material on which it lies, the presence of snow will reduce heat transfer upwards, especially for fresh snow with a low-density. This could, for example, reduce the seasonal freezing of soil, slow down the freezing of the active-layer (seasonally thawed layer), or protect permafrost from cooling. Alternatively, if the air is warmer than the material beneath the snow, heat transfer downwards from the air is reduced and the presence of snow cover can increase the thickness of seasonal soil freeze and protect permafrost from warming. Which process applies depends on the timing of the snowfall, its thickness, and its duration (e.g., Zhang, 2005; Smith et al., 2012).

For the above reasons, the timing of snowfall and the persistence of snow cover are of major importance. Whereas snow falling on glaciers and ice sheets in summer has a strongly positive (sustaining) effect on the mass budget, early snow cover can reduce radiative and conductive cooling and freezing of the active layer. During winter, snowfall is the most important source of nourishment for most glaciers, but radiative cooling of frozen ground is strongly reduced by thick snow cover (Zhang, 2005).

[END BOX 4.1 HERE]

4.4 Ice Sheets

4.4.1 Background

Since AR4, satellite, airborne and in situ observations have greatly improved our ability to identify and quantify change in the vast polar ice sheets of Antarctica and Greenland. As a direct consequence, our understanding of the underlying drivers of ice-sheet change is also much improved. These observations and the insights they yield are discussed below, while the attribution of recent ice sheet change, projection of future changes in ice sheets, and their future contribution to sea level rise are discussed elsewhere (Chapter 10 and Chapter 13 respectively).

4.4.2 Changes in Mass of Ice Sheets

The current state of mass balance of the Greenland and Antarctic ice sheets is assessed below, but is introduced by a discussion of the improvements in techniques of measurement and understanding of the change made since AR4 (e.g., Lemke et al., 2007; Cazenave et al., 2009; Chen et al., 2011).

4.4.2.1 Techniques

The three broad techniques for measuring ice-sheet mass balance are the mass budget method, repeated altimetry, and measurement of temporal variations in the Earth's gravity field. Each method has been applied to both ice sheets by multiple groups, and over time scales ranging from multiple years to decades (Figure 4.13 and Figure 4.14). The peripheral glaciers, surrounding but not strictly a part of the ice sheets, are not treated in the same manner by each technique. Peripheral glaciers are generally excluded from estimates using the mass budget method, they are sometimes, but not always, included in altimetric estimates, and they are almost always included in gravity estimates.

[INSERT FIGURE 4.13 HERE]

Figure 4.13: Key variable related to the determination of the Greenland ice sheet mass changes. (a) mean surface mass balance for 1989–2004 from regional atmospheric climate modelling (Ettema et al., 2009); (b) ice sheet velocity for 2007–2009 determined from satellite data, showing fastest flow in red, fast flow in blue, and slower flow in green and yellow (Rignot and Mouginot, 2012); (c) changes in ice sheet surface elevation for 2003–2008 determined from ICESat altimetry, with elevation decrease in red to increase in blue (Pritchard et al., 2009). (d-e) Temporal evolution of ice loss determined from GRACE time-variable gravity, shown in centimetres of water per year for the periods (a) 2003–2012, (b) 2003–2006 and (c) 2006–2012, colour coded red (loss) to blue (gain) (Velicogna, 2009). Fields shown in (a) and (b) are used together with ice thickness (see Figure 4.18) in the mass budget method.

[INSERT FIGURE 4.14 HERE]

Figure 4.14: Key fields relating to the determination of Antarctica ice sheet mass changes. (a) mean surface mass balance for 1989–2004 from regional atmospheric climate modelling (van den Broeke et al., 2006); (b) ice sheet velocity for 2007–2009 determined from satellite data, showing fastest flow in red, fast flow in blue, and slower flow in green and yellow (Rignot et al., 2011a); (c) changes in ice sheet surface elevation for 2003–2008 determined from ICESat altimetry, with elevation decrease in red to increase in blue (Pritchard et al., 2009). (d–e) Temporal evolution of ice loss determined from GRACE time-variable gravity, shown in centimetres of water per year for the periods (a) 2003–2012, (b) 2003–2006 and (c) 2006–2012, colour coded red (loss) to blue (gain) (Velicogna, 2009). Fields shown in (a) and (b) are used together with ice thickness (see Figure 4.18) in the mass budget method.

4.4.2.1.1 Mass budget method

The mass budget method (see Glossary) relies on estimating the difference between net surface balance over the ice sheet (input) and perimeter ice discharge flux (output). This method requires comparison of two very large numbers, and even small percentage errors in either may result in large errors in total mass balance. For ice discharge, perimeter fluxes are calculated from measurements of ice velocity and ice thickness at the grounding line. Knowledge of perimeter fluxes has improved significantly since AR4 for both ice sheets (Rignot et al., 2011b) as a result of more complete ice-thickness data (Bamber et al., 2013; Fretwell et al., 2013) and velocity data from satellite radar interferometry and other techniques (Joughin et al., 2010b; Rignot et al., 2011a). However, incomplete ice thickness mapping still causes uncertainties in ice discharge of 2–15% in Antarctica (Rignot et al., 2008b) and 10% in Greenland (Howat et al., 2011; Rignot et al., 2011c).

Regional atmospheric climate models (see Glossary) verified using independent in situ data are increasingly preferred to produce estimates of surface mass balance over models that are recalibrated or corrected with in situ data (Box et al., 2009), downscaling of global re-analysis data (see Glossary) (Hanna et al., 2011), or interpolation of in-situ measurements (Arthern et al., 2006; Bales et al., 2009). In Antarctica, surface mass balance (excluding ice shelves) for 1979–2010 is estimated at $1983 \pm 122 \text{ Gt yr}^{-1}$ (van de Berg et al., 2006; Lenaerts et al., 2012) with interannual variability of 114 Gt yr^{-1} driven by snowfall variability (Figure 4.14). Comparison with 750 in situ observations indicates an overall uncertainty of 6% for total ice sheet mass balance, ranging from 5–20% for individual drainage basins (van de Berg et al., 2006; Rignot et al., 2008b; Lenaerts et al., 2012; Shepherd et al., 2012). In Greenland, total snowfall (697 Gt yr^{-1}) and rainfall (46 Gt yr^{-1}) minus runoff (248 Gt yr^{-1}) and evaporation/sublimation (26 Gt yr^{-1}) yield a surface mass balance of $469 \pm 82 \text{ Gt yr}^{-1}$ for 1958–2007 (Ettema et al., 2009). The 17% uncertainty is based on a comparison of model outputs with 350 in situ accumulation observations and, in the absence of runoff data, an imposed 20% uncertainty in runoff (Howat et al., 2011). Interannual variability in surface mass balance is large (107 Gt yr^{-1}) due to the out-of-phase relationship between the variability in precipitation (78 Gt yr^{-1}) and runoff (67 Gt yr^{-1}).

4.4.2.1.2 Repeated altimetry

Repeated altimetric survey allows measurement of rates of surface-elevation change, and after various corrections (for changes in snow density and bed elevation; or if the ice is floating, for tides and sea level) reveals changes in ice sheet mass. Satellite radar altimetry (SRALT) has been widely used (Thomas et al., 2008b; Wingham et al., 2009), as has laser altimetry from airplanes (Krabill et al., 2002; Thomas et al., 2009) and satellites (Pritchard et al., 2009; Abdalati et al., 2010; Sorensen et al., 2011; Zwally et al., 2011). Both radar and laser methods have significant challenges. The field-of-view of early SRALT sensors was ~20 km diameter, and as a consequence, interpretation of the data they acquired over ice sheets with undulating surfaces or significant slopes was complex. Similarly, for radar altimeters, estimates are affected by penetration of the radar signal below the surface, which depends on characteristics such as snow density and wetness, and by wide orbit separation (Thomas et al., 2008b). Errors in surface-elevation change are typically determined from the internal consistency of the measurements, often after iterative removal of surface elevation-change values that exceed some multiple of the local value of their standard deviation; this results in very small error estimates (Zwally et al., 2005).

Laser altimeters have been used from aircraft for many years, but satellite laser altimetry, available for the first time from NASA's ICESat satellite launched in 2003, has provided many new results since AR4. Laser altimetry is easier to validate and interpret than radar data; the field-of-view is small (1 m diameter for airborne lasers, 60 m for ICESat), and there is negligible penetration below the surface. However, clouds

limit data acquisition, and accuracy is affected by atmospheric conditions, laser-pointing errors, and data scarcity.

Knowledge of the density of the snow and firn in the upper layers of an ice sheet is required to convert altimetric measurements to mass change. However snow densification rates are sensitive to snow temperature and wetness. Warm conditions favour more rapid densification (Arthern et al., 2010; Li and Zwally, 2011). Consequently, recent Greenland warming has probably caused surface lowering simply from this effect. Corrections are inferred from models that are difficult to validate and are typically $<2 \text{ cm yr}^{-1}$. ICESat derived surface elevation changes supplemented with differenced ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) satellite digital elevation models were used for outlet glaciers in southeast Greenland (Howat et al., 2008) and for the northern Antarctic Peninsula (Shuman et al., 2011). Laser surveys from airborne platforms over Greenland yield elevation estimates accurate to 10 cm along reference targets (Krabill et al., 1999; Thomas et al., 2009) and 15 cm for ICESat using ground-based high-resolution GPS measurements (Siegfried et al., 2011). For a 5-year separation between surveys, this is an uncertainty of 2.0 cm yr^{-1} for airborne platforms and 3 cm yr^{-1} for ICESat.

Early in 2013, NASA released an elevation correction for ICESat (National Snow and Ice Data Center, 2013) that is relevant to several studies cited in this chapter, but was not produced too late to be included in those studies. This correction improves shot-to-shot variability in ICESat elevations, although spatial averaging and application of inter-campaign bias corrections derived from calibration data and used in many studies, already mitigates the impact of the higher variability. The correction also changes elevation trend estimates over the 2003–2009 ICESat mission period by up to -1.4 cm yr^{-1} .

To date, a thorough treatment of the impact of this finding has not been published in the peer-reviewed literature, but the overall magnitude of the effect is reported to be at the level of 1.4 cm yr^{-1} . For many studies of glaciers, ice sheets and sea ice this is substantially lower (in some cases, an order of magnitude lower) than the signal of change, but elsewhere (e.g. for elevation changes in East Antarctica) it may have an impact. However, multiple lines of evidence, of which ICESat is only one, are used to arrive at the conclusions presented in this chapter. To the degree to which it can be assessed, there is *high confidence* that the substantive conclusions this chapter will not be affected by revisions of the ICESat data products.

4.4.2.1.3 Temporal variations in Earth gravity field

Since 2002, the GRACE (Gravity Recovery and Climate Experiment) satellite mission has surveyed Earth's time-variable gravity field. Time-variable gravity provides a direct estimate of the ice-mass change at a spatial resolution of about 300 km (Wahr, 2007). GRACE data yielded early estimates of trends in ice-mass changes over the Greenland and Antarctic ice sheets and confirmed regions of ice loss in coastal Greenland and West Antarctica (Luthcke et al., 2006; Velicogna and Wahr, 2006b, 2006a). With extended time series, now more than ten years, estimates of ice sheet mass change from GRACE have lower uncertainties than in AR4 (e.g., Harig and Simons, 2012; King et al., 2012). The ice-loss signal from the last decade is also more distinct because the numbers have grown significantly higher (e.g., Wouters et al., 2008; Cazenave et al., 2009; Chen et al., 2009; Velicogna, 2009). The estimates of ice loss based on data from GRACE vary between published studies due to the time-variable nature of the signal, along with other factors that include: (1) data-centre specific processing, (2) specific methods used to calculate the mass change, and (3) contamination by other signals within the ice sheet (e.g., glacial isostatic adjustment or GIA, see Glossary) or outside the ice sheet (continental hydrology, ocean circulation). Many of these differences have been reduced in studies published since AR4, resulting in greater agreement between GRACE estimates (Shepherd et al., 2012).

In Antarctica, the GIA signal is similar in magnitude to the ice-loss signal, with an uncertainty of $\pm 80 \text{ Gt yr}^{-1}$ (Velicogna and Wahr, 2006b; Riva et al., 2009; Velicogna, 2009). Correction for the GIA signal is addressed using numerical models, (e.g., Ivins and James, 2005; Paulson et al., 2007; Peltier, 2009). A comparison of recent GIA models (Tarasov and Peltier, 2002; Fleming and Lambeck, 2004; Peltier, 2004; Ivins and James, 2005; Simpson et al., 2009; Whitehouse et al., 2012) with improved constraints on ice-loading history, indicate better agreement with direct observations of vertical land movements (Thomas et al., 2011a), despite a potential discrepancy between far-field sea-level records and common Northern-hemisphere deglaciation models. In Greenland, the GIA correction is less than 10% of the GRACE signal with an error of $\pm 19 \text{ Gt yr}^{-1}$. However, since the GIA rate is constant over the satellite's lifetime, GIA uncertainty does not affect the

estimate of any change in the rate of ice mass-loss (acceleration/deceleration). In Antarctica, the adoption of new GIA models has resulted in a lowering of estimated ice-sheet mass loss (King et al., 2012; Shepherd et al., 2012).

In addition to GRACE, the elastic response of the crustal deformation shown in GPS measurements of uplift rates confirms increasing rates of ice loss in Greenland (Khan et al., 2010b; Khan et al., 2010a) and Antarctica (Thomas et al., 2011a). Analysis of a 34-year time series of Earth's oblateness (J2) by satellite laser ranging also suggests that ice loss from Greenland and Antarctica has progressively dominated the change in oblateness trend since the 1990s (Nerem and Wahr, 2011).

4.4.2.2 Greenland

There is *very high confidence* that the Greenland Ice Sheet has lost ice and contributed to sea level rise over the last two decades (Ewert et al., 2012; Sasgen et al., 2012; Shepherd et al., 2012). Recent GRACE results are in better agreement than in AR4 as discussed above (Baur et al., 2009; Velicogna, 2009; Pritchard et al., 2010; Wu et al., 2010; Chen et al., 2011; Schrama and Wouters, 2011). Altimetry missions report losses comparable to those from the mass budget method and from the time-variable gravity method (Thomas et al., 2006; Zwally et al., 2011) (Figure 4.13f).

Figure 4.15 shows the cumulative ice mass loss from the Greenland Ice Sheet over the period 1992–2012 derived from 18 recent studies made by 14 different research groups (Baur et al., 2009; Cazenave et al., 2009; Slobbe et al., 2009; Velicogna, 2009; Pritchard et al., 2010; Wu et al., 2010; Chen et al., 2011; Rignot et al., 2011c; Schrama and Wouters, 2011; Sorensen et al., 2011; Zwally et al., 2011; Ewert et al., 2012; Harig and Simons, 2012; Sasgen et al., 2012). These studies do not include earlier estimates from the same researchers when those have been updated by more recent analyses using extended data. They include estimates made from satellite gravimetry, satellite altimetry and the mass budget method. Details of the studies used for Greenland are listed in Appendix Table 4.A.1 (additional studies not selected are listed in Table 4.A.2).

The mass balance for each year is estimated as a simple average of all the selected estimates available for that particular year. Figure 4.15 shows an accumulation of these estimates since an arbitrary zero on 01 January 1992. The number of estimates available varies with time, with as few as two estimates per year in the 1990s and up to 18 per year from 2004. The cumulative uncertainty in Figure 4.15 is based on the uncertainty cited in the original studies which, when the confidence level is not specifically given, is assumed to be at the 1- σ level. However, the annual estimates from different studies often do not overlap within the original uncertainties, and hence the error limits used in this assessment are derived from the absolute maximum and minimum mass balance estimate for each year. These have been converted to the 90% confidence interval (5–95%, or 1.65- σ). The cumulative error is weighted by $1/\sqrt{n}$, where n is the number of years accumulated.

[INSERT FIGURE 4.15 HERE]

Figure 4.15: Cumulative ice mass loss (and sea level equivalent, SLE) from Greenland derived as annual averages from 18 recent studies (see main text and Appendix 4.A for details).

Despite year-to-year differences between the various original analyses, this multi-study assessment yields *very high confidence* that Greenland has lost mass over the last two decades, and *high confidence* that the rate of loss has increased. The increase is also shown in several individual studies (Velicogna, 2009; Chen et al., 2011; Rignot et al., 2011c; Zwally et al., 2011) (Figure 4.13a-c). The average ice mass change to Greenland from the present assessment has been -121 [-149 to -94] Gt yr^{-1} (a sea level equivalent of 0.33 [0.41 to 0.26] mm yr^{-1}) over the period 1993 to 2010, and -229 [-290 to -169] Gt yr^{-1} (0.63 [0.80 to 0.47] mm yr^{-1} sea level equivalent) over the period 2005–2010.

Greenland changes that include and exclude peripheral glaciers cannot be cleanly separated from the mixture of studies and techniques in this assessment, but for the post 2003 period there is a prevalence of gravity studies, which do include the peripheral glaciers. Hence, although the estimated mass change in Greenland peripheral glaciers of -38 ± 7 Gt yr^{-1} over the period 2003–2009 (Gardner et al., 2013) is discussed in Section

4.3.3 (Table 4.5), these changes are included within the values for ice-sheet change quoted above, and not as part of the total mass change for glaciers.

A reconciliation of apparent disparities between the different satellite methods was made by the Ice-sheet Mass Balance Intercomparison Experiment (IMBIE) (Shepherd et al., 2012). This intercomparison combined an ensemble of satellite altimetry, interferometry, airborne radio-echo sounding and airborne gravimetry data, and regional atmospheric climate model output products, for common geographical regions and for common time intervals. Good agreement was obtained between the estimates from the different methods and, while the uncertainties of any method are sometimes large, the combination of methods considerably improves the overall certainty. (Note that, Shepherd et al., 2012, also cannot cleanly separate estimates including or excluding peripheral glaciers). For Greenland, Shepherd et al. (2012) estimate a change in mass over the period 1992–2011, averaged across the ensemble for each method, of $-142 \pm 49 \text{ Gt yr}^{-1}$ ($0.39 \pm 0.14 \text{ mm yr}^{-1}$ of sea level rise). For the same period, this present assessment, which averages across individual studies, yields a slightly slower loss, with a rate of mass change of $-125 \pm 25 \text{ Gt yr}^{-1}$ at the 90% confidence level ($0.34 \pm 0.07 \text{ mm yr}^{-1}$ SLE). Averaging across technique ensembles in the present assessment yields a loss at a rate of -129 Gt yr^{-1} (0.36 mm). Shepherd et al. (2012) confirm an increasing mass loss from Greenland, although they also identify mass balance variations over intermediate (2 to 4-year) periods.

The mass budget method shows that ice loss from the Greenland Ice Sheet is partitioned in approximately similar amounts between surface mass balance (i.e., runoff) and discharge from ice flow across the grounding line (van den Broeke et al., 2009) (*medium confidence*). However there are significant differences in the relative importance of ice-discharge and surface mass balance in various regions of Greenland (Howat et al., 2007; Pritchard et al., 2009; van den Broeke et al., 2009; Sasgen et al., 2012). Dynamic losses dominate in southeast and central west regions, and also influence losses in northwest Greenland, whereas in the central north, southwest and northeast sectors, changes in surface mass balance appear to dominate.

Over the last two decades, surface mass balance has become progressively more negative as a result of an increase in runoff and enhanced ice discharge across the grounding line due to the increased speed of some outlet glaciers. Altimetric measurements of surface height suggest slight inland thickening in 1994–2006 (Thomas et al., 2006, 2009), but this is not confirmed by regional atmospheric climate model outputs for the period 1957–2009 (Ettema et al., 2009), nor recent ice core (see Glossary) data (Buchardt et al., 2012), hence there is *low confidence* in an increase in precipitation in Greenland in recent decades. Probable changes in accumulation are however exceeded by the increased runoff especially since 2006 (van den Broeke et al., 2009). The four highest runoff years over the last 140 years occurred since 1995 (Hanna et al., 2011).

The total surface melt area has continued to increase since AR4 and has accelerated in the past few years (Fettweis et al., 2011; Tedesco et al., 2011), with an extreme melt event covering >90% of the ice sheet for a few days in July 2012 (Nghiem et al., 2012; Tedesco et al., 2013). Annual surface mass balance in 2011–2012 was 2- σ below the 2003–2012 mean. Such extreme melt events are rare and have been observed in ice core records only twice, once in 1889, and once more, seven centuries earlier in the Medieval Warm Period (Meese et al., 1994; Alley and Anandakrishnan, 1995). Over the past decade, the surface albedo of the Greenland ice sheet has decreased by up to 18% in coastal regions, with a statistically significant increase over 87% of the ice sheet due to melting and snow metamorphism, allowing more solar energy to be absorbed for surface melting (Box et al., 2012).

GRACE results show ice loss was largest in southeast Greenland during 2005 and increased in the northwest after 2007 (Khan et al., 2010a; Chen et al., 2011; Schrama and Wouters, 2011; Harig and Simons, 2012). Subsequent to 2005, ice loss decreased in the southeast. These GRACE results agree with measurements of ice discharge from the major outlet glaciers that confirm the dominance of dynamic losses in these regions (van den Broeke et al., 2009). In particular, major outlet glacier speed-up reported in AR4 occurred in west Greenland between 1996 and 2000 (Rignot and Kanagaratnam, 2006) and in southeast Greenland from 2001 to 2006 (Rignot and Kanagaratnam, 2006; Joughin et al., 2010b). In the southeast, many outlet glaciers slowed after 2005 (Howat et al., 2007; Howat et al., 2011), with many flow speeds decreasing back towards those of the early 2000s (Murray et al., 2010; Moon et al., 2012), although most are still flowing faster and discharging more ice into the ocean than they did in 1996 (Rignot and Kanagaratnam, 2006; Howat et al., 2011).

In the northwest, the increase in the rate of ice loss from 1996–2006 to 2006–2010 was probably caused partially by a higher accumulation in the late 1990s compared to earlier and later years (Sasgen et al., 2012), but ice dynamic changes also played a role as outlet glaciers in the northwest showed an increase in speed from 2000 to 2010, with the greatest increase from 2007 to 2010 (Moon et al., 2012). Longer-term observations of surface topography in the northwest sector confirm the dynamic component of this mass loss and suggest two periods of loss in 1985–1993 and 2005–2010 separated by limited mass changes (Kjaer et al., 2012). In the southeast, an 80-year long record reveals that many land-terminating glaciers retreated more rapidly in the 1930s compared to the 2000s, but marine-terminating glaciers retreated more rapidly during the recent warming (Bjørk et al., 2012).

4.4.2.3 Antarctica

Antarctic results from the gravity method are also now more numerous and consistent than in AR4 (Figure 4.14a-c). Methods combining GPS and GRACE at the regional level indicate with *high confidence* that the Antarctic Peninsula is losing ice (Ivins et al., 2011; Thomas et al., 2011a). In other areas, large uncertainties remain in the global GRACE-GPS solutions (Wu et al., 2010).

Results from the mass budget method have improved significantly since AR4 (van den Broeke et al., 2006; Rignot et al., 2008b; Rignot et al., 2011a; Lenaerts et al., 2012). Reconstructed snowfall from regional atmospheric climate models indicates higher accumulation along the coastal sectors than in previous estimates, but little difference in total snowfall. There is *medium confidence* that there has been no long-term trend in the total accumulation over the continent over the past few decades (Monaghan et al., 2006; van den Broeke et al., 2006; Bromwich et al., 2011; Frezzotti et al., 2012; Lenaerts et al., 2012). Although anomalies in accumulation have been noted in recent decades in Eastern Wilkes Land (Boening et al., 2012; Shepherd et al., 2012) and Law Dome (Van Ommen and Morgan, 2010) in East Antarctica, their overall impact on total mass balance is not significant. Satellite laser altimetry indicates that ice volume changes are concentrated on outlet glaciers and ice streams (see Glossary), as illustrated by the strong correspondence between areas of thinning (Figure 4.14f) and areas of fast flow (Figure 4.14e) (Pritchard et al., 2009).

Figure 4.16 shows the cumulative ice mass loss from the Antarctic Ice Sheet over the period 1992–2012 derived from recent studies made by 10 different research groups (Cazenave et al., 2009; Chen et al., 2009; E et al., 2009; Horwath and Dietrich, 2009; Velicogna, 2009; Wu et al., 2010; Rignot et al., 2011c; Shi et al., 2011; King et al., 2012; Tang et al., 2012). These studies do not include earlier estimates from the same researchers when those have been updated by more recent analyses using extended data. They include estimates made from satellite gravimetry, satellite altimetry and the mass balance method. Details of the studies used for Antarctica are listed in Table 4.A.3 (additional studies not selected are listed in Table 4.A.4). The number of estimates available varies with time, with only one estimate per year in the 1990s and up to 10 per year from 2003. The cumulative curves and associated errors are derived in the same way as those for Figure 4.15 (see above).

[INSERT FIGURE 4.16 HERE]

Figure 4.16: Cumulative ice mass loss (and sea level equivalent, SLE) from Antarctica derived as annual averages from 10 recent studies (see main text and Appendix 4.A for details).

Overall, there is *high confidence* that the Antarctic Ice Sheet is currently losing mass. The average ice mass change to Antarctica from the present assessment has been -97 [-135 to -58] Gt yr^{-1} (a sea level equivalent of 0.27 mm yr^{-1} [0.37 to 0.16] mm yr^{-1}) over the period 1993–2010, and -147 [-221 to -74] Gt yr^{-1} (0.41 [0.61 to 0.20] mm yr^{-1}) over the period 2005–2010. These assessments include the Antarctic peripheral glaciers.

The recent IMBIE intercomparison (Shepherd et al., 2012) for Antarctica, where the GIA signal is less well known than in Greenland, used two new GIA models (an updated version of, Ivins and James, 2005; for details see, Shepherd et al., 2012; Whitehouse et al., 2012). These new models had the effect of reducing the estimates of East Antarctic ice mass loss from GRACE data, compared with some previous estimates. For Antarctica, Shepherd et al. (2012) estimate an average change in mass for 1992–2011 of -71 ± 53 Gt yr^{-1} (0.20 ± 0.15 mm yr^{-1} of sea level equivalent). For the same period this present assessment estimates a loss of

$88 \pm 35 \text{ Gt yr}^{-1}$ at the 90% confidence level ($0.24 \pm 0.10 \text{ mm yr}^{-1}$ SLE). Averaging across technique ensembles in the present assessment, rather than individual estimates, yields no significant difference.

There is *low confidence* that the rate of Antarctic ice loss has increased over the last two decades (Chen et al., 2009; Velicogna, 2009; Rignot et al., 2011c; Shepherd et al., 2012), however, GRACE data gives *medium confidence* of increasing loss over the last decade (Chen et al., 2009; Velicogna, 2009) (Figure 4.16). For GRACE, this conclusion is independent of the GIA signal, which is constant over the measurement period. The mass budget method suggests that the increase in loss from the mass budget method is caused by an increase in glacier flow-speed in the eastern part of the Pacific sector of West Antarctica (Rignot, 2008; Joughin et al., 2010a) and the Antarctic Peninsula (Scambos et al., 2004; Pritchard and Vaughan, 2007; Rott et al., 2011). Comparison of GRACE and the mass budget method for 1992–2010 indicates an increase in the rate of ice loss of, on average, $14 \pm 2 \text{ Gt yr}^{-1}$ per year compared with $21 \pm 2 \text{ Gt yr}^{-1}$ per year on average for Greenland during the same time period (Rignot et al., 2011c). The recent IMBIE analysis (Shepherd et al., 2012) shows that the West Antarctic Ice Sheet and the Antarctic Peninsula are losing mass at an increasing rate, but that East Antarctica gained an average of $21 \pm 43 \text{ Gt yr}^{-1}$ between 1992 and 2011. Zwally and Giovinetto (2011) also estimate a mass gain for East Antarctica ($+16 \text{ Gt yr}^{-1}$ between 1992 and 2001). However, their reassessment of Antarctic change, which attempted to correct for regions of the ice sheet not included in the mass budget method (see Section 4.4.2.1.1), is not supported by the subsequent Shepherd et al. (2012) analysis which suggests that the missing regions contribute little to the total mass change.

In the near-absence of surface runoff and, as discussed above no evidence of multi-decadal change in total snowfall, Antarctic multi-decadal changes in grounded ice mass must be due to increased ice discharge, although the observational record of ice dynamics only extends from the 1970s. Over shorter time scales, however, the interannual to decadal variability in snowfall has an important impact on ice sheet mass balance (Rignot et al., 2011c).

The three techniques are in excellent agreement as to the spatial pattern of ice loss (thinning) and gain (thickening) over Antarctica (Figure 4.14). The largest ice losses are located along the northern tip of the Antarctic Peninsula where the collapse of several ice shelves in the last two decades triggered the acceleration of outlet glaciers, and in the Amundsen Sea, in West Antarctica (Figure 4.14c). On the Antarctic Peninsula, there is evidence that precipitation has increased (Thomas et al., 2008a) but the resulting ice-gain is insufficient to counteract the losses (Wendt et al., 2010; Ivins et al., 2011). There is *medium confidence* that changes in the Amundsen Sea region are due to the thinning of ice shelves (Pritchard et al., 2012) by a warm ocean (Jacobs et al., 2011), which caused grounding line retreat (1 km yr^{-1}) (Joughin et al., 2010a) and glacier thinning (Wingham et al., 2009). Indications of dynamic change are also evident in East Antarctica, primarily around Totten Glacier, from GRACE (Chen et al., 2009), altimetry (Wingham et al., 2006; Shepherd and Wingham, 2007; Pritchard et al., 2009; Flament and Remy, 2012), and satellite radar interferometry (Rignot et al., 2008b). The contribution to the total ice loss from these areas is however small and not well understood.

4.4.2.4 Ice Shelves and Floating Ice Tongues

As much as 74% of the ice discharged from the grounded ice sheet in Antarctica passes through ice shelves and floating ice tongues (Bindschadler et al., 2011). Ice shelves help to buttress and restrain flow of the grounded ice (Rignot et al., 2004; Scambos et al., 2004; Hulbe et al., 2008), and so changes in thickness (Shepherd et al., 2003; Shepherd et al., 2010; Fricker and Padman, 2012), and extent (Doake and Vaughan, 1991; Scambos et al., 2004) of ice shelves influence current ice sheet change. Indeed, nearly all of the outlet glaciers and ice streams that are experiencing high rates of ice loss flow into thinning or disintegrated ice shelves (Pritchard et al., 2012), although many of the larger ice shelves exhibit stable conditions (King et al., 2009; Shepherd et al., 2010; Pritchard et al., 2012).

Around the Antarctic Peninsula, the reduction in ice-shelf extent has been ongoing for several decades (Cook and Vaughan, 2010; Fricker and Padman, 2012), and has continued since AR4 with substantial collapse of a section of Wilkins Ice Shelf (Humbert et al., 2010), which had been retreating since the late 1990s (Scambos et al., 2000). Overall, 7 of 12 ice shelves around the Peninsula have retreated in recent decades with a total loss of $28,000 \text{ km}^2$, and a continuing rate of loss of around $6,000 \text{ km}^2$ per decade (Cook and Vaughan, 2010).

There is *high confidence* that this retreat of ice shelves along the Antarctic Peninsula has been related to changing atmospheric temperatures (e.g., Scambos et al., 2000; Morris and Vaughan, 2003; Marshall et al., 2006; Holland et al., 2011). There is *low confidence* that changes in the ocean have also contributed (e.g., Shepherd et al., 2003; Holland et al., 2011; Nicholls et al., 2012; Padman et al., 2012).

4.4.3 Total Ice Loss from Both Ice Sheets

The total ice loss from both ice sheets for the twenty years 1992–2011 (inclusive) has been 4,260 [3060 to 5460] Gt, equivalent to 11.7 [8.4 to 15.1] mm of sea level. However, the rate of change has increased with time and most of this ice has been lost in the second decade of the twenty-year period. From the data presented in Figure 4.17, the average loss in Greenland has very likely increased from 34 [–6 to 74] Gt yr^{–1} over the decade 1992–2001 (sea-level equivalent, 0.09 [–0.02 to 0.20] mm yr^{–1}), to 215 [157 to 274] Gt yr^{–1} over the decade 2002–2011 (0.59 [0.43 to 0.76] mm yr^{–1}). In Antarctica, the loss has likely increased 30 [–37 to 97] Gt yr^{–1} (sea level equivalent, 0.08 [–0.10 to 0.27] mm yr^{–1}) for 1992–2001, to 147 [72 to 221] Gt yr^{–1} for 2002–2011 (0.40 [0.20 to 0.61] mm yr^{–1}). Over the last five years (2007–2011), the loss from both ice sheets combined has been equivalent to 1.2 ± 0.4 mm yr^{–1} of sea level (Figure 4.17, Table 4.6).

[INSERT FIGURE 4.17 HERE]

Figure 4.17: Rate of ice sheet loss in sea level equivalent averaged over 5-year periods between 1992 and 2011. These estimates are derived from the data in Figure 4.15 and Figure 4.16.

Table 4.6: Average rates of ice sheet loss given as mm of sea level equivalent, derived as described for Figure 4.15 and Figure 4.16 using estimates listed in Appendix Table 4.A.1 and Table 4.A.3.

Period	Ice sheet loss (mm yr ^{–1} SLE)	
<i>Greenland</i>		
2005–2010 (6-year)	0.63	±0.17
1993–2010 (18-year)	0.33	±0.08
<i>Antarctica</i>		
2005–2010 (6-year)	0.41	±0.20
1993–2010 (18-year)	0.27	±0.11
<i>Combined</i>		
2005–2010 (6-year)	1.04	±0.37
1993–2010 (18-year)	0.60	±0.18

4.4.4 Causes of Changes in Ice Sheets

4.4.4.1 Climatic Forcing

Changes in ice sheet mass balance are the result of an integrated response to climate, and it is imperative that we understand the context of current change within the framework of past changes and natural variability.

4.4.4.1.1 Snowfall and surface temperature

Ice sheets experience large inter-annual variability in snowfall and local trends may deviate significantly from the long-term trend in integrated snowfall. However, as in AR4, the available data do not suggest any significant long-term change in accumulation in Antarctica, except for the Antarctic Peninsula (Monaghan et al., 2006; Ettema et al., 2009; Bromwich et al., 2011) (van den Broeke et al., 2009).

Increasing air temperature will (when above the freezing point) increase the amount of surface melt, and can also increase the moisture bearing capacity of the air, and hence can increase snowfall. Over Greenland, temperature has risen significantly since the early 1990s, reaching values similar to those in the 1930s (Box et al., 2009). The year 2010 was an exceptionally warm year in west Greenland with Nuuk having the warmest year since the start of the temperature record in 1873 (Tedesco et al., 2011). In West Antarctica, the

warming since the 1950s (Steig et al., 2009; Ding et al., 2011; Schneider et al., 2012; Bromwich et al., 2013), the magnitude and seasonality of which are still debated, has not manifested itself in enhanced surface melting (Tedesco and Monaghan, 2009; Kuipers Munneke et al., 2012) nor in increased snowfall (Monaghan et al., 2006; Bromwich et al., 2011; Lenaerts et al., 2012). Statistically significant summer warming has been observed on the east coast of the northern Antarctic Peninsula (Marshall et al., 2006; Chapman and Walsh, 2007), with extension of summer melt duration (Barrand et al., 2013), while East Antarctica has showed summer cooling (Turner et al., 2005). In contrast, the significant winter warming at Faraday/Vernadsky station on the western Antarctic Peninsula is attributable to a reduction of sea ice extent (Turner et al., 2005).

4.4.4.1.2 *Ocean thermal forcing*

Since AR4, observational evidence has contributed to *medium* confidence that the interaction between ocean waters and the periphery of large ice sheets plays a major role in present ice sheet changes (Holland et al., 2008; Pritchard et al., 2012). Ocean waters provide the heat that can drive high melt rates beneath ice shelves (Jacobs et al., 1992; Holland and Jenkins, 1999; Rignot and Jacobs, 2002; Pritchard et al., 2012) and at marine-terminating glacier fronts (Holland et al., 2008; Rignot et al., 2010; Jacobs et al., 2011).

Ocean circulation delivers warm waters to ice sheets. Variations in wind patterns associated with the North Atlantic Oscillation (Jacobs et al., 1992; Hurrell, 1995), and tropical circulations influencing West Antarctica (Ding et al., 2011; Steig et al., 2012), are probable drivers of increasing melt at some ice-sheet margins. In some parts of Antarctica, changes in the Southern Annular Mode (Thompson and Wallace, 2000, see Glossary) may also be important. Observations have established that warm waters of sub-tropical origin are present within several fjords in Greenland (Holland et al., 2008; Myers et al., 2009; Straneo et al., 2010; Christoffersen et al., 2011; Danialt et al., 2011).

Satellite records and *in situ* observations indicate warming of the Southern Ocean (see Chapter 3) since the 1950s (Gille, 2002; Gille, 2008). This warming is confirmed by data from robotic ocean buoys (Argo floats) (Boening et al., 2008) but the observational record remains short and, close to Antarctica, there are only limited observations from ships (Jacobs et al., 2011), short-duration moorings and data from instrumented seals (Charrassin et al., 2008; Costa et al., 2008).

4.4.4.2 *Ice Sheet Processes*

4.4.4.2.1 *Basal lubrication*

Ice flows in part by sliding over the underlying rock and sediment, which is lubricated by water at the ice base: a process known as basal lubrication (see Glossary). In many regions close to the Greenland Ice Sheet margin, abundant summer meltwater on the surface of the ice sheet forms large lakes. This surface water can drain to the ice sheet bed, thus increasing basal water pressure, reducing basal friction and increasing ice flow speed (Zwally et al., 2002b).

Such drainage events are common in southwest and northeast Greenland, but rare in the most rapidly changing southeast and northwest regions (Selmes et al., 2011). The effect can be seen in diurnal flow variations of some land-terminating regions (Das et al., 2008; Shepherd et al., 2009), and after lake-drainage events, when 50–110% short-term speed-up of flow has been observed. However, the effect is temporally and spatially restricted (Das et al., 2008). The summer increase in speed over the annual mean is only ~10–20%, the increase is less at higher elevations (Bartholomew et al., 2011), and observations suggest most lake drainages do not affect ice sheet velocity (Hoffman et al., 2011). Theory and field studies suggest an initial increase in flow rate with increased surface meltwater supply (Bartholomew et al., 2011; Palmer et al., 2011), but if the supply of surface water continues to increase and subglacial drainage becomes more efficient, basal water pressure, and thus basal motion, is reduced (van de Wal et al., 2008; Schoof, 2010; Sundal et al., 2011; Shannon et al., 2012). Overall, there is high confidence that basal lubrication is important in modulating flow in some regions, especially southwest Greenland, but there is also high confidence that it does not explain recent dramatic regional speed-ups that have resulted in rapid increases in ice loss from calving glaciers.

4.4.4.2.2 *Cryo-hydrologic warming*

Percolation and refreezing of surface meltwater that drains through the ice column may alter the thermal regime of the ice sheet on decadal time scales (Phillips et al., 2010). This process is known as cryo-hydrologic warming, and it could affect ice rheology and hence ice flow.

4.4.4.2.3 *Ice shelf buttressing*

Recent changes in marginal regions of the Greenland and Antarctic ice sheets include some thickening and slowdown of outlet glaciers, but mostly thinning and acceleration (e.g., Pritchard et al., 2009; Sorensen et al., 2011), with some glacier speeds increasing two to eightfold (Joughin et al., 2004; Rignot et al., 2004; Scambos et al., 2004; Luckman and Murray, 2005; Rignot and Kanagaratnam, 2006; Howat et al., 2007). Many of the largest and fastest glacier changes appear to be at least partly a response to thinning, shrinkage or loss of ice shelves or floating ice tongues (MacGregor et al., 2012; Pritchard et al., 2012). This type of glacier response is consistent with classical models of ice shelf buttressing proposed 40 years ago (Hughes, 1973; Weertman, 1974; Mercer, 1978; Thomas and Bentley, 1978).

4.4.4.2.4 *Ice-ocean interaction*

Since AR4 it has become far more evident that the rates of submarine melting can be very large (e.g., Motyka et al., 2003). The rate of melting is proportional to the product of ocean thermal forcing (difference between ocean temperature and the in situ freezing point of seawater) and water flow speed at the ice-ocean interface (Holland and Jenkins, 1999). Melt rates along marine-terminating glacier margins are one-to-two orders of magnitude greater than for ice shelves because of the additional buoyancy forces provided by the discharge of sub-glacial melt water at the glacier base (Motyka et al., 2003; Jenkins, 2011; Straneo et al., 2012; Xu et al., 2012). In South Greenland, there is *medium confidence* that the acceleration of glaciers from the mid-1990s to mid-2000s was due to the intrusion of ocean waters of sub-tropical origin into glacial fjords (Holland et al., 2008; Howat et al., 2008; Murray et al., 2010; Straneo et al., 2010; Christoffersen et al., 2011; Motyka et al., 2011; Straneo et al., 2011; Rignot and Mouginot, 2012). Models suggest that the increase in ice melting by the ocean contributed to the reduction of backstress experienced by glaciers and subsequent acceleration (Payne et al., 2004; Schoof, 2007; Nick et al., 2009; Nick et al., 2013; O'Leary and Christoffersen, 2013): changes in the floating mixture of sea ice, iceberg debris and blown snow in front of the glacier may also play a part (Amundson et al., 2010).

4.4.4.2.5 *Iceberg calving*

Calving of icebergs from marine-terminating glaciers and ice-shelves is important in their overall mass balance, but the processes that initiate calving range from seasonal melt-driven processes (Benn et al., 2007) to ocean swells and tsunamis (MacAyeal et al., 2006; Brunt et al., 2011), or the culmination of a response to gradual change (Doake et al., 1998; Scambos et al., 2000). Some of these processes show strong climate influence, while others do not. Despite arguments of rather limited progress in this area (Pfeffer, 2011), there have been some recent advances (Joughin et al., 2008a; Błaszczyk et al., 2009; Amundson et al., 2010; Nick et al., 2010; Otero et al., 2011; Nick et al., 2013) and continental-scale ice sheet models currently rely on improved parameterisations (Alley et al., 2008; Pollard and DeConto, 2009; Levermann et al., 2012). Recently more realistic models have been developed allowing the dependence of calving and climate to be explicitly investigated (e.g., Nick et al., 2013).

4.4.5 *Rapid Ice Sheet Changes*

The estimates of sea-level rise presented in AR4 explicitly excluded future rapid dynamical changes (see Glossary) in ice flow, and stated that “understanding of these processes is limited and there is no consensus on their magnitude”. Considerable efforts have been made since AR4 to fill this knowledge gap. Chapter 13 discusses observed and likely future sea-level, including model projections of changes in the volume stored in the ice sheets: in this section we summarise the processes thought to be potential causes of rapid changes in ice flow, and emphasise new observational evidence that these processes are already underway.

“Rapid ice sheet changes” are defined as changes that are of sufficient speed and magnitude to impact on the mass budget and hence rate of sea level rise on timescales of several decades or shorter. A further consideration is whether and under what circumstances any such changes are “irreversible”, i.e., would take several decades to centuries to reverse under a different climate forcing. For example, an effectively irreversible change might be the loss of a significant fraction of the Greenland Ice Sheet, because at its new

lower (and therefore warmer) surface elevation, the ice sheet would be able to grow thicker only slowly even in a cooler climate (Ridley et al., 2010) (Section 13.4.3.3).

Observations suggest that some observed changes in ice shelves and glaciers on the Antarctic Peninsula are irreversible. These ice bodies continue to experience rapid and irreversible retreat, coincident with air temperatures rising at four to six times the global average rate at some stations (Vaughan et al., 2003), and with warm Circumpolar Deep Water becoming widespread on the western continental shelf (Martinson et al., 2008). Collapse of floating ice shelves on the Antarctic Peninsula, such as the 2002 collapse of the Larsen B Ice Shelf which is unprecedented in the last 10,000 years, has resulted in speed up of tributary glaciers by 300–800% (De Angelis and Skvarca, 2003; Rignot et al., 2004; Rott et al., 2011; Scambos et al., 2004). Even if iceberg calving was to cease entirely, regrowth of the Larsen B ice shelf to its pre-collapse state would take centuries based on the ice-shelf speed and size prior to its collapse (Rignot et al., 2004).

Surface melt that becomes runoff is a major contributor to mass loss from the Greenland Ice Sheet, which results in a lower (hence warmer) ice sheet surface and a lower surface albedo (allowing the surface to absorb more solar radiation), both processes further increase melt. The warm summers of the last two decades (van den Broeke et al., 2009; Hanna et al., 2011), and especially in 2012 (Hall et al., 2013), are unusual in the multi-centennial record. Exceptionally high melt events have affected even the far north of Greenland, e.g., with the partial collapse of the floating ice tongues of Ostensfeld Gletscher and Zachariae Isstrom in 2000–2006 (Moon and Joughin, 2008).

The importance that subsurface warm waters play in melting the periphery of ice sheets in Greenland and Antarctica, and the evolution of these ice sheets has become much clearer since AR4 (see Sections 4.4.3.1 and 4.4.3.2). New observations in Greenland and Antarctica, as well as advances in theoretical understanding, show that regions of ice sheets that are grounded well below sea level are most likely to experience rapid ice mass loss, especially if the supply of heat to the ice margin increases (Schoof, 2007; Holland et al., 2008; Joughin and Alley, 2011; Motyka et al., 2011; Young et al., 2011a; Joughin et al., 2012; Ross et al., 2012) (See also Figure 4.18). Where this ice meets the ocean and does not form an ice shelf, warm waters can increase melting at the ice front, causing undercutting, higher calving rates, ice-front retreat (Motyka et al., 2003; Benn et al., 2007; Thomas et al., 2011a), consequent speed-up and thinning. Surface runoff also increases subglacial water discharge at the grounding line, which enhances ice melting at the ice front (Jenkins, 2011; Xu et al., 2012). Where an ice shelf is present, ice melt by the ocean may cause thinning of the shelf as well as migration of the grounding line further inland into deep basins, with a major impact on buttressing, flow speed and thinning rate (Thomas et al., 2011a).

[INSERT FIGURE 4.18 HERE]

Figure 4.18: Subglacial and seabed topography for Greenland and Antarctica derived from digital compilations (Bamber et al., 2013; Fretwell et al., 2013). Blue areas highlight the marine-based parts of the ice sheets, which are extensive in Antarctica, but in Greenland, relate to specific glaciers troughs. Selected sections through the ice sheet show reverse bed gradients that exist beneath some glaciers in both ice sheets.

The influence of the ocean on the ice sheets is controlled by the delivery of heat to the ice sheet margins, particularly to ocean cavities beneath ice shelf shelves and to calving fronts (Jenkins and Doake, 1991; Jacobs et al., 2011). The amount of heat delivered is a function of the temperature and salinity of ocean waters; ocean circulation; and the bathymetry of continental shelves, in fjords near glacier fronts and beneath ice shelves, most of which are not known in sufficient detail (Jenkins and Jacobs, 2008; Holland et al., 2010; Dinniman et al., 2012; Galton-Fenzi et al., 2012; Padman et al., 2012). Changes in any of these parameters would have a direct and rapid impact on melt rates and potentially on calving fluxes (See Chapter 13).

Ice grounded on a reverse bed-slope, deepening towards the ice sheet interior, is potentially subject to the marine ice sheet instability (Weertman, 1974; Schoof, 2007) (See Chapter 13, Box 13.2). Much of the bed of the West Antarctic Ice Sheet (WAIS) lies below sea level and on a reverse bed-slope, with basins extending to depths greater than 2 km (Figure 4.18). The marine parts of the WAIS contain ~3.4 m of equivalent sea level rise (Bamber et al., 2013; Fretwell et al., 2013) and a variety of evidence strongly suggests that the ice sheet volume has been much smaller than present in the last 1 million years, during periods with temperatures similar to those predicted in the next century (see also, Chapter 5) (Kopp et al., 2009). Potentially unstable marine ice sheets also exist in East Antarctica, e.g., in Wilkes Land (Young et al.,

2011a), and these contain more ice than WAIS (9 m sea level equivalent for Wilkes Land). In northern Greenland, ice is also grounded below sea level, with reverse slopes (Figure 4.18, Joughin et al., 1999).

Observations since AR4 confirm that rapid changes are indeed occurring at the marine margins of ice sheets, and that these changes have been observed to penetrate hundreds of kilometres inland (Pritchard et al., 2009; Joughin et al., 2010b).

The Amundsen Sea sector of West Antarctica is grounded significantly below sea level and is the region of Antarctica changing most rapidly at present. Pine Island Glacier has sped-up 73% since 1974 (Rignot, 2008) and has thinned throughout 1995–2008 at increasing rates (Wingham et al., 2009) due to grounding line retreat. There is *medium confidence* that retreat was caused by the intrusion of warm ocean water into the sub-ice shelf cavity (Jenkins et al., 2010; Jacobs et al., 2011; Steig et al., 2012). The neighbouring Thwaites, Smith and Kohler glaciers are also speeding-up, thinning and contributing to increasing mass loss (Figure 4.14). The present rates of thinning are more than one order of magnitude larger than millennial-scale thinning rates in this area (Johnson et al., 2008). Changes in velocity, elevation, thickness and grounding line position observed in the past 2-3 decades in the Pine Island/Thwaites Glacier sector are not inconsistent with the development of a marine ice sheet instability triggered by a change in climate forcing, but neither are they inconsistent solely with a response to external environmental (probably oceanic) forcing.

In Greenland, there is *medium confidence* that the recent rapid retreat of Jakobshavn Isbrae was caused by the intrusion of warm ocean water beneath the floating ice tongue (Holland et al., 2008; Motyka et al., 2011) combined with other factors, such as weakening of the floating mixture of sea ice, iceberg debris and blown snow within ice rifts (Joughin et al., 2008b; Amundson et al., 2010). There is *medium confidence* that recent variations in southeast Greenland's glaciers have been caused by intrusion of warm waters of sub-tropical origin into glacial fjords. Since AR4 it has become clear that the mid-2000s speed up of southeast Greenland glaciers, which caused a doubling of ice loss from the Greenland ice sheet (Luthcke et al., 2006; Rignot and Kanagaratnam, 2006; Howat et al., 2008; Wouters et al., 2008), was a pulse which was followed by a partial slow down (Howat et al., 2008; Murray et al., 2010). While changes in elevation in the north are not as large as in the south, marine sectors were thinning in 2003–2008 (Pritchard et al., 2009; Sorensen et al., 2011).

In contrast to the rapidly changing marine margins of the ice sheets, land-terminating regions of the Greenland Ice Sheet are changing more slowly, and these changes are largely explained by changes in the input of snow and loss of meltwater (Sole et al., 2011). Surface meltwater, while abundant on the Greenland Ice Sheet, does not seem to be driving significant changes in basal lubrication that impact on ice sheet flow (Joughin et al., 2008b; Selmes et al., 2011; Sundal et al., 2011).

In Greenland, the observed changes are not all irreversible. The Helheim Glacier in southeast Greenland accelerated, retreated and increased its calving flux during the period 2002–2005 (Howat et al., 2011; Andresen et al., 2012), but its calving flux similarly increased during the late 1930s – early 1940s (Andresen et al., 2012): an episode from which the glacier subsequently recovered and re-advanced (Joughin et al., 2008b). The collapse of the floating tongue of Jakobshavn Isbrae in 2002 and consequent loss of buttressing has considerably increased ice flow speeds and discharge from the ice sheet. At present, the glacier grounding line is retreating 0.5-0.6 km/yr (Thomas et al., 2011b; Rosenau et al., 2013), with speeds in excess of 11 km/yr (Moon et al., 2012), and the glacier is retreating on a bed that deepens further inland, which could be conducive to a marine instability. However, there is evidence that Jakobshavn Isbrae has undergone significant margin changes over the last ~8,000 years which may have been both more and less extensive than the recent ones (Young et al., 2011b).

Since AR4, many new observations indicate that changes in ice sheets can happen more rapidly than was previously recognised. Similarly, evidence presented since AR4 indicates that interactions with both the atmosphere and ocean are key drivers of decadal ice-sheet change. So, although our understanding of the detailed processes that control the evolution of ice sheets in a warming climate remains incomplete, there is no indication in observations of a slowdown in the mass loss from ice sheets; instead, recent observations suggest an ongoing increase in mass loss.

4.5 Seasonal Snow

4.5.1 Background

Snowfall is a component of total precipitation and, in that context, is discussed in Chapter 2 (See Section 2.3.1.3); here we discuss accumulated snow as a climatological indicator. Snow is measured using a variety of instruments and techniques, and reported using several metrics, including: snow cover extent (SCE; see Glossary); the seasonal sum of daily snowfall; snow depth (SD); snow cover duration (SCD), i.e., number of days with snow exceeding a threshold depth; or snow water equivalent (SWE; see Glossary).

Long-duration, consistent records of snow are rare owing to many challenges in making accurate and representative measurements. While weather stations in snowy inhabited areas often report snow depth, records of snowfall are often patchy or use techniques that change over time (e.g., Kunkel et al., 2007). The density of stations and the choice of metric also varies considerably from country to country. The longest satellite-based record of SCE is the visible-wavelength weekly product of the National Oceanic and Atmospheric Administration (NOAA) dating to 1966 (Robinson et al., 1993), but this only covers the Northern Hemisphere (NH). Satellite mapping of snow depth and SWE has lower accuracy than SCE, especially in mountainous and heavily forested areas. Measurement challenges are particularly acute in the Southern Hemisphere (SH), where only about 11 long-duration in situ records continue to recent times: seven in the central Andes and four in southeast Australia. Owing to concerns about quality and duration, global satellite microwave retrievals of SWE are of less use in the data-rich NH than in the data-poor SH.

4.5.2 Hemispheric View

By blending in situ and satellite records, Brown and Robinson (2011) have updated a key indicator of climate change, namely the time series of NH SCE (Figure 4.19). This time series shows significant reductions over the past 90 years with most of the reductions occurring in the 1980s, and is an improvement over that presented in AR4 in several ways, not least because the uncertainty estimates are explicitly derived through the statistical analysis of multiple datasets. Snow cover decreases are largest in spring (Table 4.7), and the rate of decrease increases with latitude in response to larger albedo feedbacks (Déry and Brown, 2007). Averaged March and April NH SCE decreased 0.82% [0.53–1.10%] per decade over the 1922–2012 period, 1.59% [0.86–2.33%] per decade over the 1967–2012 period, and 2.24% [1.12–3.35%] per decade over the 1979–2012 period. In a new development since AR4, both absolute and relative loss in June SCE now exceed the losses in March–April SCE: 11.7% [8.8–14.6%] per decade or 53% [40–66%] total over the 1967–2012 period, and 14.8% [10.3–19.3%] per decade over the 1979–2012 period. Note that these percentages differ from those in the paper which were calculated relative to the mean over the 1979–2000 period, rather than relative to the starting point. The loss rate of June SCE exceeds the loss rate for CMIP5 model projections of June SCE and also exceeds the well-known loss of September sea ice extent (Derksen and Brown, 2012). Viewed another way, the NOAA SCE data indicate that, owing to earlier spring snowmelt, the duration of the snow season averaged over NH grid points declined by 5.3 days per decade since winter 1972–1973 (Choi et al., 2010).

Over Eurasia, in situ data show significant increases in winter snow accumulation but a shorter snowmelt season (Bulygina et al., 2009). From analysis of passive microwave satellite data since 1979, significant trends toward a shortening of the snowmelt season have been identified over much of Eurasia (Takala et al., 2009) and the pan-Arctic region (Tedesco et al., 2009), with a trend toward earlier melt of about 5 days per decade for the beginning of the melt season, and a trend of about 10 days per decade later for the end of the melt season.

[INSERT FIGURE 4.19 HERE]

Figure 4.19: March–April NH snow cover extent (SCE, circles) over the period of available data, filtered with a 13-term smoother and with shading indicating the 95% confidence interval; and June SCE (red crosses, from satellite data alone), also filtered with a 13-term smoother. The width of the smoothed 95% confidence interval is influenced by the interannual variability in SCE. Updated, from Brown and Robinson (2011). For both time series the anomalies are calculated relative to the 1971–2000 mean.

Table 4.7: Least-squares linear trend in Northern Hemisphere snow cover extent (SCE) in 10^6 sq km per decade for 1967–2012. The equivalent trends for 1922–2012 (only available for March and April) are -0.19^* March and -0.40^* April.

Annual	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
-0.40*	0.03	-0.13	-0.50*	-0.63*	-0.90*	-1.31*	n/a	n/a	n/a	n/a	0.17	0.34

Notes:

* denotes statistical significance at $p = 0.05$

The correlation between spring temperature and SCE (Figure 4.20) demonstrates that trends in spring SCE are linked to rising temperature, and for a well-understood reason: The spring snow cover-albedo feedback. This feedback contributes substantially to the hemispheric response to rising greenhouse gases and provides a useful test of GCMs (Fernandes et al., 2009) (see also Chapter 9). Indeed, the observed declines in land snow cover and sea ice have contributed roughly the same amount to changes in the surface energy fluxes, and the albedo feedback of the NH cryosphere is likely in the range $0.3\text{--}1.1\text{ W m}^{-2}\text{ K}^{-1}$ (Flanner et al., 2011). Brown et al. (2010) used satellite, reanalyses and in situ observations to document variability and trend in Arctic spring (May-June) SCE over the 1967–2008 period. In June, with Arctic albedo feedback at a maximum, SCE decreased 46% (as of 2012, now 53%) and air temperature explains 56% of the variability.

[INSERT FIGURE 4.20 HERE]

Figure 4.20: Relationship between NH April SCE and corresponding land air temperature anomalies over $40^{\circ}\text{N}\text{--}60^{\circ}\text{N}$ from the CRUtem4 dataset (Jones et al., 2012). Red circles indicate the years 2000–2012. The correlation is 0.76. Updated from Brown and Robinson (2011).

For the SH, as noted above, there are no correspondingly long visible-wavelength satellite records, but microwave data date from 1979. Foster et al. (2009) presented the first satellite study of variability and trends in any measure of snow for South America, in this case SWE from microwave data. They focused on the May-September period and noted large year-to-year variability and some lower frequency variability—the July with most extensive snow cover had almost 6 times as much as the July with the least extensive snow cover—but no trends.

4.5.3 Trends from In Situ Measurements

AR4 stimulated a review paper (Brown and Mote, 2009) that synthesized modelling results as well as observations from many countries. They showed that decreases in various metrics of snow are most likely to be observed in spring and at locations where air temperatures are close to the freezing point, because changes in air temperature there are most effective at reducing snow accumulation, increasing snowmelt, or both. However, unravelling the competing effects of rising temperatures and changing precipitation remains an important challenge in understanding and interpreting observed changes. Figure 4.21 shows a compilation of many published trends observed at individual locations; data were obtained either from tables in the published papers, or (when the numerical results in the figures were not tabulated) directly from the author, in some cases including updates to the published datasets. The figure shows that in most studies, a majority of sites experienced declines during the varying periods of record, and where data on site mean temperature or elevation were available, warmer/lower sites (red circles) were more likely to experience declines.

Some in situ studies in addition to those in Figure 4.21 deserve discussion. Ma and Qin (2012) described trends by season at 754 stations aggregated by region in China over 1951–2009; they found statistically significant trends: positive in winter SD in northwest China, and negative in SD and SWE in spring for China as a whole and spring SWE for the Qinghai-Tibetan Plateau. Marty and Meister (2012) noted changes at six high-elevation ($>2200\text{ m}$) sites in the European Alps of Switzerland, Austria, and Germany, consistent with Figure 4.21: no change in SD in midwinter, shortening of SCD in spring, and reduction in spring SWE and SD coincident with warming. For the Pyrenees, Lopez-Moreno and Vicente-Serrano (2007) derived proxy SD for 106 sites since 1950 from actual SD measurements since 1985 and weather measurements; they noted declines in spring SD that were related to changes in atmospheric circulation. In the SH, of seven records in the Andes, none have significant trends in maximum SWE (Masiokas et al., 2010) over their periods of record. Of four records in Australia discussed in AR4, all show decreases in spring SWE over their respective periods of record (Nicholls, 2005), and the only one that has been updated since the Nicholls (2005) paper shows a statistically significant decrease of 37% (Sanchez-Bayo and Green, 2013).

[INSERT FIGURE 4.21 HERE]

Figure 4.21: Compilation of studies (rows) showing trends at individual stations (symbols in each row, along with percentage of trends that are negative). For each study, if more than one quantity was presented, only the one representing spring conditions is shown. a) Number of days per year with SD >20 cm at 675 sites in northern Eurasia, 1966–2010 (Bulygina et al., 2011). b) March–April–May snowfall for 500 stations in California, aggregated into 4 regions (Christy, 2012). c) maximum SWE at 393 sites in Norway, 1961–2009 (Skaugen et al., 2012); statistically significant trends are denoted by solid circles. d) SD at 560 sites in China, 1957–2012 (Ma and Qin, 2012); statistically significant trends are denoted by solid red circles. e) Snow cover duration at 15 sites in the Romanian Carpathians, 1961–2003 (Micu, 2009). f) 1 April SWE at 799 sites, 1950–2000, in western North America (Mote, 2006). g) Difference between 1990s and 1960s March SD at 89 sites in Japan (Ishizaka, 2004). h) SCD at 15 sites for starting years near 1931, ending 2000 (Petkova et al., 2004). i) SCD at 18 sites in Italy, 1950–2009 (Valt and Cianfarra, 2010). j) SCD at 34 sites in Switzerland, 1948–2007, from Marty (2008). See text for definitions of abbreviations. For b) through j), the quantity plotted is the percentage change of a linear fit divided by the number of years of the fit. For studies with more than 50 sites, the median, upper and lower quartiles are shown with vertical lines. In a few cases, some trends lie beyond the edges of the graph; these are indicated by a numeral at the corresponding edge of the graph, e.g., 2 sites >2% yr⁻¹ in row f). Colours indicate temperature or, for studies e) and i), elevation using the lowest and highest site in the respective dataset to set the colour scale. Note the prevalence of negative trends at lower/warmer sites.

4.5.4 Changes in Snow Albedo

In addition to reductions in snow cover extent, which will reduce the mean reflectivity of particular regions, the reflectivity (albedo) of the snow itself may also be changing in response to human activities. Unfortunately, there are extremely limited data on the changes of albedo over time, and we must rely instead on analyses from ice cores, direct recent observations, and modelling. Flanner et al. (2007), using a detailed snow radiative model coupled to a GCM and estimates of biomass burning, estimated that the human-induced radiative forcing by deposition of black carbon on snow cover is +0.054 (0.007–0.13) W m⁻² globally, of which 80% is from fossil fuels. However, spatially comprehensive surveys of impurities in Arctic snow in the late 2000s and mid-1980s suggested that impurities decreased between those two periods (Doherty et al., 2010) and hence albedo changes have probably not made a significant contribution to recent reductions in Arctic ice and snow.

4.6 Lake and River Ice

The assessment of changes in lake and river ice is made more difficult by several factors. Until the satellite era, some nations collected data from numerous lakes and rivers and others none; many published studies focus on a single lake or river. Many records have been discontinued (Prowse et al., 2011), and consistency of observational methods is a challenge, especially for date of ice break-up of ice on rivers when the process of break-up can take as long as 3 months (Beltaos and Prowse, 2009).

The most comprehensive description is the analysis of 75 lakes, mostly in Scandinavia and the northern US, but with one each in Switzerland and Russia (Benson et al., 2012). Examining 150-, 100-, and 30-year periods ending in spring 2005, they found the most rapid changes in the most recent 30-year period (*medium confidence*) with trends in freeze-up 1.6 days per decade later and breakup 1.9 days per decade earlier. Wang et al. (2012) found a total ice cover reduction on the north American Great Lakes of 71% over the 1973–2010 period of record, using weekly ice charts derived from satellite observations (*medium confidence*). Jensen et al. (2007) examined data from 65 water bodies in the Great Lakes region between Minnesota and New York (not including the Great Lakes themselves) and found trends in freeze-up 3.3 days per decade later, trends in breakup 2.1 days/decade earlier, and rates of change over 1975–2004 that were bigger than those over 1846–1995. Spatial patterns in trends are ambiguous: (Latifovic and Pouliot, 2007) found larger trends in higher latitudes over Canada, but Hodgkins et al (2002) found larger trends in lower latitudes in the northeastern US.

In the only reported study since the 1990s of ice on southern hemisphere lakes, Green (2011) suggested on the basis of available evidence that break-up of ice cover on Blue Lake in the Snowy Mountains of Australia had shifted from November to October between observation periods 1970–1972 and 1998–2010.

Several studies made quantitative connections between ice cover and temperature. For instance, Benson et al. (2012) found significant correlations between mean ice duration and mean Northern Hemisphere land air temperature in fall-winter-spring ($r^2 = 0.48$) and between spring air temperature and breakup ($r^2 = 0.36$); see also the review by Prowse et al. (2011).

Studies of changes in river ice have used both disparate data and time intervals, ranging in duration from multi-decade to over two centuries, and most focus on a single river. Beltaos and Prowse (2009), summarizing most available information for northern rivers, noted an almost universal trend towards earlier break-up dates but considerable spatial variability in those for freeze-up, and noted too that changes were often more pronounced during the last few decades of the twentieth century. They noted that the 20th Century increase in mean air temperature in spring and autumn has produced in many areas a change of about 10 to 15 days toward earlier break-up and later freeze-up, although the relationship with air temperatures is complicated by the roles of snow accumulation and spring runoff.

In summary, the limited evidence available for freshwater (lake and river) ice indicates that ice duration is decreasing and average seasonal ice cover shrinking (*low confidence*), and the following general patterns (each of which has exceptions): rates of change in timing are generally, but not universally, (1) higher for spring breakup than fall freeze-up; (2) higher for more recent periods; (3) higher at higher elevations (Jensen et al., 2007); (4) quantitatively related to temperature changes.

4.7 Frozen Ground

4.7.1 Background

Frozen ground occurs across the world at high latitudes, in mountain regions, beneath glacial ice and beneath lakes and seas. It is a product of cold weather and climate, and can be diurnal, seasonal, or perennial. Wherever the ground remains at or below 0°C for at least two consecutive years, it is called permafrost (Van Everdingen, 1998), and this too can occur beneath the land surface (terrestrial permafrost) and beneath the seafloor (subsea permafrost). In this chapter, the term permafrost refers to terrestrial permafrost unless specified.

Both the temperature and extent of permafrost are highly sensitive to climate change, but the responses may be complex and highly heterogeneous (e.g., Osterkamp, 2007). Similarly, the annual freezing and thawing of seasonally frozen ground, is coupled to the land-surface energy and moisture fluxes, and thus to climate. Since, permafrost and seasonally frozen ground, can contain significant fractions of ice, changes in landscapes, ecosystems and hydrological processes can occur when it forms or degrades (Jorgenson et al., 2006; Gruber and Haeberli, 2007; White et al., 2007). Furthermore, frozen organic soils contain considerable quantities of carbon, more than twice the amount currently in the atmosphere (Tarnocai et al., 2009), and permafrost thawing exposes previously frozen carbon to microbial degradation and releases radiatively active gases, such as CO₂ and CH₄, into the atmosphere (Zimov et al., 2006; Schuur et al., 2009; Schaefer et al., 2011) (for a detailed assessment of this issue, see Chapter 6). Similarly, recent evidence suggests that degradation of permafrost may also permit the release of nitrous oxide (N₂O), which is also radiatively active (Repo et al., 2009; Marushchak et al., 2011). Finally, permafrost degradation may directly affect the lives of people, both in northern and high-mountain areas, through impacts on the landscape, vegetation and infrastructure (WGII, Chapter 28).

4.7.2 Changes in Permafrost

4.7.2.1 Permafrost Temperature

The ice-content and temperature of permafrost are the key parameters that determine its physical state. Permafrost temperature is a key parameter used to document changes to permafrost. Permafrost temperature measured at a depth where seasonal variations cease to occur is generally used as an indicator of long-term change and to represent the mean annual ground temperature (Romanovsky et al., 2010a). For most sites this depth occurs in the upper 20 m.

In the southern hemisphere, permafrost temperatures as low as -23.6°C have been observed in the Antarctic (Vieira et al., 2010), but in the northern hemisphere, permafrost temperatures generally range from -15°C to close to the freezing point (Figure 4.22) (Romanovsky et al., 2010a). They are usually coldest in high Arctic regions and gradually increase southwards, but substantial differences do occur at the same latitude. For example; as a result of the proximity to warm ocean currents, the southern limit of permafrost is farther north, and permafrost temperature is higher in Scandinavia, and north-western Russia, than it is in Arctic regions of Siberia and North America (Romanovsky et al., 2010a).

In Russia, permafrost temperature measurements reach back to the early 1930s (Romanovsky et al., 2010b), in North America to the late 1940s (Brewer, 1958), and in China to the early 1960s (Zhou et al., 2000; Zhao et al., 2010). Systematic measurements, however, mostly began in the late 1970s and early 1980s (Zhou et al., 2000; Osterkamp, 2007; Smith et al., 2010). In addition, since the AR4, considerable effort (especially during the International Polar Year) has gone into enhancing the observation network and to establishing a baseline against which future changes in permafrost can be measured (Romanovsky et al., 2010a). However, it should be noted that there still exist comparatively few measurements of permafrost temperature in the Southern Hemisphere (Vieira et al., 2010).

[INSERT FIGURE 4.22 HERE]

Figure 4.22: Time series of mean annual ground temperatures at depths between 10 and 20 m for boreholes throughout the circumpolar northern permafrost regions (Romanovsky et al., 2010a). Data sources are from Romanovsky et al. (2010b) and Christiansen et al. (2010). Measurement depth is 10m for Russian boreholes, 15 m for Gulkana and Oldman, and 20 m for all other boreholes. Borehole locations are: ZS-124 – 67.48°N 063.48°E ; 85-8A – 61.68°N 121.18°W ; Gulkana – 62.28°N 145.58°W ; YA-1 – 67.58°N 648°E ; Oldman – 66.48°N 150.68°W ; Happy Valley – 69.18°N 148.88°W ; Svalbard – 78.28°N 016.58°E ; Deadhorse – 70.28°N 148.58°W ; and West Dock – 70.48°N 148.58°W . The rate of change ($^{\circ}\text{C}/\text{decade}$) in permafrost temperature over the period of each site record is: ZS-124: 0.53 ± 0.07 ; YA-1: 0.21 ± 0.02 ; West Dock: 0.64 ± 0.08 ; Deadhorse: 0.82 ± 0.07 ; Happy Valley: 0.34 ± 0.05 ; Gaibrath Lake: 0.35 ± 0.07 ; Gulkana: 0.15 ± 0.03 ; Old Man: 0.40 ± 0.04 ; and Svalvard: 0.63 ± 0.09 . (The trends are *very likely* range, 90%)

In most regions, and at most sites, permafrost temperatures have increased during the past three decades (*high confidence*): at rather fewer sites, permafrost temperatures show little change, or slight decrease (Figure 4.22; Table 4.8). However, it is important to discriminate between *cold permafrost*, with mean annual ground temperatures below -2°C , and *warm permafrost at temperatures above -2°C* (Cheng and Wu, 2007; Smith et al., 2010; Wu and Zhang, 2010). Warm permafrost is mostly found in the discontinuous permafrost zone, while cold permafrost exists in the continuous permafrost zone and only occasionally in the discontinuous permafrost zone (Romanovsky et al., 2010a).

Overall, permafrost temperature increases are greater in cold permafrost than they are in warm permafrost (*high confidence*). This is especially true for warm ice-rich permafrost, due to heat absorbed by partial melting of interstitial ice, slowing and attenuating temperature change (Romanovsky et al., 2010a). The temperatures of cold permafrost across a range of regions have increased by up to 2°C since the 1970s (Table 4.8, Callaghan et al., 2011), however, the timing of warming events has shown considerable spatial variability (Romanovsky et al. 2010a).

Temperatures of warm permafrost have also increased over the last 3 decades, but generally by less than 1°C . Warm permafrost is sometimes nearly isothermal with depth; as is observed in mountain regions such as the European Alps (Noetzli and Vonder Muehll, 2010), Scandinavia (Christiansen et al., 2010), the Western Cordillera of North America (Smith et al., 2010; Lewkowicz et al., 2011), the Qinghai-Tibetan Plateau (Zhao et al., 2010; Wu et al., 2012) and in the northern high-latitudes in the southern margins of discontinuous permafrost regions (Romanovsky et al., 2010b; Smith et al., 2010). In such areas, permafrost temperatures have shown little or no change, indicating that permafrost is thawing internally but remaining very close to the melting point (Smith et al., 2010). Cooling of permafrost due to atmospheric temperature fluctuations has been observed; for example in the eastern Canadian Arctic until the mid-1990s (Smith et al., 2010); but some examples have been short-lived and others controlled by site-specific conditions (Marchenko et al., 2007; Wu and Zhang, 2008; Noetzli and Vonder Muehll, 2010; Zhao et al., 2010). In at least one case in the Antarctic, permafrost warming has been observed in a region with almost stable air temperatures (Guglielmin and Cannone, 2012).

Table 4.8: Permafrost temperatures during the International Polar Year (2007–2009) and their recent changes. Each line may refer to one or more measurements sites.

Region	Permafrost Temperature During IPY (°C)	Permafrost Temperature Change (°C)	Depth (m)	Period of Record	Source
<i>North America</i>					
Northern Alaska	–5.0 to –10.0	0.6–2.7	10–20	early 1980s–2009	(Osterkamp, 2007; Smith et al., 2010; Romanovsky et al., 2010a)
Mackenzie Delta and Beaufort coastal region	–0.5 to –8.0	1.0–2.0	12–20	late 1960s–2009	(Burn and Kokelj, 2009; Burn and Zhang, 2009; Smith et al., 2010)
Canadian High Arctic	–11.8 to –14.3	1.2–1.7	12–15	1978–2008	(Smith et al., 2010; Smith et al., 2012)
Interior of Alaska,	0.0 to –5.0	0.0–0.8	15–20	1985–2009	(Osterkamp, 2008; Smith et al., 2010; Romanovsky et al., 2010a)
Central and Southern Mackenzie Valley	>–2.2	0.0–0.5	10–12	1984–2008	(Smith et al., 2010)
Northern Quebec	>–5.6	0.0–1.8	12–20	1993–2008	(Allard et al., 1995; Smith et al., 2010)
<i>Europe</i>					
European Alps	>–3	0.0–0.4	15–20	1990s–2010	(Haeberli et al., 2010; Noetzli and Vonder Muehll, 2010; Christiansen et al., 2012)
Russian European North	–0.1 to –4.1	0.3–2.0	8–22	1971–2010	(Malkova, 2008; Oberman, 2008; Romanovsky et al., 2010b; Oberman, 2012)
Nordic Countries	–0.1 to –5.6	0.0–1.0	2–15	1999–2009	(Christiansen et al., 2010; Isaksen et al., 2011)
<i>Northern and Central Asia</i>					
Northern Yakutia	–4.3 to –10.8	0.5–1.5	14–25	early 1950s–2009	(Romanovsky et al., 2010b)
Trans-Baykal region	–4.7 to –5.1	0.5–0.8	19–20	late 1980s–2009	(Romanovsky et al., 2010b)
Qinghai-Xizang Plateau	–0.2 to –3.4	0.2–0.7	6	1996–2010	(Cheng and Wu, 2007; Li et al., 2008; Wu and Zhang, 2008; Zhao et al., 2010)
Tian Shan	–0.4 to –1.1	0.3–0.9	10–25	1974–2009	(Marchenko et al., 2007; Zhao et al., 2010)
Mongolia	0.0 to <–2.0	0.2–0.6	10–15	1970–2009	(Sharkhuu et al., 2007; Zhao et al., 2010; Ishikawa et al., 2012)
<i>Others</i>					
Maritime Antarctica	–0.5 to –3.1	NA	20–25	2007–2009	(Vieira et al., 2010)
Continental Antarctica	–13.9 to –19.1	NA	20–30	2005–2008	(Vieira et al., 2010; Guglielmin et al., 2011)
East Greenland	–8.1	NA	3.25	2008–2009	(Christiansen et al., 2010)

Permafrost warming is mainly in response to increased air temperature and changing snow cover (see Box 4.1). In cold permafrost regions, especially in tundra regions with low ice content (such as bedrock) where permafrost warming rates have been greatest, changes in snow cover may play an important role (Zhang, 2005; Smith et al., 2010). In forested areas, especially in warm ice-rich permafrost, changes in permafrost temperature are reduced by the effects of the surface insulation (Smith et al., 2012; Throop et al., 2012) and latent heat (Romanovsky et al., 2010a).

4.7.2.2 *Permafrost Degradation*

Permafrost degradation refers to a decrease in thickness and/or areal extent. In particular, the degradation can be manifested by a deepening of summer thaw, or top-down or bottom-up permafrost thawing, and a development of taliks (see Glossary). Other manifestations of degradation include geomorphologic changes such as the formation of thermokarst terrain (see Glossary, Jorgenson et al., 2006), expansion of thaw lakes (Sannel and Kuhry, 2011), active-layer detachment slides along slopes, rock falls (Ravelle et al., 2010), and destabilized rock glaciers (Kääb et al., 1997; Haeberli et al., 2006; Haeberli et al., 2010). Although most permafrost has been degrading since the Little Ice Age (Halsey et al., 1995), the trend was relatively modest until the past two decades, during which the rate of degradation has increased in some regions (Romanovsky et al., 2010b).

Significant permafrost degradation has been reported in the Russian European North (*medium confidence*). Warm permafrost with a thickness of 10–15 m thawed completely in the period 1975–2005 in the Vorkuta area (Oberman, 2008). And although boundaries between permafrost types are not easy to map, the southern permafrost boundary in this region is reported to have moved north by about 80 km and the boundary of continuous permafrost has moved north by 15–50 km (Oberman, 2008) (*medium confidence*). Taliks have also developed in relatively thick permafrost during the past several decades. In the Vorkuta region, the thickness of existing closed taliks increased by 0.6–6.7 m over the past 30 years (Romanovsky et al., 2010b). Permafrost thawing and talik formation has occurred in the Nadym and Urengoy regions in north western Russian (Drozдов et al., 2010). Long-term permafrost thawing has been reported around the city of Yakutsk, but this in this case, the thawing may have been caused mainly by forest fires or human disturbance (Fedorov and Konstantinov, 2008). Permafrost degradation has also been reported on the Qinghai-Xizang (Tibet) Plateau (Cheng and Wu, 2007; Li et al., 2008).

Coastal erosion and permafrost degradation appear to be evident along many Arctic coasts in recent years, with complex interactions between them (Jones et al., 2009). In part, these interactions arise from the thermal and chemical impact of sea water on cold terrestrial permafrost (Rachold et al., 2007). Similar impacts arise for permafrost beneath new thaw lakes, which have been formed in recent years (e.g., Sannel and Kuhry, 2011). In northern Alaska, estimates of permafrost thawing under thaw lakes are in the range 0.9–1.7 cm a⁻¹ (Ling and Zhang, 2003).

Since AR4, destabilized rock glaciers have received increased attention from researchers. A rock glacier is a mass of perennially-frozen rock fragments on a slope, that contains ice in one or more forms and shows evidence of past or present movement (Van Everdingen, 1998; Haeberli et al., 2006). Time series acquired over recent decades by terrestrial surveys indicate acceleration of some rock glaciers as well as seasonal velocity changes related to ground temperatures (Bodin et al., 2009; Noetzli and Vonder Muehll, 2010; Schoeneich et al., 2010; Delaloye et al., 2011). Similarly, photo-comparison and photogrammetry has indicated collapse-like features on some rock glaciers (Roer et al., 2008). The clear relationship between mean annual air temperature at the rock glacier front and rock glacier velocity points to a likely temperature influence and a plausible causal connection to climate (Kaab et al., 2007). Strong surface lowering of rock glaciers has been reported in the Andes (Bodin et al., 2010), indicating melting of ground ice in rock glaciers and permafrost degradation.

4.7.3 *Subsea Permafrost*

Subsea permafrost is similar to its terrestrial counterpart, but lies beneath the coastal seas. And as with terrestrial permafrost, subsea permafrost is a substantial reservoir and/or a confining layer for gas hydrates (Koch et al., 2009) it is roughly estimated that subsea permafrost contains 2–65 Pg of CH₄ hydrate (McGuire et al., 2009). Observations of gas release on the East Siberian Shelf and high methane concentrations in water-column and air above (Shakhova et al., 2010b; Shakhova et al., 2010a) have led to the suggestion that permafrost thawing creates pathways for gas release.

Subsea permafrost in the Arctic is generally relict terrestrial permafrost (Vigdorichik, 1980), inundated after the last glaciation and now degrading under the overlying shelf sea. Permafrost may, however, also form when the sea is shallow, permitting sediment freezing through bottom-fast winter sea ice (Solomon et al., 2008; Stevens et al., 2010). A 76-year record of bottom water temperature in the Laptev Sea (Dmitrenko et

al., 2011) showed warming of 2.1°C since 1985 in the near-shore zone (<10 m water depth), as lengthening summers reduced sea ice extent and increased solar heating. Degradation rates of the ice-bearing permafrost following inundation have been estimated to be 1–20 cm a⁻¹ on the East Siberian Shelf (Overduin et al., 2007) and 1–4 cm a⁻¹ in the Alaskan Beaufort Sea (Overduin et al., 2012).

4.7.4 Changes in Seasonally-Frozen Ground

Seasonally-frozen ground is a soil layer that freezes and thaws annually, which may, or may not, overlie terrestrial permafrost, and also includes some portions of the Arctic seabed that freeze in winter. A key parameter regarding seasonally-frozen ground overlying permafrost is the active-layer thickness (ALT, see Glossary), which indicates the depth of the seasonal freeze-thaw cycle, and which is dependent on climate and other factors; for example, vegetation cover (Smith et al., 2009).

4.6.4.1 Changes in Active-Layer Thickness

Many observations have revealed a general positive trend in the thickness of the active layer (see Glossary) for discontinuous permafrost regions at high latitudes (*medium confidence*). Based on measurements from the International Permafrost Association (IPA) Circumpolar Active Layer Monitoring (CALM) programme, active-layer thickening has been observed since the 1970s and has accelerated since 1995 in northern Europe (Akerman and Johansson, 2008; Callaghan et al., 2010), and on Svalbard and Greenland since the late-1990s (Christiansen et al., 2010). The ALT has increased significantly in the Russian European North (Mazhitova, 2008), East Siberia (Fyodorov-Davydov et al., 2008), and Chukotka (Zamolodchikov, 2008) since the mid-1990s. Burn and Kokelj (2009) found, for a site in the Mackenzie Delta area, that ALT increased by 8 cm between 1983 and 2008, although the record does exhibit high inter-annual variability as has been observed at other sites in the region (Smith et al., 2009). ALT has increased since the mid-1990s in the eastern portion of the Canadian Arctic with the largest increase occurring at bedrock sites in the discontinuous permafrost zone (Smith et al., 2010).

The interannual variations and trends of the active-layer thickness in Northern America, European North and Northern Asia from 1990 to 2012 are presented in Figure 4.23. Large regional variations in the yearly variability patterns and trends are apparent. While increases in ALT is occurring in the Eastern Canadian Region (Smith et al., 2009), a slightly declining trend is observed in the Western Canadian Region (Figure 23a). In European North, the trends in the study areas are similar and consistently positive (Figure 23b). On the other hand, in Northern Asia, trends are generally strongly positive with the exception of West Siberia, where the trend is slightly negative (Figure 23c). On the interior of Alaska, slightly increasing ALT from 1990 to 2010 was followed by anomalous increases in 2011 and in 2012. Overall, a general increase in ALT has been observed over various stations and regions (*medium confidence*). The general increase is shown in Figure 4.23d which shows the results of analysis of data from around 44 stations in Russia indicating a change of almost 0.2 m from 1950 to 2008.

[INSERT FIGURE 4.23 HERE]

Figure 4.23: Active layer thickness from different locations for slightly different periods between 1990 and 2012 in (a) Northern America, (b) European North, and (c) Northern Asia. The dashed lines represents linear fit to each set of data. ALT data for Northern America, Northern Asia and European North were obtained from the International Permafrost Association (IPA) CALM website (<http://www.udel.edu/Geography/calm/about/permafrost.html>). The number of Russian Hydrometeorological Stations (RHM) stations has expanded from 31 stations as reported from Frauenfeld et al. (2004) and Zhang et al. (2005) to 44 stations and the time series has extended from 1990 to 2008. (d) Departures from the mean of active layer thickness in Siberia from 1950 to 2008. The red asterisk represents the mean composite value, the shaded area indicates the standard deviation, and the black line is the trend. Data for Siberia stations were obtained from the Russian Hydrometeorological Stations (RHM).

At some measurement sites on the Qinghai-Tibetan Plateau, ALT was reported to be increasing at 7.8 cm yr⁻¹ over a period from 1995 through 2010 (Wu and Zhang, 2010). The high rates may have been the result of local disturbances since more recent studies indicate rates of 1.33 cm yr⁻¹ for the period 1981–2010, and 3.6 cm yr⁻¹ for the period 1998–2010 (e.g., Zhao et al., 2010; Li et al., 2012a).

During the past decade, increases in ALT up to 4.0 cm yr⁻¹ were observed in Mongolian sites characterized as a warm permafrost region (Sharkhuu et al., 2007). Changes in ALT were also detected in Tian Shan

(Marchenko et al., 2007; Zhao et al., 2010), and in the European Alps, where increases in ALT were largest during years of hot summers but a strong dependence on surface and subsurface characteristics was noted (Noetzli and Vonder Muehll, 2010).

No trend in ALT was observed on the Alaskan North Slope from 1993–2010 (Streletskiy et al., 2008; Shiklomanov et al., 2010) and also in the Mackenzie Valley (Smith et al., 2009) and in the West Siberia (Vasiliev et al., 2008) since the mid-1990s (Figure 4.23). At some sites, such as at Western Canada (C5) and Western Siberia (R1) (Figure 23), the active layer thickness was actually decreasing.

The penetration of thaw into ice-rich permafrost at the base of the active layer is often accompanied by loss of volume due to consolidation. At several sites, this has been shown to cause surface subsidence (*medium confidence*). Results from ground-based measurements at selected sites on the North Slope of Alaska indicate 11–13 cm in surface subsidence over the period 2001–2006 (Streletskiy et al., 2008), 4–10 cm from 2003 to 2005 in the Brooks Range (Overduin and Kane, 2006), and up to 20 cm in the Russian European North (Mazhitova and Kaverin, 2007). Subsidence has also been identified using space-borne interferometric synthetic aperture radar (InSAR) data. Surface deformation was detected using InSAR over permafrost on the North Slope of Alaska during the 1992–2000 thaw seasons and a long-term surface subsidence of 1–4 cm per decade (Liu et al., 2010). Such subsidence could explain why in situ measurements at some locations reveal negligible trends in ALT changes during the past two decades, despite the fact that atmospheric and permafrost temperatures increased during that time.

4.7.4.2 Changes in Seasonally Frozen Ground in Areas not Underlain by Permafrost

An estimate based on monthly mean soil temperatures from 387 stations across Russia, suggested that the thickness of seasonally frozen ground decreased by about 0.32 m during the period 1930–2000 (Figure 4.24) (Frauenfeld and Zhang, 2011). Inter-decadal variability was such that no trend could be identified until the late-1960s, after which seasonal freeze depths decreased significantly until the early-1990s. From then, until about 2008, no further change was evident. Such changes are closely linked with the freezing index, but also with mean annual air temperatures, and snow depth (Frauenfeld and Zhang, 2011).

Thickness of seasonally frozen ground in western China decreased by 20–40 cm since the early 1960s (Li et al., 2008). While on the Tibetan Plateau, the seasonally frozen depth decreased by up to 33 cm since the middle of 1980s (Li et al., 2009). Evidence from the satellite record indicates that the onset dates of spring thaw advanced by 14 days, while the autumn freeze date was delayed by 10 days on the Qinghai-Xizang (Tibetan) Plateau from 1988 through 2007 (Li et al., 2012b)

[INSERT FIGURE 4.24 HERE]

Figure 4.24: Annual anomalies of the average thickness of seasonally frozen depth in Russia from 1930 to 2000. Each data point represents a composite from 320 stations as compiled at the Russian Hydrometeorological Stations (RHM) (upper right inset). The composite was produced by taking the sum of the thickness measurements from each station and dividing the result by the number of stations operating in that year. Although the total number of stations is 320, the number providing data may be different for each year but the minimum was 240. The yearly anomaly was calculated by subtracting the 1971–2000 mean from the composite for each year. The thin lines indicate the 1- σ (*likely*) uncertainty range. The line shows a negative trend of –4.5 cm per decade or a total decrease in the thickness of seasonally frozen ground of 31.9 cm from 1930 to 2000 (Frauenfeld and Zhang, 2011).

4.8 Synthesis

Observations show that the cryosphere has been in transition during the last few decades and that the strong and significant changes reported in AR4 have continued, and in many cases accelerated. The number of in situ and satellite observations of cryospheric parameters has increased considerably since AR4 and the use of the new data in trend analyses, and also in process studies, has enabled increased confidence in the quantification of most of the changes. A graphical depiction and a text summary of observed changes in the various components of the cryosphere are provided in Figure 4.25. They reveal a general decline in all components of the cryosphere, but the magnitude of the decline varies regionally and there are isolated cases where an increase is observed.

Some of the observed changes since AR4 have been considerable and unexpected. One of the most visible was the dramatic decline in the September minimum sea ice cover in the Arctic in 2007, which was followed by a record low value in 2012, supporting observations that the thicker components of the Arctic sea ice cover are decreasing. The trend in extent for Arctic sea ice is $-3.8 \pm 0.3\%$ per decade (*very likely*) while that for multiyear ice is $-13.5 \pm 2.5\%$ per decade (*very likely*). Observations also show marked decreases in Arctic ice thickness and volume. The pattern of melt on the surface of the Greenland ice sheet has also changed radically, with melt occurring in 2012 over almost the entire surface of the ice sheet for the first time during the satellite era. The ice mass loss in Greenland has been observed to have increased from 34 [–6 to 74] Gt yr⁻¹ for the period 1992–2001 to 215 [157 to 274] Gt yr⁻¹ for the period 2002–2011 while the estimates of mass loss in Antarctica have increased from 30 [–37 to 97] Gt yr⁻¹ during the 1992–2001 period to 147 [72 to 221] Gt yr⁻¹ during the 2002–2011 period. Observed mass loss from glaciers has also increased, with the global mass loss (excluding the glaciers peripheral to the ice sheets) estimated to be 226 [91 to 361] Gt yr⁻¹ during the 1971–2009 period, 275 [140 to 410] Gt yr⁻¹ over the 1993–2009 period, and 301 [166 to 436] over the 2005–2009 period. A large majority of observing stations report decreasing trends in snow depth, snow duration, or snow water equivalent, and the largest decreases are typically observed at locations with temperatures close to freezing. Most lakes and rivers with long-term records have exhibited declines in ice duration and average seasonal ice cover. Permafrost has also been degrading and retreating to the north while permafrost temperatures have increased in most regions since the 1980s.

The observed positive trend of sea ice extent in the Antarctic that was regarded as small and insignificant in AR4, has persisted, and increased slightly to about $1.5 \pm 0.2\%$ per decade. The higher-than-average Antarctic sea ice extent in recent years has been mainly due to increases in the Ross Sea region, which more than offset the declines in the Bellingshausen Sea and Amundsen Sea. Ice production in coastal polynyas (regarded as “sea ice factories”) along the Ross Sea ice shelves have been observed to be increasing. Recent work suggests strengthening of the zonal (east-west) winds and accompanying ice drift accounts for some of the increasing sea ice extent.

Satellite data have provided the ability to observe large-scale changes in the cryosphere at relatively good temporal and spatial resolution throughout the globe. Largely because of the availability of high resolution satellite data, the first globally complete inventory of glacier outlines has been generated, leading to a more precise determination of the past, current and future contribution of glaciers to sea level rise. As more data accumulate, and as more capable sensors are launched, the data become more valuable for studies related to change assessment. The advent of new satellites and airborne missions has provided powerful tools that have enabled breakthroughs in the capability to measure some parameters and enhance our ability to interpret results. However, a longer record of measurements of the cryosphere will help increase confidence in the results, reduce uncertainties in the long-term trends, and bring more critical insights into the physical processes controlling the changes. There is thus a need for the continuation of the satellite records, and a requirement for longer and more reliable historical data from in situ measurements and proxies.

The sea level equivalent of mass loss from the Greenland and the Antarctic ice sheets over the period 1993–2010, has been about 6 mm (including 1.7 mm from glaciers around Greenland) and 3 mm, respectively. The reliability of observations of ice loss from the ice sheets has been enhanced with the introduction of advanced satellite observation techniques. The ice-loss from glaciers between 1993 and 2009 measured in terms of sea level equivalent (excluding those peripheral to the ice sheets) is estimated to be 13 mm. The inset to Figure 4.25 shows the cumulative sea level equivalent from glaciers and the ice sheets in Greenland and Antarctica. These have been contributing dominantly to sea level rise in recent decades. The contribution of the cryosphere to sea level change is discussed more fully in Chapter 13.

The overall consistency in the negative changes observed in the various components of the cryosphere (Figure 4.25), and the acceleration of these changes in recent decades, provides a strong signal of climate change. Regional differences in the magnitude and direction of the signals are apparent, but these are not unexpected considering the large variability and complexity of atmospheric and oceanic circulations. It is *very likely*, however, that the Arctic has changed substantially since 1979.

INSERT FIGURE 4.25 HERE]

Figure 4.25: Schematic summary of the dominant observed variations in the cryosphere. The inset figure summarises the assessment of the sea level equivalent of ice loss from the ice sheets of Greenland and Antarctica, together with the contribution from all glaciers except those in the periphery of the ice sheets (Section 4.3.4).

FAQ 4.1: Are Glaciers in Mountain Regions Disappearing?

In many mountain ranges around the world, glaciers are disappearing in response to the atmospheric temperature increases of past decades. Disappearing glaciers have been reported in the Canadian Arctic and Rocky Mountains, the Andes, Patagonia, the European Alps, the Tien Shan, Altai and Terskey Alatau, tropical mountains in South America, Africa and Asia, and elsewhere. In these regions, more than 600 glaciers have disappeared over the past decades. Even if there is no further warming, many more glaciers will disappear. It is also likely that some mountain ranges will lose most, if not all, of their glaciers.

In all mountain regions where glaciers exist today, glacier volume has decreased considerably over the past 150 years. Over that time, many small glaciers have disappeared. With some local exceptions, glacier shrinkage (area and volume reduction) was globally widespread and particularly strong during the 1940s and since the 1980s. However, there were also phases of relative stability during the 1890s, 1920s and 1970s, as indicated by long-term measurements of length changes and by modelling of mass balance. Conventional *in situ* measurements—and increasingly, airborne and satellite measurements—offer robust evidence in most glacierized regions that the rate of glacier area reduction was higher over the past two decades than previously, and that glaciers continue to shrink. In a few regions, however, individual glaciers are behaving differently and advanced while most others were in retreat (e.g., on the coasts of New Zealand, Norway and Southern Patagonia (Chile), or in the Karakoram range in Asia). In general, these advances are the result of special topographic and/or climate conditions (e.g., increased precipitation).

It can take several decades for a glacier to adjust its extent to an instantaneous change in climate, so most glaciers are currently larger than they would be if they were in balance with current climate. Because the time required for the adjustment increases with glacier size, larger glaciers will continue to shrink over the next few decades, even if temperatures stabilise. Smaller glaciers will also continue to shrink, but they will adjust their extent faster and many will ultimately disappear entirely.

Many factors influence the future development of each glacier, and whether it will disappear: for instance, its size, slope, elevation range, distribution of area with elevation, and its surface characteristics (e.g., the amount of debris cover). These factors vary substantially from region to region, and also between neighbouring glaciers. External factors, such as the surrounding topography and the climatic regime, are also important for future glacier evolution. Over shorter time scales (one or two decades), each glacier responds individually and differently in detail to climate change.

Over periods longer than about 50 years, the response is more coherent and less dependent on local environmental details, which means that long-term trends in glacier development can be well modelled. Such models are built on an understanding of basic physical principles. For example, an increase in local mean air temperature, with no change in precipitation, will cause an upward shift of the equilibrium line altitude (ELA, see Glossary) by about 150 m for each degree Celsius of atmospheric warming. Such an upward shift and its consequences for glaciers of different size and elevation range are illustrated in FAQ 4.1, Figure 1.

Initially, all glaciers have an accumulation area (white) above and an ablation area (light blue) below the ELA (FAQ 4.1, Figure 1a). As the ELA shifts upwards, the accumulation area shrinks and the ablation area expands, thus increasing the area over which ice is lost through melt (FAQ 4.1, Figure 1b). This imbalance results in an overall loss of ice. After several years, the glacier front retreats, and the ablation area shrinks until the glacier has adjusted its extent to the new climate (FAQ 4.1, Figure 1c). Where climate change is sufficiently strong to raise the ELA permanently above the glacier's highest point (FAQ 4.1, Figure 1b, right) the glacier will eventually disappear entirely (FAQ 4.1, Figure 1c, right). Higher glaciers, which retain their accumulation areas, will shrink but not disappear (FAQ 4.1, Figure 1c, left and middle). A large valley glacier might lose much of its tongue, probably leaving a lake in its place (FAQ 4.1, Figure 1c, left). Besides

air temperature, changes in the quantity and seasonality of precipitation influence the shift of the ELA as well. Glacier dynamics (e.g., flow speed) also plays a role, but is not considered in this simplified scheme.

Many observations have confirmed that different glacier types do respond differently to recent climate change. For example, the flat, low-lying tongues of large valley glaciers (such as in Alaska, Canada or the Alps) currently show the strongest mass losses, largely independent of aspect, shading or debris cover. This type of glacier is slow in adjusting its extent to new climatic conditions and mainly reacts by thinning without substantial terminus retreat. In contrast, smaller mountain glaciers, with fairly constant slopes, adjust more quickly to the new climate by changing the size of their ablation area more rapidly. (FAQ 4.1, Figure 1c, middle).

The long-term response of most glacier types can be determined very well with the approach illustrated in FAQ 4.1, Figure 1. However, modelling short-term glacier response, or the long-term response of more complex glacier types (e.g., those that are heavily debris-covered, fed by avalanche snow, have a disconnected accumulation area, are of the surging type, or calve into water), is difficult. These cases require detailed knowledge of other glacier characteristics, such as mass balance, ice thickness distribution, and internal hydraulics. For the majority of glaciers world-wide, such data are unavailable, and their response to climate change can thus only be approximated with the simplified scheme shown in (FAQ 4.1, Figure 1).

The Karakoram-Himalaya mountain range, for instance, has a large variety of glacier types and climatic conditions, and glacier characteristics are still only poorly known. This makes determining their future evolution particularly uncertain. However, gaps in knowledge are expected to decrease substantially in coming years, thanks to increased use of satellite data (e.g., to compile glacier inventories or derive flow velocities) and extension of the ground-based measurement network.

In summary, the fate of glaciers will be variable, depending on both their specific characteristics and future climate conditions. More glaciers will disappear, others will lose most of their low-lying portions, and others might not change substantially. Where the ELA is already above the highest elevation on a particular glacier, that glacier is destined to disappear entirely unless climate cools. Similarly, all glaciers will disappear in those regions where the ELA rises above their highest elevation in the future.

[INSERT FAQ 4.1, FIGURE 1 HERE]

FAQ 4.1, Figure 1: Schematic of three types of glaciers located at different elevations, and their response to an upward shift of the equilibrium line altitude (ELA). a) For a given climate, the ELA has a specific altitude (ELA1), and all glaciers have a specific size. b) Due to a temperature increase, the ELA shifts upwards to a new altitude (ELA2), initially resulting in reduced accumulation and larger ablation areas for all glaciers. c) After glacier size has adjusted to the new ELA, the valley glacier (left) has lost its tongue and the small glacier (right) has disappeared entirely.

[BEGIN FAQ 4.2 HERE]

FAQ 4.2: How is Sea Ice Changing in the Arctic and Antarctic?

The sea ice covers on the Arctic Ocean and on the Southern Ocean around Antarctica have quite different characteristics, and are showing different changes with time. Over the past 34 years (1979–2012), there has been a downward trend of 3.8% per decade in the annual average extent of sea ice in the Arctic. The average winter thickness of Arctic Ocean sea ice has thinned by approximately 1.8 m between 1978 and 2008, and the total volume (mass) of Arctic sea ice has decreased at all times of year. The more rapid decrease in the extent of sea ice at the summer minimum is a consequence of these trends. In contrast, over the same 34-year period, the total extent of Antarctic sea ice shows a smaller increase of 1.5% per decade, but there are strong regional differences in the changes around the Antarctic. Measurements of Antarctic sea ice thickness are too few to be able to judge whether its total volume (mass) is decreasing, steady, or increasing.

A large part of the total Arctic sea ice cover lies above 60°N (FAQ 4.2, Figure 1) and is surrounded by land to the south with openings to the Canadian Arctic Archipelago, and the Bering, Barents, and Greenland seas. Some of the ice within the Arctic basin survives for several seasons, growing in thickness by freezing of

seawater at the base and by deformation (ridging and rafting). Seasonal sea ice grows to only ~2 m in thickness but sea ice that is more than one year old (perennial ice) can be several metres thicker. Arctic sea ice drifts within the basin, driven by wind and ocean currents: the mean drift pattern is dominated by a clockwise circulation pattern in the western Arctic and a Transpolar Drift Stream that transports Siberian sea ice across the Arctic and exports it from the basin through the Fram Strait.

Satellites with the capability to distinguish ice and open water have provided a picture of the sea ice cover changes. Since 1979, the annual average extent of ice in the Arctic has decreased by 3.8% per decade. The decline in extent at the end of summer (in late-September) has been even greater at 11% per decade, reaching a record minimum in 2012. The decadal average extent of the September minimum Arctic ice cover has decreased for each decade since satellite records began. Submarine and satellite records suggest that the thickness of Arctic ice, and hence the total volume, is also decreasing. Changes in the relative amounts of perennial and seasonal ice are contributing to the reduction in ice volume. Over the 34-year record, approximately 17% of this type of sea ice per decade has been lost to melt and export out of the basin since 1979 and 40% since 1999. While the area of Arctic sea ice coverage can fluctuate from year to year because of variable seasonal production, the proportion of thick perennial ice, and the total sea ice volume, can only recover slowly.

Unlike the Arctic, the sea ice cover around Antarctica is constrained to latitudes north of 78°S because of the presence of the continental land mass. The Antarctic sea ice cover is largely seasonal, with an average thickness of only ~1 m at the time of maximum extent in September. Only a small fraction of the ice cover survives the summer minimum in February, and very little Antarctic sea ice is more than two years old. The ice edge is exposed to the open ocean and the snowfall rate over Antarctic sea ice is higher than in the Arctic. When the snow load from snowfall is sufficient to depress the ice surface below sea level, seawater infiltrates the base of the snow pack and snow-ice is formed when the resultant slush freezes. Consequently, snow-to-ice conversion (as well as basal freezing as in the Arctic) contributes to the seasonal growth in ice thickness and total ice volume in the Antarctic. Snow-ice formation is sensitive to changes in precipitation and thus changes in regional climate. The consequence of changes in precipitation on Antarctic sea ice thickness and volume remains a focus for research.

Unconstrained by land boundaries, the latitudinal extent of the Antarctic sea ice cover is highly variable. Near the Antarctic coast, sea ice drift is predominantly from east to west, but further north, it is from west to east and highly divergent. Distinct clockwise circulation patterns that transport ice northward can be found in the Weddell and Ross Seas, while the circulation is more variable around East Antarctica. The northward extent of the sea ice cover is controlled in part by the divergent drift that is conducive in winter months to new ice formation in persistent open water areas (polynyas) along the coastlines. These zones of ice formation result in saltier and thus denser ocean water and become one of the primary sources of the deepest water found in the global oceans.

Over the same 34-year satellite record, the annual extent of sea ice in the Antarctic increased at about 1.5% per decade. However, there are regional differences in trends with decreases seen in the Bellingshausen and Amundsen seas, but a larger increase in sea ice extent in the Ross Sea that dominates the overall trend. Whether the smaller overall increase in Antarctic sea ice extent is meaningful as an indicator of climate is uncertain because the extent varies so much from year to year and from place to place around the continent. Results from a recent study suggest that these contrasting trends in ice coverage may be due to trends in regional wind speed and patterns. Without better ice thickness and ice volume estimates, it is difficult to characterize how Antarctic sea ice cover is responding to changing climate, or which climate parameters are most influential.

There are large differences in the physical environment and processes that affect the state of Arctic and Antarctic sea ice cover and contribute to their dissimilar responses to climate change. The long, and unbroken, record of satellite observations have provided a clear picture of the decline of the Arctic sea ice cover, but available evidence precludes us from making robust statements about overall changes in Antarctic sea ice and their causes.

[INSERT FAQ 4.2, Figure 1 HERE]

FAQ 4.2, Figure 1: The mean circulation pattern of sea ice and the decadal trends (%) in annual anomalies in ice extent (i.e., after removal of the seasonal cycle), in different sectors of the Arctic and Antarctic. Arrows show the average direction and magnitude of ice drift. The average sea ice cover for the period 1979 through 2012, from satellite observations, at maximum (minimum) extent is shown as orange (grey) shading.

Appendix 4.A: Details of Available and Selected Ice Sheet Mass Balance Estimates from 1992 to 2012

All comprehensive mass balance estimates available for Greenland, and the sub-set of those selected for this assessment (Section 4.4.2) are listed in Tables 4.A.1 and 4.A.2. Those available for Antarctica are shown in Tables 4.A.3 and 4.A.4. These studies include estimates made from satellite gravimetry (GRACE), satellite altimetry (radar and laser) and the mass balance (flux) method. The studies selected for this assessment are the latest made by different research groups, for each of Greenland and Antarctica. The tables indicate whether smaller glaciers peripheral to the ice sheet are included, or excluded, in the estimate, and explain why some studies were not selected (e.g., earlier estimates from the same researchers have been updated by more recent analyses using extended data).

Table 4.A.1: Sources used for calculation of ice loss from Greenland.

Source	Method	Start	End	Gt yr ⁻¹	Uncertainty	Peripheral Glaciers	Comment
(Ewert et al., 2012)	Laser alt.	2003.8	2008.2	-185	28	excluded	
	GRACE	2002.7	2009.5	-191	21	included	
(Harig and Simons, 2012)	GRACE	2003.0	2011.0	-200	6	included	Yearly estimates used in compilation. GIA uncertainty not provided.
(Sasgen et al., 2012)	GRACE	2002.7	2011.7	-240	18	included	Yearly estimates used in compilation.
	Flux	2002.7	2011.7	-244	53	excluded	Yearly estimates used in compilation.
(Chen et al., 2011)	Laser alt.	2003.8	2009.8	-245	28	included	
	GRACE	2002.3	2005.3	-144	25	included	
(Rignot et al., 2011c)	GRACE	2005.3	2009.9	-248	43	included

Review Editors: Jonathan Bamber (UK), Philippe Huybrechts (Belgium), Peter Lemke (Germany)

Date of Draft: 7 June 2013

Figures

Figure 4.1: The cryosphere in the Northern and Southern Hemispheres in polar projection. The map of the Northern Hemisphere shows the sea ice cover during minimum summer extent (13th September 2012). The yellow line is the average location of the ice edge (15% ice concentration) for the yearly minima from 1979 to 2012. Areas of continuous permafrost (see Glossary) are shown in dark pink, discontinuous permafrost in light pink. The green line along the southern border of the map shows the maximum snow extent while the black line across North America, Europe and Asia shows the contour for the 50% snow extent. The Greenland ice sheet (blue/grey) and locations of glaciers (small golden dots) are also shown. The map of the Southern Hemisphere shows approximately the maximum sea ice cover during an austral winter (13th September 2012). The yellow line shows the average ice edge (15% ice concentration) during maximum extent of the sea ice cover from 1979 to 2012. Some of the elements (e.g., some glaciers and snow) located at low latitudes are not visible in this projection (see Figure 4.8). The source of the data for sea ice, permafrost, snow and ice sheet are datasets held at the National Snow and Ice Data Center (NSIDC), University of Colorado, on behalf of the North American Atlas, Instituto Nacional de Estadística, Geografía e Informática (Mexico), Natural Resources Canada, U.S. Geological Survey, Government of Canada, Canada Centre for Remote Sensing and The Atlas of Canada. Glacier locations were derived from the multiple datasets compiled in the Randolph Glacier Inventory (Arendt et al., 2012).

Figure 4.2: (a) Plots of decadal averages of daily sea ice extent in the Arctic (1979 to 1988 in red, 1989 to 1998 in blue, 1999 to 2008 in gold) and a four-year average daily ice extent from 2009 to 2012 in black. Maps ice concentration trends (1979–2012) in (b) winter, (c) spring, (d) summer and (e) autumn (updated from Comiso, 2010).

Figure 4.3: Ice extent in the Arctic from 1870 to 2011. (a) Annual ice extent, and (b) seasonal ice extent using averages of mid-month values derived from in situ and other sources including observations from the Danish meteorological stations from 1870 to 1978 (updated from, Walsh and Chapman, 2001). Ice extent from a joint Hadley and NOAA project (called HADISST1_Ice) from 1900 to 2011 is also shown. The yearly and seasonal averages for the period from 1979 to 2011 are shown as derived from SMMR and SSM/I passive microwave data (called SBA and NT1) using procedures in Comiso and Nishio (2008), and Cavalieri et al. (1984), respectively; and from AMSR2 procedures (called ABA and NT2) from Comiso and Nishio (2008) and Markus and Cavalieri (2000). In (b), data from the different seasons are shown in different colours to illustrate variation between seasons, with SBA data from the procedure in Comiso and Nishio (2008) shown in black.

Figure 4.4: Annual perennial (blue) and multiyear (green) sea ice extent (a) and sea ice area (b) in the Central Arctic from 1979 to 2012 as derived from satellite passive microwave data. Perennial ice values are derived from summer ice minimum values, while the multiyear ice values are averages of those from December, January and February. The gold lines (after 2002) are from AMSR-E data (updated from Comiso, 2012).

Figure 4.5: The distribution of winter sea ice thickness in the Arctic and the trends in average, first-year (FY and multiyear (MY) ice thickness derived from ICESat data between 2004 and 2008 (Kwok, 2009).

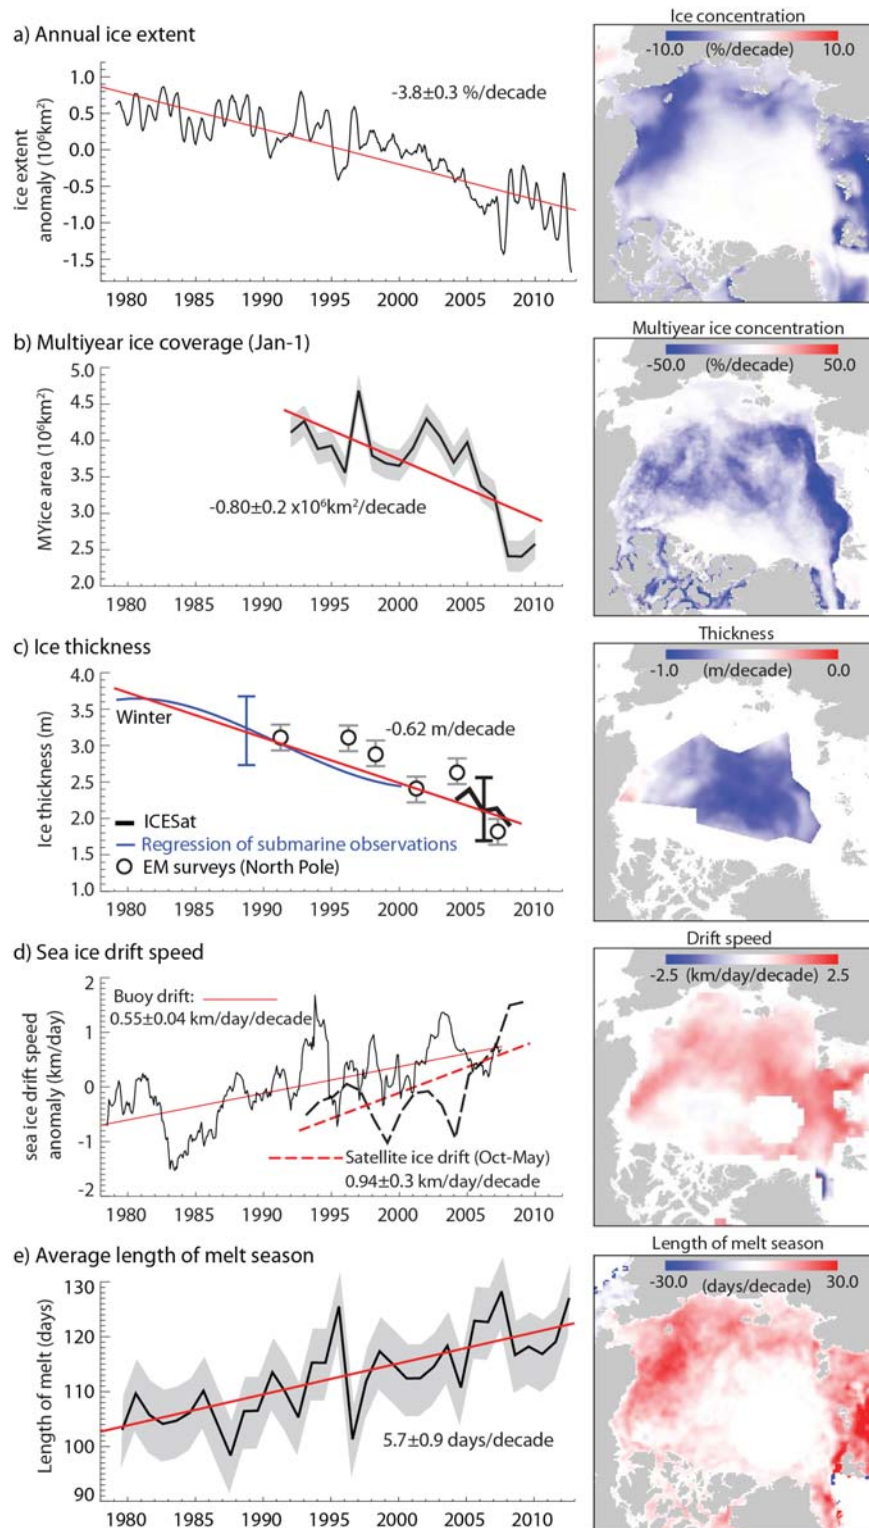

Figure 4.6: Summary of linear decadal trends (red lines) and pattern of changes in: (a) Anomalies in Arctic sea ice extent from satellite passive microwave observations (Comiso and Nishio, 2008, updated to include 2012). Uncertainties are discussed in the text. (b) Multiyear sea ice coverage on January 1st from analysis of the QuikSCAT time series (Kwok, 2009); grey band shows uncertainty in the retrieval. (c) Sea ice thickness from submarine (blue), satellites (black) (Kwok and Rothrock, 2009), and in-situ/EM surveys (circles) (Haas et al., 2008); trend in submarine ice thickness is from multiple regression of available observations within the data release area (Rothrock et al., 2008). Error bars show uncertainties in observations. (d) Anomalies in buoy (Rampal et al., 2009) and satellite-derived sea ice drift speed (Spreen et al., 2011). (e) Length of melt season (updated from, Markus et al., 2009); grey band shows the basin-wide variability.

Figure 4.7: (a) Plots of decadal averages of daily sea ice extent in the Antarctic (1979 to 1988 in red, 1989 to 1998 in blue, 1999 to 2008 in gold) and a four-year average daily ice extent from 2009 to 2012 in black. Maps of ice concentration trends (1979–2012) in (b) winter, (c) spring, (d) summer and (e) autumn (updated from Comiso, 2010).

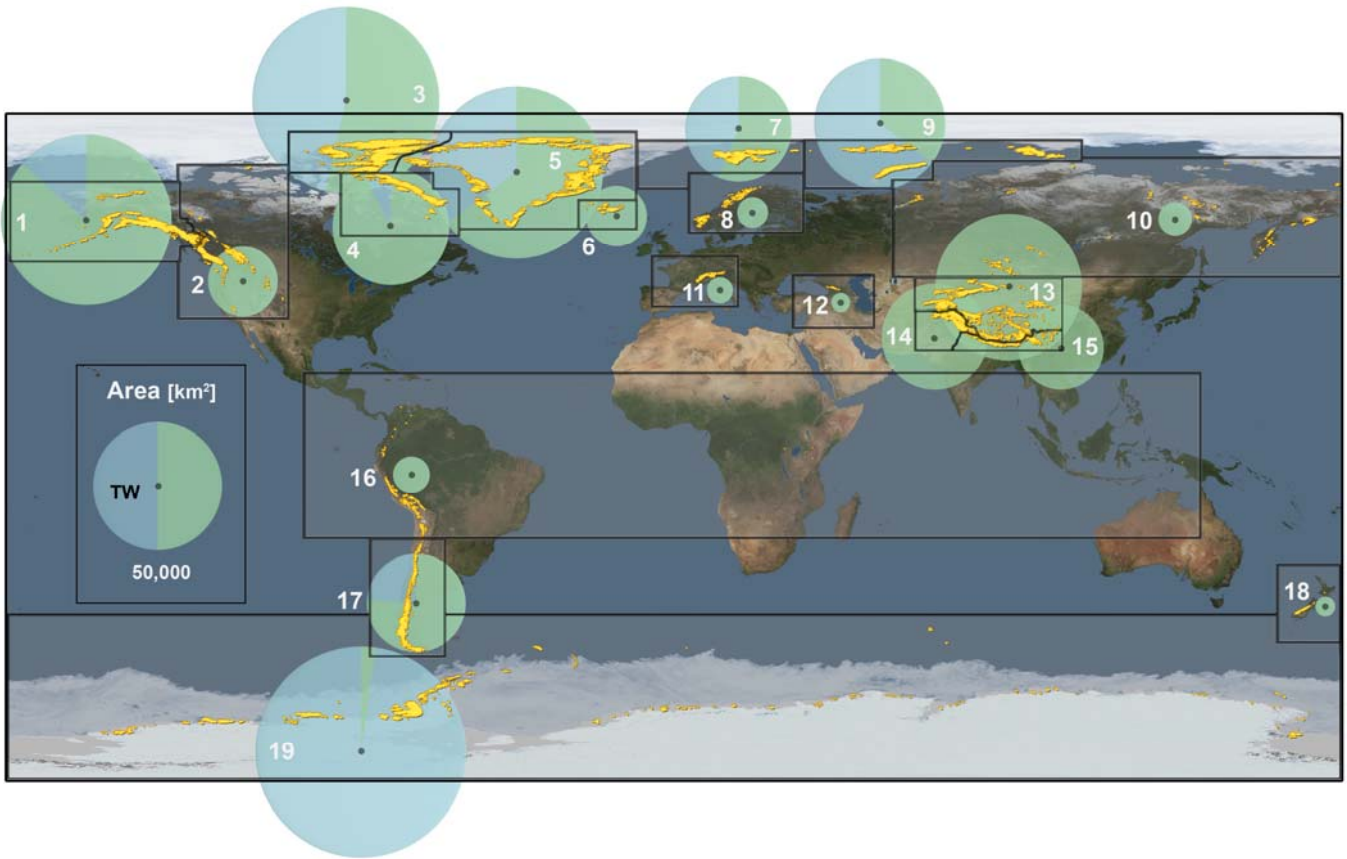

Figure 4.8: Global distribution of glaciers (yellow, area increased for visibility) and area covered (diameter of the circle), sub-divided into the 19 RGI regions (white number) referenced in Table 4.2. The area percentage covered by tidewater (TW) glaciers in each region is shown in green. Data from Arendt et al. (2012) and Gardner et al. (2013).

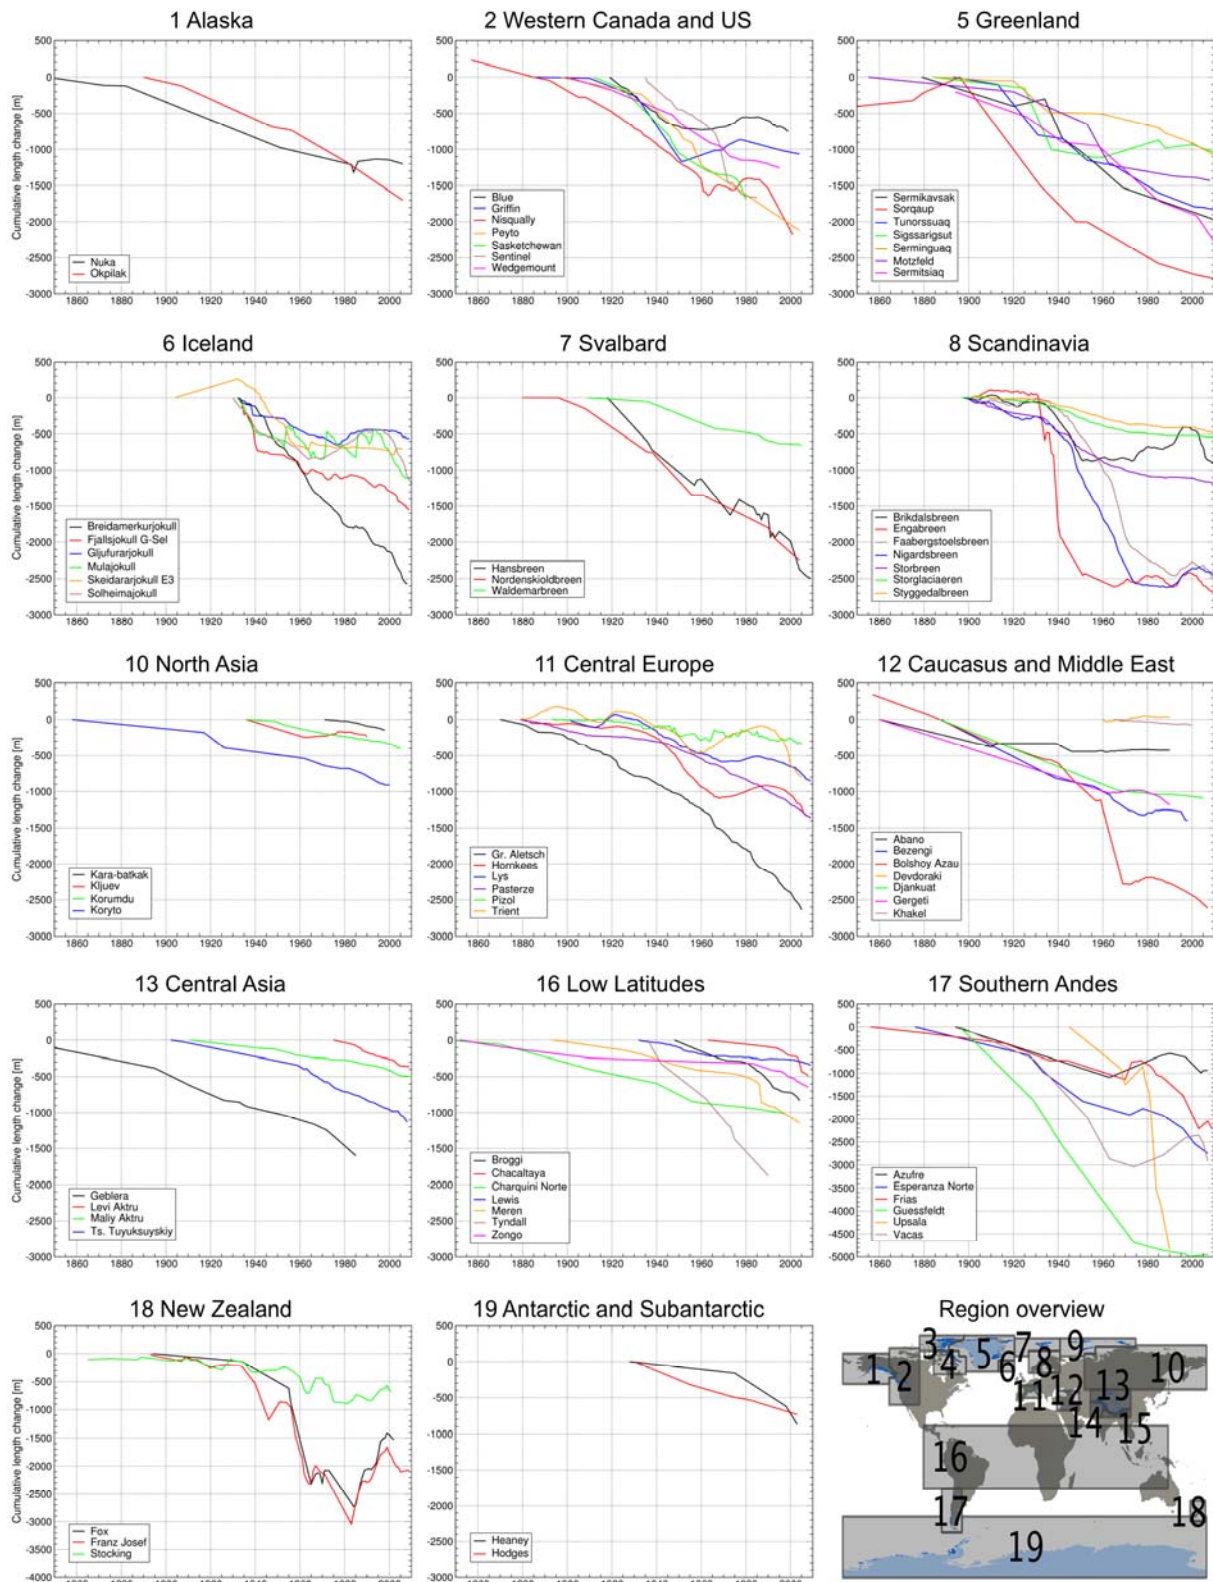

Figure 4.9: Selection of long-term cumulative glacier length changes as compiled from in situ measurements (WGMS, 2008), reconstructed data points added to measured time series (region 5) from Leclercq et al. (2012), and additional time series from reconstructions (regions 1, 2, 7, 10, 12, 16, 17, and 18) from Leclercq and Oerlemans (2012). Independent of their (highly variable) temporal density, all measurement points are connected by straight lines. The glacier Mulajokull (region 6) is of surge type and some of the glaciers showing strong retreat either terminate (Guessfeldt and Upsala in region 17) or terminated (Engabreen and Nigardsbreen in region 8) in lakes. For region 11, many more time series are available (see, WGMS, 2008), but are not shown for graphical reasons.

Figure 4.10: Mean annual relative area-loss rates for 16 out of the 19 RGI regions of Figure 4.8. Each line shows a measurement of the rate of percentage change in area over a mountain range from a specific publication (for sources see Table 4.SM.1), the length of the line shows the period used for averaging.

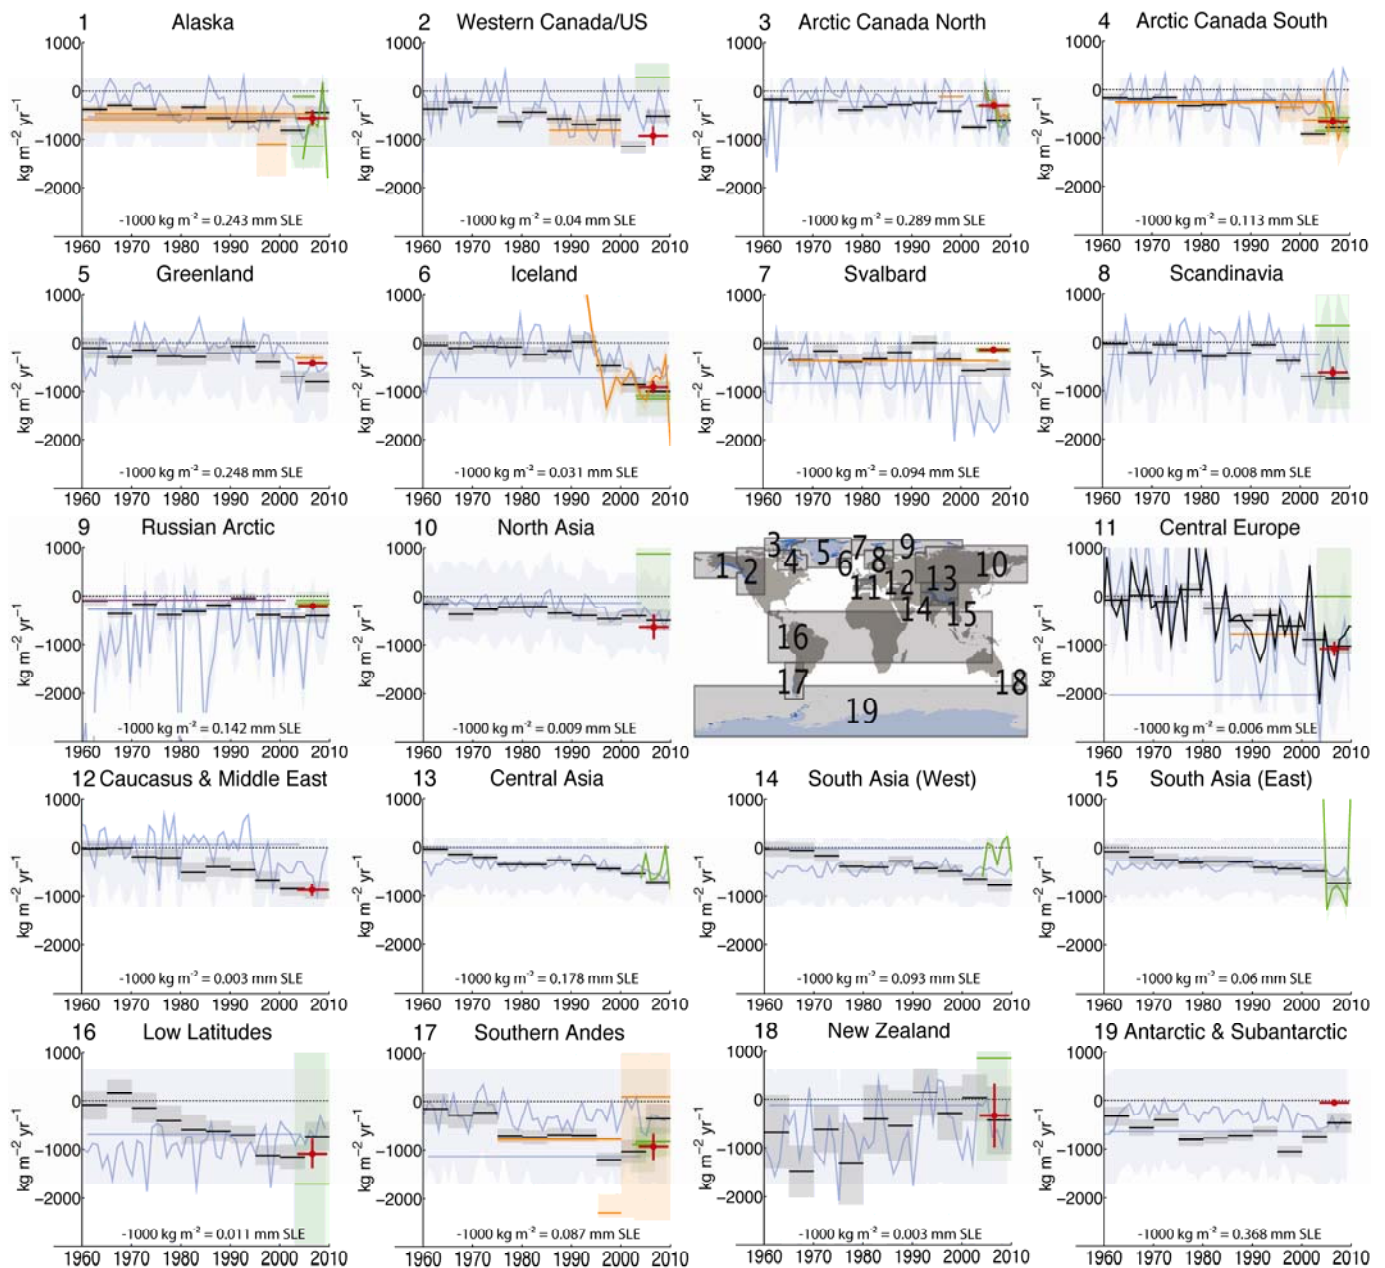

Figure 4.11: Regional glacier mass budgets in units of $\text{kg m}^{-2} \text{yr}^{-1}$ for the world's 19 glacierized regions (Figure 4.8 and Table 4.2). Estimates are from modelling with climate data (blue: Hock et al., 2009; Marzeion et al., 2012), repeat gravimetry (green: Chen et al., 2007; Luthcke et al., 2008; Peltier, 2009; Matsuo and Heki, 2010; Wu et al., 2010; Gardner et al., 2011; Ivins et al., 2011; Schrama and Wouters, 2011; Jacob et al., 2012, updated for RGI regions), repeat volume area scaling (magenta: Glazovsky and Macheret, 2006), interpolation of local glacier records (black: Cogley, 2009a; Huss, 2012), or airborne and/or satellite repeat topographic mapping (orange: Arendt et al., 2002; Rignot et al., 2003; Abdalati et al., 2004; Schiefer et al., 2007; Paul and Haeberli, 2008; Berthier et al., 2010; Moholdt et al., 2010; Nuth et al., 2010; Gardner et al., 2011; Gardner et al., 2012; Moholdt et al., 2012; Willis et al., 2012; Björnsson et al., 2013; Bolch et al., 2013). Mass-budget estimates are included only for study domains that cover $\sim 50\%$ or more of the total regional glacier area. Mass-budget estimates include 90% confidence envelopes (not available from all studies). Conversions from specific mass budget in kg m^{-2} to mm SLE are given for each region. Gravimetric estimates are often not accompanied by estimates of glacierized area (required for conversion from Gt yr^{-1} to $\text{kg m}^{-2} \text{yr}^{-1}$); in such cases the RGI regional glacier areas were used.

Figure 4.12: Global cumulative (top graphs) and annual (lower graphs) glacier mass change for (a) 1801–2010 and (b) 1961–2010. The cumulative estimates are all set to zero mean over 1986–2005. Estimates are based on glacier length variations (updated from, Leclercq et al., 2011), from area-weighted extrapolations of individual directly and geodetically measured glacier mass budgets (updated from, Cogley, 2009b), and from modelling with atmospheric variables as input (Marzeion et al., 2012; Hirabayashi et al., 2013). Uncertainties are based on comprehensive error analyses in Cogley (2009b) and Marzeion et al. (2012) and on assumptions about the representativeness of the sampled glaciers in Leclercq et al. (2011). Hirabayashi et al (2013) give a bulk error estimate only. For clarity in the bottom panels, uncertainties are only shown for the Cogley and Marzeion curves excluding Greenland (GL). The blue bars (panel a, top) show the number of measured single-glacier mass balances per pentad in the updated Cogley (2009b) time series. The mean 2003–2009 estimate of Gardner et al. (2013) is added to the bottom panel b.

Figure 4.13: Key variable related to the determination of the Greenland ice sheet mass changes. (a) mean surface mass balance for 1989–2004 from regional atmospheric climate modelling (Ettema et al., 2009); (b) ice sheet velocity for 2007–2009 determined from satellite data, showing fastest flow in red, fast flow in blue, and slower flow in green and yellow (Rignot and Mouginot, 2012); (c) changes in ice sheet surface elevation for 2003–2008 determined from ICESat altimetry, with elevation decrease in red to increase in blue (Pritchard et al., 2009). (d–e) Temporal evolution of ice loss determined from GRACE time-variable gravity, shown in centimetres of water per year for the periods (a) 2003–2012, (b) 2003–2006 and (c) 2006–2012, colour coded red (loss) to blue (gain) (Velicogna, 2009). Fields shown in (a) and (b) are used together with ice thickness (see Figure 4.18) in the mass budget method.

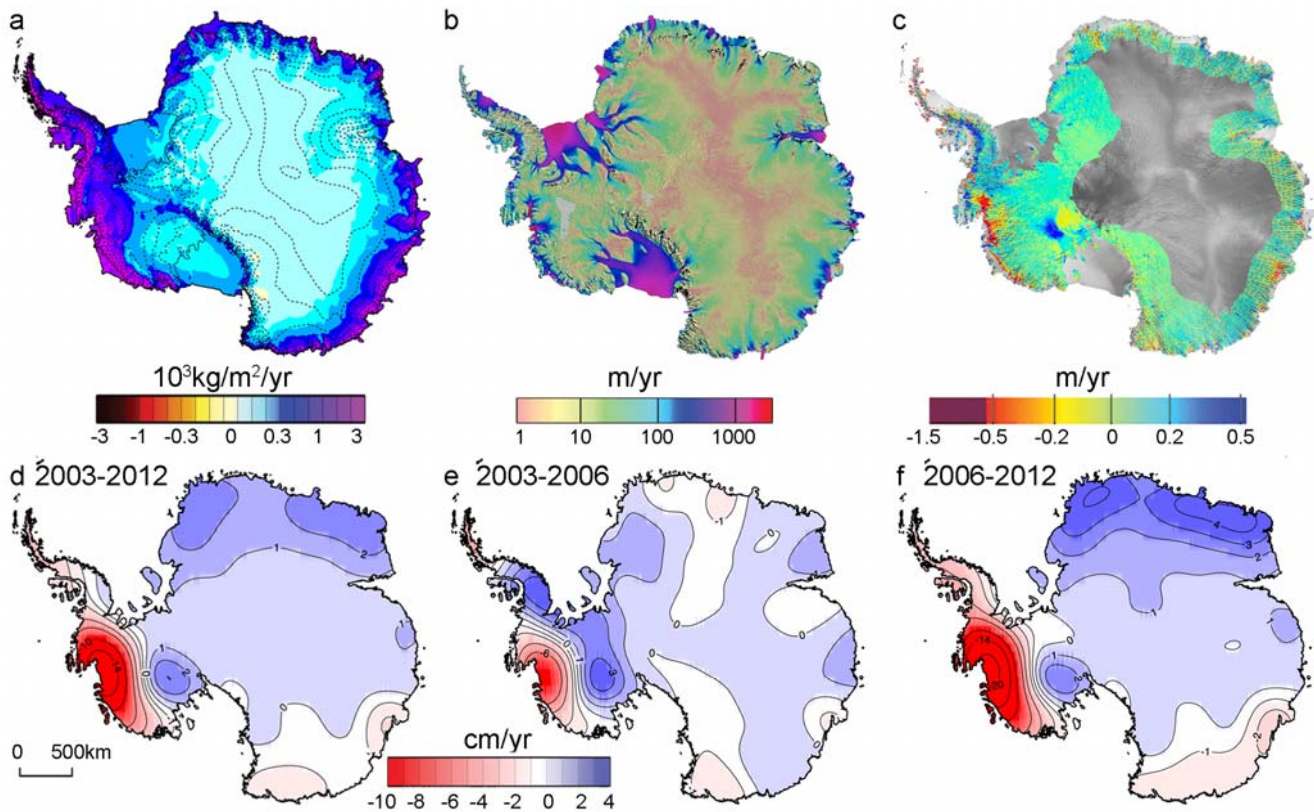

Figure 4.14: Key fields relating to the determination of Antarctica ice sheet mass changes. (a) mean surface mass balance for 1989–2004 from regional atmospheric climate modelling (van den Broeke et al., 2006); (b) ice sheet velocity for 2007–2009 determined from satellite data, showing fastest flow in red, fast flow in blue, and slower flow in green and yellow (Rignot et al., 2011a); (c) changes in ice sheet surface elevation for 2003–2008 determined from ICESat altimetry, with elevation decrease in red to increase in blue (Pritchard et al., 2009). (d–e) Temporal evolution of ice loss determined from GRACE time-variable gravity, shown in centimetres of water per year for the periods (a) 2003–2012, (b) 2003–2006 and (c) 2006–2012, colour coded red (loss) to blue (gain) (Velicogna, 2009). Fields shown in (a) and (b) are used together with ice thickness (see Figure 4.18) in the mass budget method.

Figure 4.15: Cumulative ice mass loss (and sea level equivalent, SLE) from Greenland derived as annual averages from 18 recent studies (see main text and Appendix 4.A for details).

Figure 4.16: Cumulative ice mass loss (and sea level equivalent, SLE) from Antarctica derived as annual averages from 10 recent studies (see main text and Appendix 4.A for details).

Figure 4.17: Rate of ice sheet loss in sea level equivalent averaged over 5-year periods between 1992 and 2011. These estimates are derived from the data in Figure 4.15 and Figure 4.16.

Figure 4.18: Subglacial and seabed topography for Greenland and Antarctica derived from digital compilations (Bamber et al., 2013; Fretwell et al., 2013). Blue areas highlight the marine-based parts of the ice sheets, which are extensive in Antarctica, but in Greenland, relate to specific glaciers troughs. Selected sections through the ice sheet show reverse bed gradients that exist beneath some glaciers in both ice sheets.

Figure 4.19: March-April NH snow cover extent (SCE, circles) over the period of available data, filtered with a 13-term smoother and with shading indicating the 95% confidence interval; and June SCE (red crosses, from satellite data alone), also filtered with a 13-term smoother. The width of the smoothed 95% confidence interval is influenced by the interannual variability in SCE. Updated, from Brown and Robinson (2011). For both time series the anomalies are calculated relative to the 1971–2000 mean.

Figure 4.20: Relationship between NH April SCE and corresponding land air temperature anomalies over 40°N–60°N from the CRUtem4 dataset (Jones et al., 2012). Red circles indicate the years 2000–2012. The correlation is 0.76. Updated from Brown and Robinson (2011).

Figure 4.21: Compilation of studies (rows) showing trends at individual stations (symbols in each row, along with percentage of trends that are negative). For each study, if more than one quantity was presented, only the one representing spring conditions is shown. a) Number of days per year with SD >20 cm at 675 sites in northern Eurasia, 1966–2010 (Bulygina et al., 2011). b) March–April–May snowfall for 500 stations in California, aggregated into 4 regions (Christy, 2012). c) maximum SWE at 393 sites in Norway, 1961–2009 (Skaugen et al., 2012); statistically significant trends are denoted by solid circles. d) SD at 560 sites in China, 1957–2012 (Ma and Qin, 2012); statistically significant trends are denoted by solid red circles. e) Snow cover duration at 15 sites in the Romanian Carpathians, 1961–2003 (Micu, 2009). f) 1 April SWE at 799 sites, 1950–2000, in western North America (Mote, 2006). g) Difference between 1990s and 1960s March SD at 89 sites in Japan (Ishizaka, 2004). h) SCD at 15 sites for starting years near 1931, ending 2000 (Petkova et al., 2004). i) SCD at 18 sites in Italy, 1950–2009 (Valt and Cianfarra, 2010). j) SCD at 34 sites in Switzerland, 1948–2007, from Marty (2008). See text for definitions of abbreviations. For b) through j), the quantity plotted is the percentage change of a linear fit divided by the number of years of the fit. For studies with more than 50 sites, the median, upper and lower quartiles are shown with vertical lines. In a few cases, some trends lie beyond the edges of the graph; these are indicated by a numeral at the corresponding edge of the graph, e.g., 2 sites >2% yr⁻¹ in row f). Colours indicate temperature or, for studies e) and i), elevation using the lowest and highest site in the respective dataset to set the colour scale. Note the prevalence of negative trends at lower/warmer sites.

Figure 4.22: Time series of mean annual ground temperatures at depths between 10 and 20 m for boreholes throughout the circumpolar northern permafrost regions (Romanovsky et al., 2010a). Data sources are from Romanovsky et al. (2010b) and Christiansen et al. (2010). Measurement depth is 10m for Russian boreholes, 15 m for Gulkana and Oldman, and 20 m for all other boreholes. Borehole locations are: ZS-124 – 67.48°N 063.48°E; 85-8A – 61.68°N 121.18°W; Gulkana – 62.28°N 145.58°W; YA-1 – 67.58°N 648°E; Oldman – 66.48°N 150.68°W; Happy Valley – 69.18°N 148.88°W; Svalbard – 78.28°N 016.58°E; Deadhorse – 70.28°N 148.58°W; and West Dock – 70.48°N 148.58°W. The rate of change (°C/decade) in permafrost temperature over the period of each site record is: ZS-124: 0.53 ± 0.07 ; YA-1: 0.21 ± 0.02 ; West Dock: 0.64 ± 0.08 ; Deadhorse: 0.82 ± 0.07 ; Happy Valley: 0.34 ± 0.05 ; Gaibrath Lake: 0.35 ± 0.07 ; Gulkana: 0.15 ± 0.03 ; Old Man: 0.40 ± 0.04 ; and Svalvard: 0.63 ± 0.09 . (The trends are *very likely* range, 90%)

Figure 4.23: Active layer thickness from different locations for slightly different periods between 1990 and 2012 in (a) Northern America, (b) European North, and (c) Northern Asia. The dashed lines represents linear fit to each set of data. ALT data for Northern America, Northern Asia and European North were obtained from the International Permafrost Association (IPA) CALM website (<http://www.udel.edu/Geography/calm/about/permafrost.html>). The number of Russian Hydrometeorological Stations (RHM) stations has expanded from 31 stations as reported from Frauenfeld et al. (2004) and Zhang et al. (2005) to 44 stations and the time series has extended from 1990 to 2008. (d) Departures from the mean of active layer thickness in Siberia from 1950 to 2008. The red asterisk represents the mean composite value, the shaded area indicates the standard deviation, and the black line is the trend. Data for Siberia stations were obtained from the Russian Hydrometeorological Stations (RHM).

Figure 4.24: Annual anomalies of the average thickness of seasonally frozen depth in Russia from 1930 to 2000. Each data point represents a composite from 320 stations as compiled at the Russian Hydrometeorological Stations (RHM) (upper right inset). The composite was produced by taking the sum of the thickness measurements from each station and dividing the result by the number of stations operating in that year. Although the total number of stations is 320, the number providing data may be different for each year but the minimum was 240. The yearly anomaly was calculated by subtracting the 1971–2000 mean from the composite for each year. The thin lines indicate the $1\text{-}\sigma$ (*likely*) uncertainty range. The line shows a negative trend of -4.5 cm per decade or a total decrease in the thickness of seasonally frozen ground of 31.9 cm from 1930 to 2000 (Frauenfeld and Zhang, 2011).

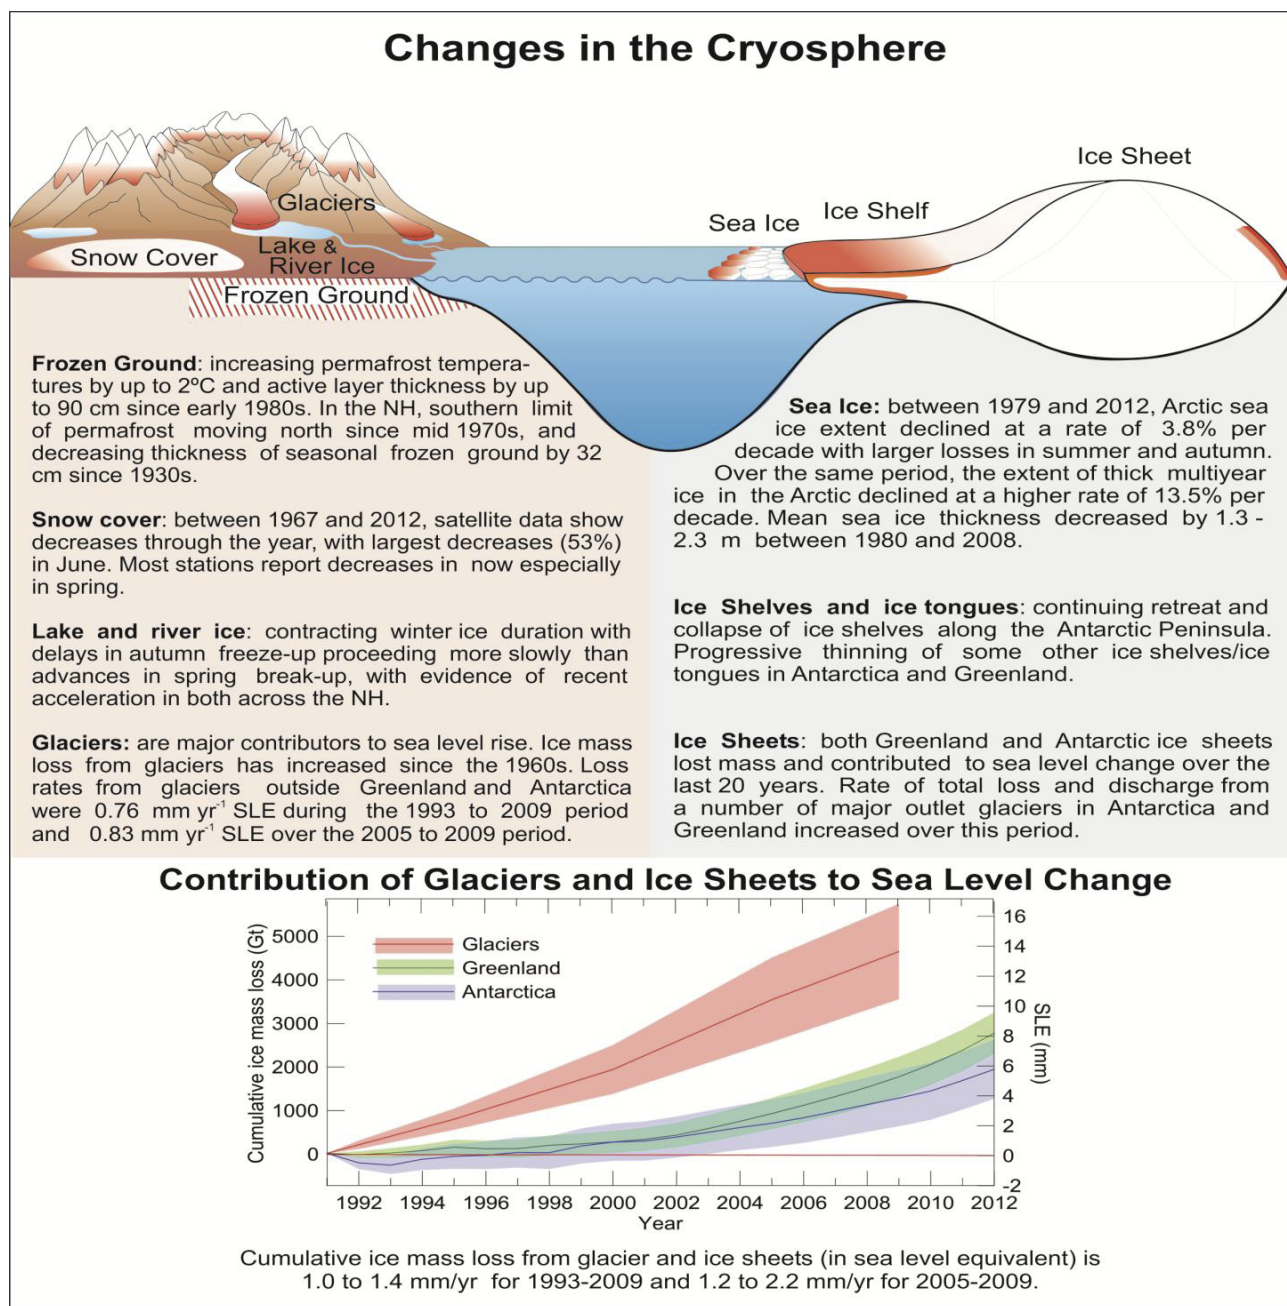

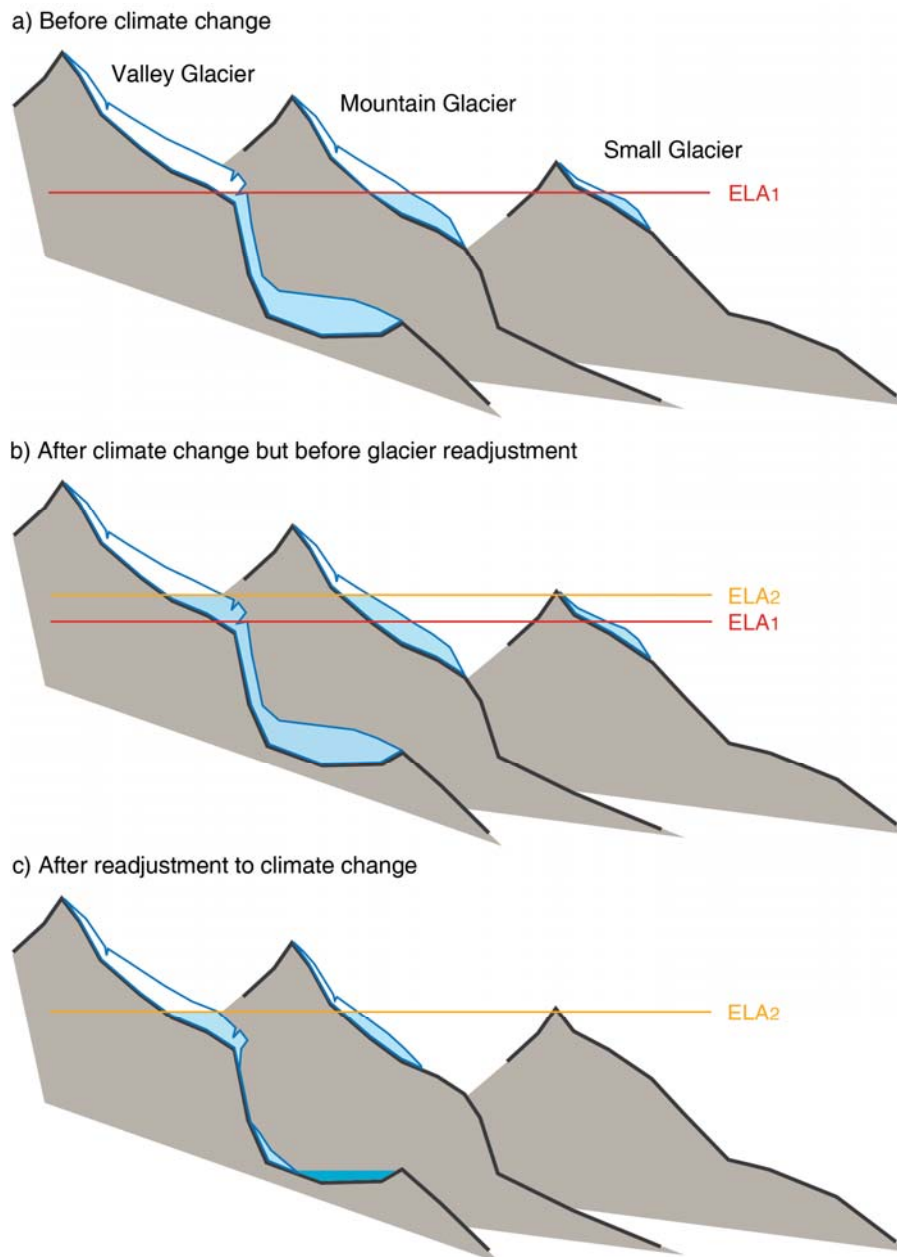

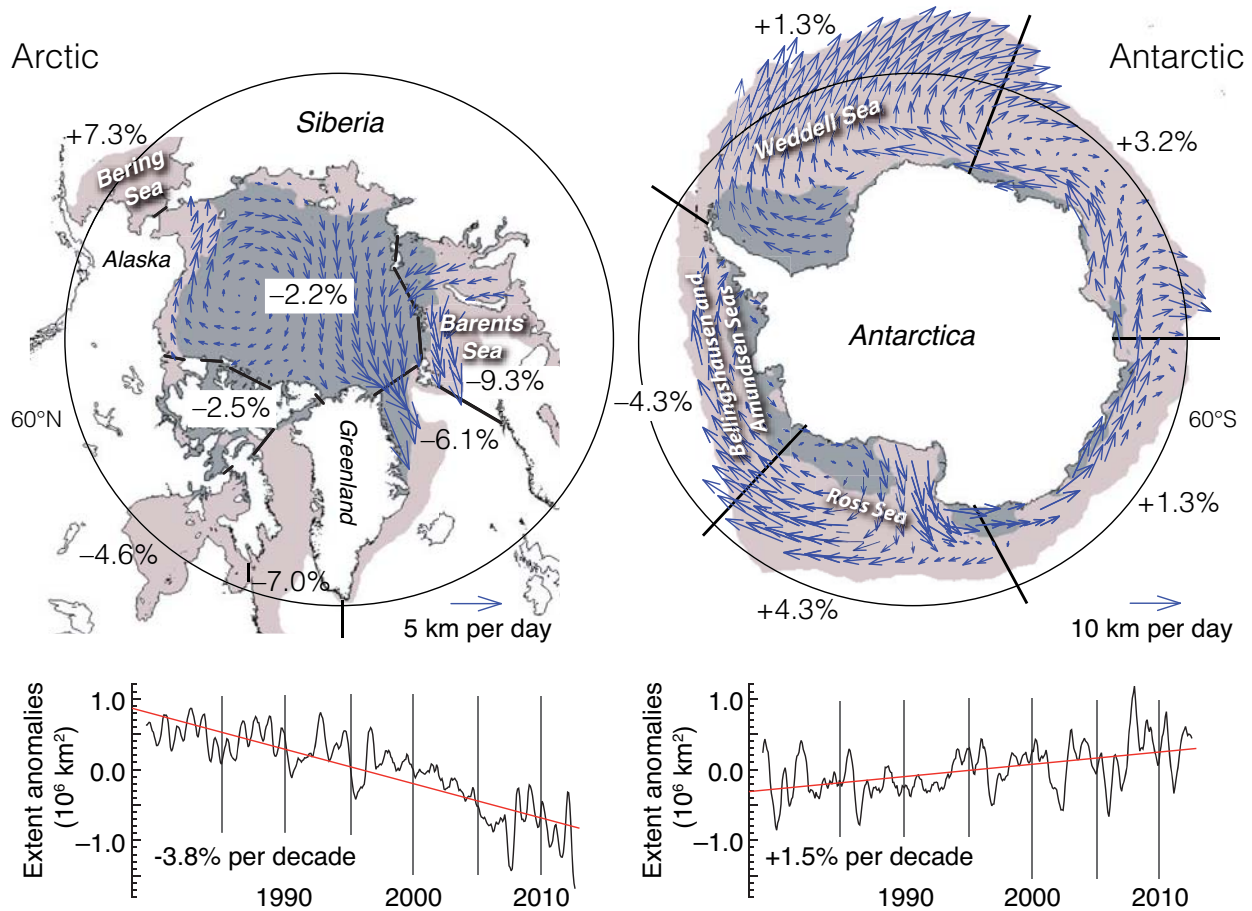

Figure 4.25: Schematic summary of the dominant observed variations in the cryosphere. The inset figure summarises the assessment of the sea level equivalent of ice loss from the ice sheets of Greenland and Antarctica, together with the contribution from all glaciers except those in the periphery of the ice sheets (Section 4.3.4).

FAQ 4.1, Figure 1: Schematic of three types of glaciers located at different elevations, and their response to an upward shift of the equilibrium line altitude (ELA). a) For a given climate, the ELA has a specific altitude (ELA1), and all glaciers have a specific size. b) Due to a temperature increase, the ELA shifts upwards to a new altitude (ELA2), initially resulting in reduced accumulation and larger ablation areas for all glaciers. c) After glacier size has adjusted to the new ELA, the valley glacier (left) has lost its tongue and the small glacier (right) has disappeared entirely.

FAQ 4.2, Figure 1: The mean circulation pattern of sea ice and the decadal trends (%) in annual anomalies in ice extent (i.e., after removal of the seasonal cycle), in different sectors of the Arctic and Antarctic. Arrows show the average direction and magnitude of ice drift. The average sea ice cover for the period 1979 through 2012, from satellite observations, at maximum (minimum) extent is shown as orange (grey) shading.

Executive Summary

Greenhouse-Gas Variations and Past Climate Responses

It is a fact that present-day (2011) concentrations of the atmospheric greenhouse gases carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O) exceed the range of concentrations recorded in ice cores during the past 800,000 years. Past changes in atmospheric greenhouse-gas concentrations can be determined with *very high confidence*¹ from polar ice cores. Since AR4 these records have been extended from 650,000 years to 800,000 years ago. [5.2.2]

With *very high confidence*, the current rates of CO₂, CH₄ and N₂O rise in atmospheric concentrations and the associated radiative forcing are unprecedented with respect to the highest resolution ice core records of the last 22,000 years. There is *medium confidence* that the rate of change of the observed greenhouse gas rise is also unprecedented compared with the lower resolution records of the past 800,000 years. [5.2.2]

There is *high confidence* that changes in atmospheric CO₂ concentration play an important role in glacial-interglacial cycles. While the primary driver of glacial-interglacial cycles lies in the seasonal and latitudinal distribution of incoming solar energy driven by changes in the geometry of the Earth's orbit around the Sun ("orbital forcing"), reconstructions and simulations together show that the full magnitude of glacial-interglacial temperature and ice volume changes cannot be explained without accounting for changes in atmospheric CO₂ content and the associated climate feedbacks. During the last deglaciation, it is *very likely*² that global mean temperature increased by 3°C to 8°C. While the mean rate of global warming was *very likely* 0.3°C to 0.8°C per thousand year, two periods were marked by faster warming rates, *likely* between 1°C and 1.5°C per thousand year, although regionally and on shorter time scales higher rates may have occurred [5.3.2]

New estimates of the equilibrium climate sensitivity based on reconstructions and simulations of the Last Glacial Maximum (21,000 years to 19,000 years ago) show that values below 1°C as well as above 6°C for a doubling of atmospheric CO₂ concentration are *very unlikely*. In some models climate sensitivity differs between warm and cold climates because of differences in the representation of cloud feedbacks. [5.3.3]

With *medium confidence*, global mean surface temperature was significantly above pre-industrial level during several past periods characterised by high atmospheric CO₂ concentrations. During the mid-Pliocene (3.3 to 3.0 million years ago), atmospheric CO₂ concentrations between 350 ppm and 450 ppm (*medium confidence*) occurred when global mean surface temperatures were approximately 2°C to 3.5°C (*medium confidence*) higher than for pre-industrial climate [5.3.1]. During the Early Eocene (52 to 48 million years ago), atmospheric CO₂ concentrations exceeded ~1000 ppm (*medium confidence*) when global mean surface temperatures were 9°C to 14°C (*medium confidence*) higher than for pre-industrial conditions. [5.3.1]

New temperature reconstructions and simulations of past climates show with *high confidence* polar amplification in response to changes in atmospheric CO₂ concentration. For high CO₂ climates such as the Early Eocene (52 to 48 million years ago) or mid-Pliocene (3.3 to 3.0 million years ago), and low CO₂ climates such as the Last Glacial Maximum (21,000 to 19,000 years ago), sea-surface and land-surface air temperature reconstructions and simulations show a stronger response to changes in atmospheric greenhouse gas concentrations at high latitudes as compared to the global average. [Box 5.1, 5.3.1, 5.3.3]

¹ In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

² In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99-100% probability, Very likely 90-100%, Likely 66-100%, About as likely as not 33-66%, Unlikely 0-33%, Very unlikely 0-10%, Exceptionally unlikely 0-1%. Additional terms (Extremely likely: 95-100%, More likely than not >50-100%, and Extremely unlikely 0-5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

Global Sea Level Changes During Past Warm Periods

The current rate of global mean sea level change, starting in the late 19th-early 20th century, is, with *medium confidence*, unusually high in the context of centennial-scale variations of the last two millennia. The magnitude of centennial-scale global mean sea level variations did not exceed 25 cm over the past few millennia (*medium confidence*). [5.6.3]

There is *very high confidence* that the maximum global mean sea level during the last interglacial period (129,000 to 116,000 years ago) was at least 5 m higher than present and *high confidence* that it did not exceed 10 m above present. The best estimate is 6 m higher than present. Based on ice-sheet model simulations consistent with elevation changes derived from a new Greenland ice core, the Greenland ice sheet *very likely* contributed between 1.4 and 4.3 m sea level equivalent, implying with *medium confidence* a contribution from the Antarctic ice sheet to the global mean sea level during the last interglacial period. [5.6.2]

There is *high confidence* that global mean sea level was above present during some warm intervals of the mid-Pliocene (3.3 to 3.0 million years ago), implying reduced volume of polar ice sheets. The best estimates from various methods imply with *high confidence* that sea level has not exceeded +20 m during the warmest periods of the Pliocene, due to deglaciation of the Greenland and West Antarctic ice sheets and areas of the East Antarctic ice sheet. [5.6.1]

Observed Recent Climate Change in the Context of Interglacial Climate Variability

New temperature reconstructions and simulations of the warmest millennia of the last interglacial period (129,000 to 116,000 years ago) show with *medium confidence* that global mean annual surface temperatures were never more than 2°C higher than pre-industrial. Greater warming at high-latitudes, seasonally and annually, confirm the importance of cryosphere feedbacks to the seasonal orbital forcing. During these periods, atmospheric greenhouse-gas concentrations were close to the pre-industrial level. [5.3.4, Box. 5.1]

There is *high confidence* that annual mean surface warming since the 20th century has reversed long-term cooling trends of the past 5,000 years in mid-to-high latitudes of the Northern Hemisphere. New continental- and hemispheric-scale annual surface temperature reconstructions reveal multi-millennial cooling trends throughout the past 5,000 years. The last mid-to-high latitude cooling trend persisted until the 19th century, and can be attributed with *high confidence* to orbital forcing, according to climate model simulations. [5.5.1]

There is *medium confidence* from reconstructions that the current (1980 to 2012) summer sea-ice retreat and increase in sea-surface temperatures in the Arctic are anomalous in the perspective of at least the last 2,000 years. Lower than late 20th century summer Arctic sea ice cover is reconstructed and simulated for the period between 8,000 and 6,500 years ago in response to orbital forcing. [5.5.2]

There is *high confidence* that minima in Northern Hemisphere extratropical glacier extent between 8,000 and 6,000 years ago were primarily due to high summer insolation (orbital forcing). The current glacier retreat occurs within a context of orbital forcing that would be favourable for Northern Hemisphere glacier growth. If glaciers continue to reduce at current rates, most extratropical Northern Hemisphere glaciers will shrink to their minimum extent, which existed between 8,000 and 6,000 years ago, within this century (*medium confidence*). [5.5.3]

For average annual Northern Hemisphere temperatures, the period 1983–2012 was *very likely* the warmest 30-year period of the last 800 years (*high confidence*) and *likely* the warmest 30-year period of the last 1400 years (*medium confidence*). This is supported by comparison of instrumental temperatures with multiple reconstructions from a variety of proxy data and statistical methods, and is consistent with AR4. In response to solar, volcanic and anthropogenic radiative changes, climate models simulate multidecadal temperature changes over the last 1200 years in the Northern Hemisphere, that are generally consistent in magnitude and timing with reconstructions, within their uncertainty ranges. [5.3.5]

Continental-scale surface temperature reconstructions show, with *high confidence*, multidecadal intervals during the Medieval Climate Anomaly (950 to 1250) that were in some regions as warm as in the mid-20th century and in others as warm as in the late 20th century. With *high confidence*, these intervals were not as synchronous across seasons and regions as the warming since the mid-20th century. Based on the comparison between reconstructions and simulations, there is *high confidence* that not only external orbital, solar and volcanic forcing, but also internal variability, contributed substantially to the spatial pattern and timing of surface-temperature changes between the Medieval Climate Anomaly and the Little Ice Age (1450 to 1850). [5.3.5.3, 5.5.1]

There is *high confidence* for droughts during the last millennium of greater magnitude and longer duration than those observed since the beginning of the 20th century in many regions. There is *medium confidence* that more megadroughts occurred in monsoon Asia and wetter conditions prevailed in arid Central Asia and the South American monsoon region during the Little Ice Age (1450 to 1850) compared to the Medieval Climate Anomaly (950 to 1250). [5.5.4 and 5.5.5]

With *high confidence*, floods larger than those recorded since 1900 occurred during the past five centuries in northern and central Europe, western Mediterranean region, and eastern Asia. There is *medium confidence* that modern large floods are comparable to or surpass historical floods in magnitude and/or frequency in the Near East, India, and central North America. [5.5.5]

Past Changes in Climate Modes

New results from high-resolution coral records document with *high confidence* that the El Niño-Southern Oscillation (ENSO) system has remained highly variable throughout the past 7,000 years, showing no discernible evidence for an orbital modulation of ENSO. This is consistent with the weak reduction in mid-Holocene ENSO amplitude of only 10% simulated by the majority of climate models, but contrasts with reconstructions reported in AR4 that showed a reduction in ENSO variance during the first half of the Holocene. [5.4]

With *high confidence*, decadal and multidecadal changes in the winter North Atlantic Oscillation index (NAO) observed since the 20th century are not unprecedented in the context of the past 500 years. Periods of persistent negative or positive winter NAO phases, similar to those observed in the 1960s and 1990 to 2000s, respectively, are not unusual in the context of NAO reconstructions during at least the past 500 years. [5.4]

The increase in the strength of the observed summer Southern Annular Mode since 1950 has been anomalous, with *medium confidence*, in the context of the past 400 years. No similar spatially coherent multidecadal trend can be detected in tree-ring indices from New Zealand, Tasmania and South America. [5.4]

Abrupt Climate Change and Irreversibility

With *high confidence*, the interglacial mode of the Atlantic Ocean meridional overturning circulation (AMOC) can recover from a short-term freshwater input into the subpolar North Atlantic.

Approximately 8,200 years ago, a sudden freshwater release occurred during the final stages of North America ice-sheet melting. Paleoclimate observations and model results indicate, with *high confidence*, a marked reduction in the strength of the AMOC followed by a rapid recovery, within approximately 200 years after the perturbation. [5.8.1]

Confidence in the link between changes in North Atlantic climate and low-latitude precipitation patterns has increased since AR4. From new paleoclimate reconstructions and modelling studies, there is *very high confidence* that reduced AMOC and the associated surface cooling in the North Atlantic region caused southward shifts of the Atlantic Intertropical Convergence Zone, and also affected the American (North and South), African and Asian monsoon systems. [5.7]

It is *virtually certain* that orbital forcing will be unable to trigger widespread glaciation during the next 1,000 years. Paleoclimate records indicate that, for orbital configurations close to present-day, glacial inceptions only occurred for atmospheric CO₂ concentrations significantly lower than pre-industrial levels. Climate models simulate no glacial inception during the next 50,000 years if CO₂ concentrations remain above 300 ppm. [5.8.3, Box 6.2]

There is *high confidence* that the volumes of the Greenland and West Antarctic ice sheets were reduced during periods of the past few million years that were globally warmer than present. Ice-sheet model simulations and geological data suggest that the West Antarctic ice sheet is very sensitive to subsurface Southern Ocean warming and imply with *medium confidence* a West Antarctic ice-sheet retreat if atmospheric CO₂ concentration remains above approximately 400 ppm for several millennia. [5.3.1; 5.6.1; 5.8.1]

5.1 Introduction

This chapter assesses the information on past climate obtained prior to the instrumental period. The information is based on data from various paleoclimatic archives and on modelling of past climate, and updates Chapter 6 of AR4 of IPCC Working Group I (Jansen et al., 2007).

The Earth system has responded and will continue to respond to various external forcings (solar, volcanic and orbital) and to changes in atmospheric composition. Paleoclimate data and modelling provide quantitative information on the Earth-system response to these forcings. Paleoclimate information facilitates understanding of Earth-system feedbacks on timescales longer than a few centuries, which cannot be evaluated from short instrumental records. Past climate changes also document transitions between different climate states, including abrupt events, which occurred on timescales of decades to a few centuries. They inform about multi-centennial to millennial baseline variability, against which the recent changes can be compared to assess whether or not they are unusual.

Major progress since AR4 includes the acquisition of new and more precise information from paleoclimate archives, the synthesis of regional information, and Paleoclimate Modelling Intercomparison Project Phase III (PMIP3) and Climate Modelling Intercomparison Project Phase 5 (CMIP5) simulations using the same models as for projections (see Chapter 1). This chapter assesses the understanding of past climate variations, using paleoclimate reconstructions as well as climate models of varying complexity, while the model evaluation based on paleoclimate information is covered in Chapter 9. Additional paleoclimate perspectives are included in Chapters 6, 10, and 13 (see Table 5.1).

The content of this chapter is largely restricted to topics for which substantial new information has emerged since AR4. Examples include proxy-based estimates of the atmospheric CO₂ content during the past ~65 million years (Section 5.2.2), and magnitude of sea level variations during interglacial periods (Section 5.6.2). Information from glacial climates has only been included if the underlying processes are of direct relevance for an assessment of projected climate change. The impacts of past climate changes on biological systems and past civilizations are not covered, as these topics are beyond the scope of Working Group I.

The chapter proceeds from evidence for pre-industrial changes in atmospheric composition and external solar and volcanic forcings (Section 5.2, FAQ 5.1), to global and hemispheric responses (Section 5.3). After evaluating the evidence for past changes in climate modes of variability (Section 5.4), a specific focus is given to regional changes in temperature, cryosphere and hydroclimate during the current interglacial period (Section 5.5). Sections on sea level change (Section 5.6, FAQ 5.2), abrupt climate changes (Section 5.7) and illustrations of irreversibility and recovery time scales (Section 5.8), conclude the chapter. While polar amplification of temperature changes is addressed in Box 5.1, the relationships between ice sheets, sea level, atmospheric CO₂ concentration and climate are addressed in several sections (Box 5.2, Sections 5.3.1, 5.5, and 5.8.1).

Additional information to this chapter is available in the Appendix. Processed data underlying the figures are stored in the PANGAEA database (www.pangaea.de), while model output from PMIP3 is available from: pmip3.lsce.ipsl.fr. In all sections, information is structured by time; going from past to present. Table 5.1 summarizes the past periods assessed in the subsections.

[INSERT TABLE 5.1 HERE]

Table 5.1. Summary of past periods for which climate information is assessed in the various sections of this chapter and other chapters of AR5. Calendar ages are expressed in Common Era (CE), geological ages are expressed in thousand years (ka) or million years (Ma) before present (BP), with present defined as 1950. Radiocarbon-based ages are quoted as the published calibrated ages.

5.2 Pre-Industrial Perspective on Radiative Forcing Factors

5.2.1 External Forcings

5.2.1.1 Orbital Forcing

The term "orbital forcing" is used to denote the incoming solar radiation changes originating from variations in Earth's orbital parameters as well as changes in its axial tilt. Orbital forcing is well known from precise astronomical calculations for the past and future (Laskar et al., 2004). Changes in eccentricity, longitude of perihelion (related to precession), and axial tilt (obliquity) (Berger and Loutre, 1991) predominantly affect the seasonal and latitudinal distribution and magnitude of solar energy received at the top of the atmosphere (AR4, Box 6.1; Jansen et al., 2007), and the durations and intensities of local seasons. Obliquity also modulates the annual mean insolation at any given latitude, with opposite effects at high and low latitudes. Orbital forcing is considered the pacemaker of transitions between glacials and interglacials (*high confidence*), although there is still no consensus on exactly how the different physical processes influenced by insolation changes interact to influence ice-sheet volume (Box 5.2; Section 5.3.2). The different orbital configurations make each glacial and interglacial period unique (Yin and Berger, 2010; Tzedakis et al., 2012a). Multi-millennial trends of temperature, Arctic sea ice, and glaciers during the current interglacial period, and specifically the last 2,000 years have been related to orbital forcing (Section 5.5).

5.2.1.2 Solar Forcing

Solar irradiance models (e.g., Wenzler et al., 2005) have been improved to better explain the instrumental measurements of total solar irradiance (TSI) and spectral (wavelength dependent) solar irradiance (SSI). Typical changes measured over an 11-year solar cycle are 0.1% for TSI and up to several percent for the ultra-violet (UV) part of SSI (see Section 8.4). Changes in TSI directly impact the Earth's surface (see solar Box 10.2), whereas changes in UV primarily affect the stratosphere, but can influence the tropospheric circulation through dynamical coupling (Haigh, 1996). Most models attribute all TSI and SSI changes exclusively to magnetic phenomena at the solar surface (sunspots, faculae, magnetic network), neglecting any potential internal phenomena such as changes in energy transport (see also Section 8.4). The basic concept in solar models is to divide the solar surface into different magnetic features each with a specific radiative flux. The balance of contrasting dark sunspots and bright faculae and magnetic network leads to a higher TSI value during solar cycle maxima and at most wavelengths, but some wavelengths may be out of phase with the solar cycle (Harder et al., 2009; Cahalan et al., 2010; Haigh et al., 2010). TSI and SSI are calculated by adding the radiative fluxes of all features plus the contribution from the magnetically inactive surface. These models can successfully reproduce the measured TSI changes between 1978 and 2003 (Balmaceda et al., 2007; Crouch et al., 2008), but not necessarily the last minimum of 2008 (Krivova et al., 2011). This approach requires detailed information of all the magnetic features and their temporal changes (Wenzler et al., 2006; Krivova and Solanki, 2008) (see Section 8.4).

The extension of TSI and SSI into the pre-satellite period poses two main challenges. First, the satellite period (since 1978) used to calibrate the solar irradiance models does not show any significant long-term trend. Second, information about the various magnetic features at the solar surface decreases back in time and must be deduced from proxies such as sunspot counts for the last 400 years and cosmogenic radionuclides (^{10}Be and ^{14}C) for the past Millennium (Muscheler et al., 2007; Delaygue and Bard, 2011) and the Holocene (Table 5.1) (Steinhilber et al., 2009; Vieira et al., 2011). ^{10}Be and ^{14}C records not only reflect solar activity, but also the geomagnetic field intensity and effects of their respective geochemical cycles and transport pathways (Pedro et al., 2011; Steinhilber et al., 2012). The corrections for these non-solar components, which are difficult to quantify, contribute to the overall error of the reconstructions (grey band in Figure 5.1c).

TSI reconstructions are characterized by distinct grand solar minima lasting 50–100 years (e.g., the Maunder Minimum, 1645–1715) that are superimposed upon long-term changes. Spectral analysis of TSI records reveals periodicities of 87, 104, 150, 208, 350, 510, ~980, and ~2200 years (Figure 5.1d) (Stuiver and Braziunas, 1993), but with time varying amplitudes (Steinhilber et al., 2009; Vieira et al., 2011). All reconstructions rely ultimately on the same data (sunspots and cosmogenic radionuclides), but differ in the details of the methodologies. As a result the reconstructions agree rather well in their shape, but differ in their amplitude (Figure 5.1b) (Wang et al., 2005; Krivova et al., 2011; Lean et al., 2011; Schrijver et al., 2011) (see Section 8.4.1).

Since AR4, Most recent reconstructions show a considerably smaller difference (<0.1%) in TSI between the late 20th century and the Late Maunder Minimum (1675-1715) when the sun was very quiet, compared to the often used reconstruction of Lean et al. (1995b) (0.24%) and Shapiro et al. (2011) (~0.4%). The Lean et

al. (1995a) reconstruction has been used to scale solar forcing in simulations of the last millennium prior to PMIP3/CMIP5 (Table 5.A.1). PMIP3/CMIP5 last millennium simulations have used the weak solar forcing of recent reconstructions of TSI (Schmidt et al., 2011; Schmidt et al., 2012b) calibrated (Muscheler et al., 2007; Delaygue and Bard, 2011) or spliced (Steinhilber et al., 2009; Vieira and Solanki, 2010) to Wang et al. (2005). The larger range of past TSI variability in Shapiro et al. (2011) is not supported by studies of magnetic field indicators that suggest smaller changes over the 19th and 20th centuries (Svalgaard and Cliver, 2010; Lockwood and Owens, 2011).

Note that: (1) the recent new measurement of the absolute value of TSI and TSI changes during the past decades are assessed in Section 8.4.1.1; (2) the current state of understanding the effects of galactic cosmic rays on clouds is assessed in Sections 7.4.6 and 8.4.1.5 and (3) the use of solar forcing in simulations of the last millennium is discussed in Section 5.3.5.

[INSERT FIGURE 5.1 HERE]

Figure 5.1: (a) Two reconstructions of volcanic forcing for the past 1000 years derived from ice core sulphate and used for PMIP3/CMIP5 simulations (Schmidt et al., 2011). GRA: (Gao et al., 2012); CEA: (Crowley and Unterman, 2013). Volcanic sulphate peaks identified from their isotopic composition as originating from the stratosphere are indicated by squares (green: Greenland; brown: Antarctica) (Baroni et al., 2008; Cole-Dai et al., 2009). (b) Reconstructed TSI anomalies back to the year 1000. Proxies of solar activity (e.g., sunspots, ^{10}Be) are used to estimate the parameters of the models or directly TSI. All records except LBB (Lean et al., 1995b) have been used for PMIP3/CMIP5 simulations (Schmidt et al., 2011). DB: (Delaygue and Bard, 2011); MEA: (Muscheler et al., 2007); SBF: (Steinhilber et al., 2009); WLS: (Wang et al., 2005); VSK: (Vieira et al., 2011). Prior to 1600, the 11-year cycle has been added artificially to the original data with an amplitude proportional to the mean level of TSI. (c) Reconstructed TSI anomalies (100-year low-pass filtered; grey shading: 1 standard deviation uncertainty range) for the past 9300 years (Steinhilber et al., 2009). The reconstruction is based on ^{10}Be and calibrated using the relationship between instrumental data of the open magnetic field, which modulates the production of ^{10}Be , and TSI for the past 4 solar minima. The yellow band indicates the past 1000 years shown in more details in panels a and b. Anomalies are relative to the 1976–2006 mean value (1366.14 W m^{-2}) of Wang et al. (2005). (d) Wavelet analysis (Torrence and Compo, 1998) of TSI anomalies from panel c with dashed white lines highlighting significant periodicities (Stuiver and Braziunas, 1993).

5.2.1.3 Volcanic Forcing

Volcanic activity affects global climate through the radiative impacts of atmospheric sulphate aerosols injected by volcanic eruptions (see Sections 8.4.2 and 10.3.1). Quantifying volcanic forcing in the pre-satellite period is important for historical and last millennium climate simulations, climate sensitivity estimates and detection and attribution studies. Reconstructions of past volcanic forcing are based on sulphate deposition from multiple ice cores from Greenland and Antarctica, combined with atmospheric modelling of aerosol distribution and optical depth.

Since AR4, two new reconstructions of the spatial distribution of volcanic aerosol optical depth have been generated using polar ice cores, spanning the last 1500 years (Gao et al., 2008, 2012) and 1200 years (Crowley and Unterman, 2013) (Figure 5.1a). Although the relative size of eruptions for the past 700 years is generally consistent among these and earlier studies (Jansen et al., 2007), they differ in the absolute amplitude of peaks. There are also differences in the reconstructions of Icelandic eruptions, with an ongoing debate on the magnitude of stratospheric inputs for the 1783 Laki eruption (Thordarson and Self, 2003; Wei et al., 2008; Lanciki et al., 2012; Schmidt et al., 2012a). The recurrence time of past large volcanic aerosol injections (eruptions changing the radiative forcing by more than 1 W m^{-2}) varies from 3–121 years, with long-term mean value of 35 years (Gao et al., 2012) and 39 years (Crowley and Unterman, 2013), and only 2–3 periods of 100 years without such eruptions since 850.

Hegerl et al. (2006) estimated the uncertainty of the radiative forcing for a given volcanic event to be ~50%. Differences between reconstructions (Figure 5.1a) arise from different proxy data, identification of the type of injection, methodologies to estimate particle distribution and optical depth (Kravitz and Robock, 2011), and parameterization of scavenging for large events (Timmreck et al., 2009). Key limitations are associated with ice-core chronologies (Plummer et al., 2012; Sigl et al., 2013), and deposition patterns (Moore et al., 2012).

A new independent methodology has recently been developed to distinguish between tropospheric and stratospheric volcanic aerosol deposits (Baroni et al., 2007). The stratospheric character of several large eruptions has started to be assessed from Greenland and/or Antarctic ice-core sulphur isotope data (Baroni et al., 2008; Cole-Dai et al., 2009; Schmidt et al., 2012b).

The use of different volcanic forcing reconstructions in pre-PMIP3/CMIP5 (see AR4 Chapter 6) and PMIP3/CMIP5 last millennium simulations (Schmidt et al., 2011) (Table 5.A.1), together with the methods used to implement these volcanic indices with different representations of aerosols in climate models, is a source of uncertainty in model inter-comparisons. The impact of volcanic forcing on climate variations of the last millennium climate is assessed in Sections 5.3.5, 5.4, 5.5.1 and 10.7.1.

5.2.2 Radiative Perturbations from Greenhouse Gases and Dust

5.2.2.1 Atmospheric Concentrations of CO₂, CH₄ and N₂O from Ice Cores

Complementing instrumental data, air enclosed in polar ice provides a direct record of past atmospheric well-mixed greenhouse gas (WMGHG) concentrations albeit smoothed by firm diffusion (Joos and Spahni, 2008; Köhler et al., 2011). Since AR4, the temporal resolution of ice-core records has been enhanced (MacFarling Meure et al., 2006; Ahn and Brook, 2008; Louergue et al., 2008; Lüthi et al., 2008; Mischler et al., 2009; Schilt et al., 2010; Ahn et al., 2012; Bereiter et al., 2012). During the pre-industrial part of the last 7,000 years, millennial (20 ppm CO₂, 125 ppb CH₄) and centennial variations (up to 10 ppm CO₂, 40 ppb CH₄ and 10 ppb N₂O) are recorded (see Section 6.2.2 and Figure 6.6). Significant centennial variations in CH₄ during the last glacial occur in phase with Northern Hemisphere (NH) rapid climate changes, while millennial CO₂ changes coincide with their Southern Hemisphere (SH) bipolar seesaw counterpart (Ahn and Brook, 2008; Louergue et al., 2008; Lüthi et al., 2008; Grachev et al., 2009; Capron et al., 2010b; Schilt et al., 2010; Bereiter et al., 2012).

Long-term records have been extended from 650 ka in AR4 to 800 ka (Figures 5.2, 5.3) (Louergue et al., 2008; Lüthi et al., 2008; Schilt et al., 2010). During the last 800 ka, the pre-industrial ice core WMGHG concentrations stay within well-defined natural limits with maximum interglacial concentrations of approximately 300 ppm, 800 ppb, and 300 ppb for CO₂, CH₄ and N₂O, respectively, and minimum glacial concentrations of approximately 180 ppm, 350 ppb, and 200 ppb. The new data show lower than pre-industrial (280 ppm) CO₂ concentrations during interglacial periods from 800–430 ka (MIS19 to MIS13) (Figure 5.3). It is a fact that present-day (2011) concentrations of CO₂ (390.5 ppm), CH₄ (1803 ppb) and N₂O (324 ppm) (Annex II) exceed the range of concentrations recorded in the ice core records during the past 800 ka. With *very high confidence*, the rate of change of the observed anthropogenic WMGHG rise and its radiative forcing is unprecedented with respect to the highest resolution ice core record back to 22 ka for CO₂, CH₄ and N₂O, accounting for the smoothing due to ice core enclosure processes (Joos and Spahni, 2008; Schilt et al., 2010). There is *medium confidence* that the rate of change of the observed anthropogenic WMGHG rise is also unprecedented with respect to the lower resolution records of the past 800 ka.

Progress in understanding the causes of past WMGHG variations is reported in Section 6.2.

5.2.2.2 Atmospheric CO₂ Concentrations from Geological Proxy Data

Geological proxies provide indirect information on atmospheric CO₂ concentrations for time intervals older than those covered by ice-core records (see Section 5.2.2.1). Since AR4, the four primary proxy CO₂ methods have undergone further development (Table 5.A.2). A reassessment of biological respiration and carbonate formation has reduced CO₂ reconstructions based on fossil soils by ~50% (Breecker et al., 2010). Bayesian statistical techniques for calibrating leaf stomatal density reconstructions produce consistently higher CO₂ estimates, than previously assessed (Beerling et al., 2009), resulting in more convergence between estimates from these two terrestrial proxies. Recent CO₂ reconstructions using the boron isotope proxy provide an improved understanding of foraminifer species effects and evolution of seawater alkalinity (Hönisch and Hemming, 2005) and seawater boron isotopic composition (Foster et al., 2012). Quantification of the phytoplankton cell-size effects on carbon isotope fractionation has also improved the consistency of the alkenone method (Henderiks and Pagani, 2007). These proxies have also been applied more widely and at higher temporal resolution to a range of geological archives, resulting in an increased number of

atmospheric CO₂ estimates since 65 Ma (Beerling and Royer, 2011). While there is improved consensus between the proxy CO₂ estimates, especially the marine proxy estimates, a significant degree of variation between the different techniques remains. All four techniques have been included in the assessment, as there is insufficient knowledge to discriminate between different proxy estimates on the basis of confidence (assessed in Table 5.A.2).

In the time interval between 65 and 23 Ma, all proxy estimates of CO₂ concentration span a range of 300 ppm to 1500 ppm (Figure 5.2). An independent constraint on Early Eocene atmospheric CO₂ concentration is provided by the occurrence of the sodium carbonate mineral, nahcolite, in about 50 Ma lake sediments, which precipitates in association with halite at the sediment-water interface only at CO₂ levels >1125 ppm (Lowenstein and Demicco, 2006), and thus provides a potential lower bound for atmospheric concentration (*medium confidence*) during the warmest period of the last 65 Ma – “Early Eocene Climatic Optimum” (EECO; 52–50 Ma; Table 5.1), which is inconsistent with lower estimates from stomata and paleosoils. While the reconstructions indicate a general decrease in CO₂ concentrations since ~ 50 Ma (Figure 5.2), the large scatter of proxy data precludes a robust assessment of the second-order variation around this overall trend.

Since 23 Ma, CO₂ proxy estimates are at pre-industrial levels with exception of the Middle Miocene climatic optimum (17–15 Ma) and the Pliocene (5.3–2.6 Ma), which have higher concentrations. While new CO₂ reconstructions for the Pliocene based on marine proxies have produced consistent estimates mostly in the range 350 ppm to 450 ppm (Pagani et al., 2010; Seki et al., 2010; Bartoli et al., 2011), the uncertainties associated with these marine estimates remain difficult to quantify. Several boron-derived datasets agree within error (± 25 ppm) with the ice-core records (Foster, 2008; Hönlisch et al., 2009), but alkenone data for the ice-core period are outside the error limits (Figure 5.2). We conclude that there is *medium confidence* that CO₂ levels were above pre-industrial interglacial concentration (~280 ppm) and did not exceed ~450 ppm during the Pliocene, with interglacial values in the upper part of that range between 350–450 ppm.

[INSERT FIGURE 5.2 HERE]

Figure 5.2: (Top) Orbital-scale Earth system responses to radiative forcings and perturbations from 3.5 Ma to present. Reconstructed dust mass accumulation rate is from the Atlantic sector of the Southern Ocean (red) (Martinez-Garcia et al., 2011). Sea level curve (blue) is the stacked $\delta^{18}\text{O}$ proxy for ice volume and ocean temperature (Lisiecki and Raymo, 2005) calibrated to global average eustatic sea level (Naish and Wilson, 2009; Miller et al., 2012a). Also shown are global eustatic sea level reconstructions for the last 500 kyr based on sea level calibration of the $\delta^{18}\text{O}$ curve using dated coral shorelines (grey line; Waelbroeck et al., 2002) and the Red Sea isotopic reconstruction (red line; Rohling et al., 2009). Weighted mean estimates (2 standard deviation uncertainty) for far-field reconstructions of eustatic peaks are shown for mid-Pliocene interglacials (red dots; Miller et al., 2012a). The dashed horizontal line represents present-day sea level. Tropical sea-surface temperature (black line) based on a stack of 4 alkenone-based SST reconstructions (Herbert et al., 2010). Atmospheric CO₂ measured from Antarctic ice cores (Petit et al., 1999; Siegenthaler et al., 2005) (blue line; Lüthi et al., 2008), and estimates of CO₂ from boron isotopes ($\delta^{11}\text{B}$) in foraminifera in marine sediments (blue triangles; Hönlisch et al., 2009; Seki et al., 2010; Bartoli et al., 2011), and phytoplankton alkenone-derived carbon isotope proxies (red diamonds; Pagani et al., 2010; Seki et al., 2010), plotted with 2 standard deviation. Present (2012) and pre-industrial CO₂ concentrations are indicated with long-dashed and short-dashed grey lines, respectively. (Bottom) Concentration of atmospheric CO₂ for the last 65 Ma is reconstructed from marine and terrestrial proxies (Cerling, 1992; Freeman and Hayes, 1992; Koch et al., 1992; Stott, 1992; van der Burgh et al., 1993; Sinha and Stott, 1994; Kürschner, 1996; McElwain, 1998; Ekart et al., 1999; Pagani et al., 1999b; Pagani et al., 1999a; Kürschner et al., 2001; Royer et al., 2001a; Royer et al., 2001b; Beerling et al., 2002; Beerling and Royer, 2002; Nordt et al., 2002; Greenwood et al., 2003; Royer, 2003; Pagani et al., 2005a; Pagani et al., 2005b; Lowenstein and Demicco, 2006; Fletcher et al., 2008; Kürschner et al., 2008; Beerling et al., 2009; Pearson et al., 2009; Retallack, 2009b, 2009a; Tripathi et al., 2009; Pagani et al., 2010; Seki et al., 2010; Smith et al., 2010; Bartoli et al., 2011; Doria et al., 2011; Pagani et al., 2011; Foster et al., 2012). Individual proxy methods are colour-coded (see also Table A5.1). The light blue shading is a 1-standard deviation uncertainty band constructed using block bootstrap re-sampling (Mudelsee et al., 2012) for a kernel regression through all the data points with a bandwidth of 8 Myr prior to 30 Ma, and 1 Myr from 30 Ma to present. Most of the data points for CO₂ proxies are based on duplicate and multiple analyses. The red box labelled MPWP represents the mid-Pliocene Warm Period (3.3–3.0 Ma; Table 5.1).

5.2.2.3 Past Changes in Mineral Dust Aerosol (MDA) Concentrations

Past changes in MDA are important for estimates of climate sensitivity (see Section 5.3.3) and for its supply of nutrients, especially iron to the Southern Ocean (see Section 6.2). MDA concentration is controlled by

variations in dust sources, and by changes in atmospheric circulation patterns acting on its transport and lifetime.

Since AR4, new records of past MDA flux have been obtained from deep-sea sediment and ice cores. A 4 million-year MDA-flux reconstruction from the Southern Ocean (Figure 5.2) implies reduced dust generation and transport during the Pliocene compared to Holocene levels, followed by a significant rise around 2.7 Ma when NH ice volume increased (Martinez-Garcia et al., 2011). Central Antarctic ice-core records show that local MDA deposition fluxes are ~20 times higher during glacial compared to interglacial periods (Fischer et al., 2007; Lambert et al., 2008; Petit and Delmonte, 2009). This is due to enhanced dust production in southern South America and perhaps Australia (Gaiero, 2007; De Deckker et al., 2010; Gabrielli et al., 2010; Martinez-Garcia et al., 2011; Wegner et al., 2012). The impact of changes in MDA lifetime (Petit and Delmonte, 2009) on dust fluxes in Antarctica remains uncertain (Fischer et al., 2007; Wolff et al., 2010). Equatorial Pacific glacial-interglacial MDA fluxes co-vary with Antarctic records, but with a glacial-interglacial ratio of 3–4 (Winckler et al., 2008), attributed to enhanced dust production from Asian and northern South American sources in glacial times (Maher et al., 2010). The dominant dust source regions (e.g., North Africa, Arabia and Central Asia) show complex patterns of variability (Roberts et al., 2011). A glacial increase of MDA source strength by a factor of 3–4 requires low vegetation cover, seasonal aridity, and high wind speeds (Fischer et al., 2007; McGee et al., 2010). In Greenland ice cores, MDA ice concentrations are higher by a factor of ~100 and deposition fluxes by a factor ~20 during glacial periods (Ruth et al., 2007). This is mainly due to changes in the dust sources for Greenland (Asian desert areas), increased gustiness (McGee et al., 2010), and atmospheric lifetime and transport of MDA (Fischer et al., 2007). A strong coherence is observed between dust in Greenland ice cores and aeolian deposition in European loess formations (Antoine et al., 2009).

Global data synthesis shows 2–4 times more dust deposition at the LGM (Table 5.1) than today (Derbyshire, 2003; Maher et al., 2010). Based on data-model comparisons, estimates of global mean LGM dust radiative forcing vary from -3 W m^{-2} to $+0.1 \text{ W m}^{-2}$, due to uncertainties in radiative properties. The best estimate value remains at -1 W m^{-2} as in AR4 (Claquin et al., 2003; Mahowald et al., 2006; Patadia et al., 2009; Takemura et al., 2009; Yue et al., 2010; Mahowald et al., 2011). Models may underestimate the MDA radiative forcing at high latitudes (Lambert et al., 2013).

[START BOX 5.1 HERE]

Box 5.1: Polar Amplification

Polar amplification occurs if the magnitude of zonally averaged surface temperature change at high latitudes exceeds the globally averaged temperature change, in response to climate forcings and on timescales greater than the annual cycle. Polar amplification is of global concern due to the potential effects of future warming on ice-sheet stability and, therefore, global sea level (see Sections 5.6.1, 5.8.1 and Chapter 13) and carbon-cycle feedbacks such as those linked with permafrost melting (see Chapter 6).

Some external climate forcings have an enhanced radiative impact at high latitudes, such as orbital forcing (Section 5.2.1.1), or black carbon (Section 8.3.4). Here, we focus on the latitudinal response of surface temperature to CO_2 perturbations. The magnitude of polar amplification depends on the relative strength and duration of different climate feedbacks, which determine the transient and equilibrium response to external forcings. This box first describes the different feedbacks operating in both polar regions, and then contrasts polar amplification depicted for past high CO_2 and low CO_2 climates with projected temperature patterns for the RCP8.5 future greenhouse gas emission scenario.

In the Arctic, the sea-ice/ocean-surface albedo feedback plays an important role (Curry et al., 1995; Serreze and Barry, 2011). With retreating sea ice, surface albedo decreases, air temperatures increase and the ocean can absorb more heat. The resulting ocean warming contributes to further sea ice melting. The sea-ice/ocean-surface albedo feedback can exhibit threshold behaviour when temperatures exceed the freezing point of sea ice. This may also translate into a strong seasonality of the response characteristics. Other feedbacks, including water vapour and cloud feedbacks have been suggested as important amplifiers of Arctic climate change (Vavrus, 2004; Abbot and Tziperman, 2008, 2009; Graverson and Wang, 2009; Lu and Cai, 2009; Screen and Simmonds, 2010; Bintanja et al., 2011). In continental Arctic regions with seasonal snow-cover,

changes in radiative forcing can heavily influence snow cover (Ghatak et al., 2010), and thus surface albedo. Other positive feedbacks operating on timescales of decades-to-centuries in continental high-latitude regions are associated with surface vegetation changes (Bhatt et al., 2010) and thawing permafrost (e.g., Walter et al., 2006). On glacial-to-interglacial timescales, the very slow ice sheet-albedo response to external forcings (see Box 5.2) is a major contributor to polar amplification in the NH.

An amplified response of Southern Ocean sea-surface temperature (SST) to radiative perturbations also emerges from the sea ice-albedo feedback. However, in contrast to the Arctic Ocean, which in parts is highly stratified, mixed-layer depths in the Southern Ocean typically exceed several hundreds of meters, which allows the ocean to take up vast amounts of heat (Böning et al., 2008; Gille, 2008; Sokolov and Rintoul, 2009) and damp the SST response to external forcing. This process, and the presence of the ozone hole over the Antarctic ice sheet (Thompson and Solomon, 2002, 2009), can affect the transient response of surface warming of the Southern Ocean and Antarctica, and lead to different patterns of future polar amplification on multidecadal to multi-centennial time scales. In response to rapid atmospheric CO₂ changes, climate models indeed project an asymmetric warming between the Arctic and Southern Ocean, with an earlier response in the Arctic and a delayed response in the Southern Ocean (Section 12.4.3). Above the Antarctic ice sheet, however, surface-air temperature can respond quickly to radiative perturbations due to the limited role of latent heat flux in the surface-energy budget of Antarctica.

These differences in transient and equilibrium responses of surface temperatures on Antarctica, the Southern Ocean and over continents and oceans in the Arctic domain can explain differences in the latitudinal temperature patterns depicted in Box 5.1, Figure 1 for past periods (equilibrium response) and future projections (transient response).

Box 5.1, Figure 1 illustrates the polar amplification phenomenon for three different periods of Earth's climate history using temperature reconstructions from natural archives and climate model simulations for: (i) the Early Eocene Climatic Optimum, EECO (54–48 Ma) characterised by CO₂ concentrations of 1000–2000 ppm (Section 5.2.2.2) and the absence of continental ice sheets; (ii) the mid-Pliocene Warm Period, MPWP (3.3–3.0 Ma), characterized by CO₂ concentrations in the range of 350–450 ppm (Section 5.2.2.2) and reduced Greenland and Antarctic ice sheets compared to today (see Section 5.6.1), (iii) the LGM (21–19 ka), characterized by CO₂ concentrations around 200 ppm and large continental ice sheets covering northern Europe and North America.

Throughout all three time periods, reconstructions and simulations reveal Arctic and Antarctic surface-air temperature amplification of up to 2 times the global mean (Box 5.1, Figure 1c,d), and this bipolar amplification appears to be a robust feature of the equilibrium Earth system response to changes of CO₂ concentration, irrespective of climate state. The absence (EECO), or expansion (LGM) of continental ice sheets has the potential to affect the zonally averaged surface temperatures due to the lapse-rate effect (see Box 5.2), hence contributing to polar amplification. However, polar amplification is also suppressed in zonally averaged gradients of SST compared with terrestrial surface-air temperature (Box 5.1, Figure 1), owing to the presence of high-latitude sea ice in the pre-industrial control, which places a lower limit on SST. Global mean temperature estimates for these three past climates also imply an Earth system climate sensitivity to radiative perturbations up to two times higher than the equilibrium climate sensitivity (Lunt et al., 2010; Haywood et al., 2013) (see Section 5.3.1 and Box 12.2).

Polar amplification explains in part why Greenland Ice Sheet (GIS) and the West Antarctic Ice Sheet (WAIS) appear to be highly sensitive to relatively small increases in CO₂ concentration and global mean temperature. For example, global sea level during MPWP may have been up to +20m higher than present day when atmospheric CO₂ concentrations were ~350–450 ppm and global mean surface temperature was 2°C–3°C above pre-industrial levels (see Sections 5.6.1 and 5.8.1).

Based on earlier climate data-model comparisons, it has been claimed (summarised in Huber and Caballero, 2011), that models underestimated the strength of polar amplification for high CO₂ climates by 30–50%. While recent simulations of the EECO and the MPWP exhibit a wide inter-model variability, there is generally good agreement between new simulations and data, particularly if seasonal biases in some of the marine SST proxies from high-latitude sites are considered (Hollis et al., 2012; Lunt et al., 2012; Haywood et al., 2013).

Transient polar amplification as recorded in historical instrumental data and as projected by coupled climate models for the 21st century involves a different balance of feedbacks than for the “equilibrium” past states featured in Box 5.1, Figure 1. Since 1875, the Arctic north of 60°N latitude has warmed at a rate of 1.36°C per century, approximately twice as fast as the global average (Bekryaev et al., 2010), and since 1979, Arctic land surface has warmed at an even higher rate of 0.5°C per decade (e.g., CRUTEM, Jones et al., 2012; HadCRUT4, Morice et al., 2012), (see Section 2.4). This recent warming appears unusual in the context of reconstructions spanning the past 2000 years (Section 5.5) and has been attributed primarily to anthropogenic factors (Gillett et al., 2008) (see Section 10.3.1.1.4). The fact that the strongest warming occurs in autumn and early winter (Chylek et al., 2009; Serreze et al., 2009; Polyakov et al., 2010; Screen and Simmonds, 2010; Semenov et al., 2010; Spielhagen et al., 2011) strongly links Arctic amplification to feedbacks associated with the seasonal reduction in sea-ice extent and duration, as well as the insulating effect of sea ice in winter (e.g., Soden et al., 2008; Serreze et al., 2009; Serreze and Barry, 2011). For future model projections (Box 5.1, Figure 1), following the RCP8.5 scenarios, annual mean Arctic (68°N–90°N) warming is expected to exceed the global average by 2.2–2.4 times for the period 2081–2100 compared to 1986–2005 (see Section 12.4.3.1), which corresponds to the higher end of polar amplification implied by paleo-reconstructions.

The transient response of Antarctic and Southern Ocean temperatures to the anthropogenic perturbation appears more complex, than for the Arctic region. Zonal mean Antarctic surface warming has been modest at 0.1°C per decade over the past 50 years (Steig et al., 2009; O’Donnell et al., 2010). The Antarctic Peninsula is experiencing one of the strongest regional warming trends (0.5°C per decade over the past 50 years), more than twice that of the global mean temperature. Central West Antarctica may have also experienced a similar strong warming trend as depicted by the only continuous meteorological station during the last 50 years (Bromwich et al., 2013), and borehole measurements spanning the same period (Orsi et al., 2012). Ice core records show enhanced summer melting in the Antarctic Peninsula since the 1950, which is unprecedented over the past 1000 years (Abram et al., 2013), and warming in West Antarctica that cannot be distinguished from natural variability over the last 2000 years (Steig et al., 2013) (see also Section 10.3.1.1.4, and section 5.5). Polar amplification in the Southern Ocean and Antarctica is virtually absent in the transient CMIP5 RCP4.5 future simulations (2081–2100 versus 1986–2005) (see Section 12.4.3.1), although CMIP5 RCP8.5 exhibits an amplified warming in the Southern Ocean (Box 5.1, Figure 1), much smaller in magnitude than the equilibrium response implied from paleo-reconstructions for a high-CO₂ world.

In summary, robust evidence for polar amplification in either one or both hemispheres has been found in temperatures reconstructions of past climates, in recent instrumental temperature records, and in climate model simulations of past, present, and future climate changes.

[INSERT BOX 5.1, FIGURE 1 HERE]

Box 5.1, Figure 1: Comparison of data and multi-model mean (MMM) simulations, for four periods of time, showing (a) SST anomalies, (b) zonally averaged SST anomalies, (c) zonally averaged global (green) and land (grey) surface-air temperature (SAT) anomalies and (d) land SAT anomalies. The time periods are 2081–2100 (top row), LGM (second row), MPWP (third row) and EECO (bottom row). Model temperature anomalies are calculated relative to the pre-industrial value of each model in the ensemble prior to calculating the MMM anomaly (a, d; colour shading). Zonal MMM gradients (b, c) are plotted with a shaded band indicating 2 standard deviations. Site specific temperature anomalies estimated from proxy data are calculated relative to present site temperatures and are plotted (a, d) using the same colour scale as the model data, and a circle-size scaled to estimates of confidence. Proxy data compilations for the LGM are from MARGO Project Members (2009) and Bartlein et al. (2011), for the MPWP are from Dowsett et al. (2012), Salzmann et al. (2008) and Haywood et al. (2013) and for the EECO are from Hollis et al. (2012) and Lunt et al. (2012). Model ensemble simulations for 2081–2100 are from the CMIP5 ensemble using RCP 8.5, for the LGM are seven PMIP3/CMIP5 models, for the Pliocene are from Haywood et al., (2013), and for the EECO are after Lunt et al. (2012).

5.3 Earth System Responses and Feedbacks at Global and Hemispheric Scales

This section updates the information available since AR4 on changes in surface temperature on million-year to orbital timescales and for the last 2000 years. New information on changes of the monsoon systems on glacial-interglacial timescales is also assessed.

5.3.1 High CO₂ Worlds and Temperature

Cenozoic (last 65 Ma) geological archives provide examples of natural climate states globally warmer than the present, which are associated with atmospheric CO₂ concentrations above pre-industrial levels. This relationship between global warmth and high CO₂ is complicated by factors such as tectonics and the evolution of biological systems, which play an important role in the carbon cycle (e.g., Zachos et al., 2008). Although new reconstructions of deep-ocean temperatures have been compiled since AR4 (e.g., Cramer et al., 2011), *low confidence* remains in the precise relationship between CO₂ and deep-ocean temperature (Beerling and Royer, 2011).

Since AR4 new proxy and model data have become available from three Cenozoic warm periods to enable an assessment of forcing, feedbacks and the surface-temperature response (e.g., Dowsett et al., 2012; Lunt et al., 2012; Haywood et al., 2013). These are the Paleocene-Eocene Thermal Maximum (PETM; Table 5.1), the Early Eocene Climatic Optimum (EECO; Table 5.1) and the mid-Pliocene Warm Period (MPWP; Table 5.1). Reconstructions of surface temperatures based on proxy data remain challenged by: (i) the limited number and uneven geographical distribution of sites, (ii) seasonal biases and (iii), the validity of assumptions required by each proxy method (assessed in Table 5.A.3). There is also a lack of consistency in the way uncertainties are reported for proxy climate estimates. In most cases error bars represent the analytical and calibration error. In some compilations qualitative confidence assessments are reported to account for the quality of the age control, number of samples, fossil preservation and abundance, performance of the proxy method utilized, and agreement of multiple proxy estimates (e.g., MARGO Project Members, 2009; Dowsett et al., 2012).

The PETM was marked by a massive carbon release and corresponding global ocean acidification (Zachos et al., 2005; Ridgwell and Schmidt, 2010) and, with *low confidence*, global warming of 4°C–7°C relative to pre-industrial (Sluijs et al., 2007; McInerney and Wing, 2011). The carbon release of 4500–6800 PgC over 5–20 kyr translates into a rate of emissions of ~0.5–1.0 PgC yr⁻¹ (Panchuk et al., 2008; Zeebe et al., 2009). Greenhouse gas emissions from marine methane hydrate and terrestrial permafrost may have acted as positive feedbacks (DeConto et al., 2012).

The EECO represents the last time atmospheric CO₂ concentrations may have reached a level of ~1000 ppm (Section 5.2.2.2). There were no substantial polar ice sheets, and oceanic and continental configurations, vegetation type and distribution were significantly different from today. Whereas simulated SAT are in reasonable agreement with reconstructions (Huber and Caballero, 2011; Lunt et al., 2012) (Box 5.1, Figure 1d), there are still significant discrepancies between simulated and reconstructed mean annual SST, which are reduced if seasonal biases in some of the marine proxies are considered for the high-latitude sites (Hollis et al., 2012; Lunt et al., 2012). *Medium confidence* is placed on the reconstructed global mean surface temperature anomaly estimate of 8°C–14°C.

The Pliocene is characterized by a long-term increase in global ice volume and decrease in temperature from ~3.3–2.6 Ma (Lisiecki and Raymo, 2005; Mudelsee and Raymo, 2005; Fedorov et al., 2013), which marks the onset of continental-scale glaciations in the NH. Superimposed on this trend, benthic δ¹⁸O (Lisiecki and Raymo, 2005) and an ice proximal geological archive (Lisiecki and Raymo, 2005; Naish et al., 2009a) imply moderate fluctuations in global ice volume paced by the 41 kyr obliquity cycle. This orbital variability is also evident in far-field sea level reconstructions (Miller et al., 2012a), tropical Pacific SST (Herbert et al., 2010) and Southern Ocean MDA records (Martinez-Garcia et al., 2011), and indicate a close coupling between temperature, atmospheric circulation and ice volume/sea level (Figure 5.2). The MPWP and the following 300 kyr represent the last time atmospheric CO₂ concentrations were in the range 350–450 ppm (Section 5.2.2.2, Figure 5.2). Model-data comparisons (Box 5.1, Figure 1) provide *high confidence* that mean surface temperature was warmer than pre-industrial for the average interglacial climate state during the MPWP (Dowsett et al., 2012; Haywood et al., 2013). Global mean SST is estimated at +1.7°C (without uncertainty) above the 1901–1920 mean based on large data syntheses (Lunt et al., 2010; Dowsett et al., 2012). General circulation model (GCM) results agree with this SST anomaly (to within ±0.5°C), and produce a range of

global mean SAT of +1.9°C and +3.6°C relative to the 1901–1920 mean (Haywood et al., 2013). Weakened meridional temperature gradients are shown by all GCM simulations, and have significant implications for the stability of polar ice sheets and sea level (see Box 5.1 and Section 5.6). SST gradients and the Pacific Ocean thermocline gradient along the equator were greatly reduced compared to present (Fedorov et al., 2013) (Section 5.4). Vegetation reconstructions (Salzmann et al., 2008) imply that the global extent of arid deserts decreased and boreal forests replaced tundra, and GCMs predict an enhanced hydrological cycle, but with large inter-model spread (Haywood et al., 2013). The East Asian Summer Monsoon, as well as other monsoon systems, may have been enhanced at this time (e.g., Wan et al., 2010).

Climate reconstructions for the warm periods of the Cenozoic also provide an opportunity to assess Earth-system and equilibrium climate sensitivities. Uncertainties on both global temperature and CO₂ reconstructions preclude deriving robust quantitative estimates from the available PETM data. The limited number of models for MPWP, which take into account slow feedbacks such as ice sheets and the carbon cycle, imply with *medium confidence* Earth-system sensitivity may be up to 2 times the model equilibrium climate sensitivity (ECS) (Lunt et al., 2010; Pagani et al., 2010; Haywood et al., 2013). However, if the slow amplifying feedbacks associated with ice sheets and CO₂ are considered as forcings rather than feedbacks, climate records of the past 65 Myr yield an estimate of 1.1°C–7°C (95% confidence interval) for ECS (PALAEOSENS Project Members, 2012) (see also Section 5.3.3.2).

5.3.2 Glacial-Interglacial Dynamics

5.3.2.1 Role of CO₂ in Glacial Cycles

Recent modelling work provides strong support for the important role of variations in Earth's orbital parameters in generating long-term climate variability. In particular, new simulations with GCMs (Carlson et al., 2012; Herrington and Poulsen, 2012) support the fundamental premise of the Milankovitch theory that a reduction in NH summer insolation generates sufficient cooling to initiate ice sheet growth. Climate-ice sheet models with varying degrees of complexity and forced by variations in orbital parameters and reconstructed atmospheric CO₂ concentrations simulate ice volume variations and other climate characteristics during the last and several previous glacial cycles consistent with paleoclimate records (Abe-Ouchi et al., 2007; Bonelli et al., 2009; Ganopolski et al., 2010) (see Figure 5.3).

There is *high confidence* that orbital forcing is the primary external driver of glacial cycles. However, atmospheric CO₂ content plays an important internal feedback role. Orbital-scale variability in CO₂ concentrations over the last several hundred thousand years covaries (Figure 5.3) with variability in proxy records including reconstructions of global ice-volume (Lisiecki and Raymo, 2005), climatic conditions in central Asia (Prokopenko et al., 2006), tropical (Herbert et al., 2010) and Southern Ocean SST (Pahnke et al., 2003; Lang and Wolff, 2011), Antarctic temperature (Parrenin et al., 2013), deep-ocean temperature (Elderfield et al., 2010), biogeochemical conditions in the North Pacific (Jaccard et al., 2010), and deep-ocean ventilation (Lisiecki et al., 2008). Such close linkages between CO₂ concentration and climate variability are consistent with modelling results suggesting with *high confidence* that glacial-interglacial variations of CO₂ and other greenhouse gases explain a considerable fraction of glacial-interglacial climate variability in regions not directly affected by the NH continental ice sheets (Timmermann et al., 2009; Shakun et al., 2012).

[INSERT FIGURE 5.3 HERE]

Figure 5.3: Orbital parameters and proxy records over the past 800 kyr. (a) Eccentricity, (b) obliquity, (c) precessional parameter (Berger and Loutre, 1991), (d) atmospheric concentration of CO₂ from Antarctic ice cores (Petit et al., 1999; Siegenthaler et al., 2005; Ahn and Brook, 2008; Lüthi et al., 2008), (e) tropical SST stack (Herbert et al., 2010), (f) Antarctic temperature stack based on up to seven different ice cores (Petit et al., 1999; Blunier and Brook, 2001; Watanabe et al., 2003; EPICA Community Members, 2006; Jouzel et al., 2007; Stenni et al., 2011), (g) stack of benthic δ¹⁸O, a proxy for global ice volume and deep-ocean temperature (Lisiecki and Raymo, 2005), (h) reconstructed sea level (dashed line: Rohling et al., 2010; solid line: Elderfield et al., 2012). Lines represent orbital forcing and proxy records, shaded areas represent the range of simulations with climate (GENIE-1, Holden et al., 2010a; Bern3D, Ritz et al., 2011), climate-ice sheet models of intermediate complexity (CLIMBER-2, Ganopolski and Calov, 2011) and an ice-sheet model (IcIES, Abe-Ouchi et al., 2007) forced by variations of the orbital parameters and the atmospheric concentrations of the major greenhouse gases. (i) Rate of changes of global mean temperature during Termination I based on Shakun et al. (2012).

5.3.2.2 Last Glacial Termination

It is *very likely* that global mean surface temperature increased by 3°C–8°C over the last deglaciation (see Table 5.2), which gives a *very likely* average rate of change of 0.3–0.8°C kyr⁻¹. Deglacial global warming occurred in two main steps from 17.5 to 14.5 ka and 13.0 to 10.0 ka that *likely* reached maximum rates of change between 1°C kyr⁻¹ and 1.5°C kyr⁻¹ at the millennial time scale (cf. Shakun et al., 2012; Figure 5.3i), although regionally and on shorter time scales higher rates may have occurred, in particular during a sequence of abrupt climate change events (see Section 5.7).

For the last glacial termination, a large-scale temperature reconstruction (Shakun et al., 2012) documents that temperature change in the SH lead NH temperature change. This lead can be explained by the bipolar thermal seesaw concept (Stocker and Johnsen, 2003) (see also Section 5.7) and the related changes in the inter-hemispheric ocean heat transport, caused by weakening of the AMOC during the last glacial termination (Ganopolski and Roche, 2009). SH warming prior to NH warming can also be explained by the fast sea ice response to changes in austral spring insolation (Stott et al., 2007; Timmermann et al., 2009). According to these mechanisms, SH temperature lead over the NH is fully consistent with the NH orbital forcing of deglacial ice volume changes (*high confidence*) and the importance of the climate-carbon feedbacks in glacial-interglacial transitions. The tight coupling is further highlighted by the near-zero lag between the deglacial rise in CO₂ and averaged deglacial Antarctic temperature recently reported from improved estimates of gas-ice age differences (Pedro et al., 2012; Parrenin et al., 2013). Previous studies (Monnin et al., 2001; Table 5.A.4) suggesting a temperature lead of 800 ± 600 years over the deglacial CO₂ rise probably overestimated gas-ice age differences.

5.3.2.3 Monsoon Systems

Since AR4, new high-resolution hydroclimate reconstructions using speleothems (Sinha et al., 2007; Hu et al., 2008; Wang et al., 2008; Cruz et al., 2009; Asmerom et al., 2010; Berkelhammer et al., 2010; Strikis et al., 2011; Kanner et al., 2012), lake sediments (Shanahan et al., 2009; Stager et al., 2009; Wolff et al., 2011), marine sediments (Weldeab et al., 2007b; Mulitza et al., 2008; Tjallingii et al., 2008; Ponton et al., 2012) and tree-ring chronologies (Buckley et al., 2010; Cook et al., 2010a) have provided a more comprehensive view on the dynamics of monsoon systems on a variety of timescales. Water isotope-enabled modelling experiments (LeGrande and Schmidt, 2009; Lewis et al., 2010; Pausata et al., 2011) and evaluation of marine and terrestrial data (Clemens et al., 2010) document that speleothem δ¹⁸O variations in some monsoon regions can be explained as a combination of changes in local precipitation and large-scale moisture transport.

This subsection focuses on the response of monsoon systems to orbital forcing on glacial-interglacial timescales. Proxy data including speleothem δ¹⁸O from southeastern China (Wang et al., 2008), northern Borneo (Meckler et al., 2013), eastern Brazil (Cruz et al., 2005), and the Arabian Peninsula (Bar-Matthews et al., 2003), along with marine-based records off northwestern Africa (Weldeab et al., 2007a) and from the Arabian Sea (Schulz et al., 1998) document hydrological changes that are dominated by eccentricity-modulated precessional cycles. Increasing boreal summer insolation can generate a strong inter-hemispheric surface temperature gradients that leads to large-scale decreases in precipitation in the SH summer monsoon systems and increased hydrological cycle in the NH tropics (Figure 5.4a,d,g). Qualitatively similar, out-of-phase inter-hemispheric responses to insolation forcing have also been documented in coupled time-slice and transient GCM simulations (Braconnot et al., 2008; Kutzbach et al., 2008) (see also Figure 5.4d,g). The similarity in response in both proxy records and models provide *high confidence* that orbital forcing induces inter-hemispheric rainfall variability. Across longitudes, the response of precipitation may, however, be different for the same orbital forcing (Shin et al., 2006; Marzin and Braconnot, 2009). For example, in the mid-Holocene drier conditions occurred in central North America (Diffenbaugh et al., 2006) and wetter conditions in northern Africa (Liu et al., 2007b; Hély et al., 2009; Tierney et al., 2011). There is further evidence for east-west shifts of precipitation in response to orbital forcing in South America (Cruz et al., 2009).

[INSERT FIGURE 5.4 HERE]

(b) Temperature changes in Greenland (°C) reconstructed from NGRIP ice core on SS09 timescale (Huber et al., 2006), location indicated by orange star in c. (c) Location of proxy records displayed in panels a,b,d-i in relation to the global monsoon regions (cyan shading) (Wang and Ding, 2008). (d) Reconstructed (red) standardized negative $\delta^{18}O$ anomaly in East Asian Summer Monsoon region derived from Hulu (Wang et al., 2001) and Sanbao (Wang et al., 2008) cave speleothem records, China and simulated standardized multi-model average (black) of annual mean rainfall anomalies averaged over region 108°E–123°E and 25°N–40°N using the transient runs conducted with LOVECLIM (Timm et al., 2008), FAMOUS (Smith and Gregory, 2012), and the HadCM3 snapshot simulations (Singarayer and Valdes, 2010). (e) $\delta^{18}O$ from Xiaobailong cave, China (Cai et al., 2010). (f) Standardized negative $\delta^{18}O$ anomalies (red) in Huangye (Tan et al., 2011) and Wanxian (Zhang et al., 2008) caves, China and simulated standardized annual mean and 30-year low pass filtered rainfall anomalies (black) in region 100°E–110°E, 20°N–35°N, ensemble averaged over externally forced AOGCM experiments conducted with CCSM4, ECHO-G, MPI-ESM, CSIRO-Mk3L-1-2, MIROC, HADCM3 (Table 5.A.1). (g) Standardized negative $\delta^{18}O$ anomaly (blue) from Botuvéra speleothem, Brazil (Cruz et al., 2005) and simulated standardized multi-model average (black) of annual mean rainfall anomalies averaged over region 45°W–60°W and 35°S–15°S using same experiments as in panel d. (h) Standardized $\delta^{18}O$ anomaly (blue) from Pacupahuain cave, Peru (Kanner et al., 2012). (i) Standardized negative $\delta^{18}O$ anomalies (blue) from Cascayunga Cave, Peru (Reuter et al., 2009) and Pumacocha Lake, Peru (Bird et al., 2011) and simulated standardized annual mean and 30-year low-pass filtered rainfall anomalies (black) in region 76°W–70°W, 16°S–8°S, ensemble averaged over the same model simulations as in f. HS4/5 denote Heinrich stadials 4 and 5, and LIA Little Ice Age (Table 5.1).

[START BOX 5.2 HERE]

Box 5.2: Climate-Ice sheet Interactions

Ice sheets have played an essential role in Earth's climate history (see Sections 5.3, 5.6, 5.7). They interact with the atmosphere, the ocean-sea ice system, the lithosphere and the surrounding vegetation (see Box 5.2, Figure 1). They serve as nonlinear filters and integrators of climate effects caused by orbital and greenhouse gas forcings (Ganopolski and Calov, 2011), while at the same time affecting the global climate system on a variety of timescales (see Section 5.7).

Ice sheets form when annual snow accumulation exceeds melting. Growing ice sheets expand on previously vegetated areas, thus leading to an increase of surface albedo, further cooling and an increase in net surface mass balance. As ice sheets grow in height and area, surface temperatures drop further as a result of the lapse-rate effect, but also snow accumulation decreases because colder air holds less moisture (inlay in Box 5.2, Figure 1). This so-called elevation-desert effect (Oerlemans, 1980) is an important negative feedback for ice sheets which limits their growth. Higher elevation ice sheets can be associated with enhanced calving at their margins, because the ice flow will be accelerated directly by increased surface slopes and indirectly by lubrication at the base of the ice sheet. Calving, grounding line processes, basal lubrication and other forms of thermo-mechanical coupling may have played important roles in accelerating glacial terminations following phases of relatively slow ice sheet growth, hence contributing to the temporal saw-tooth structure of the recent glacial-interglacial cycles (Figure 5.3).

Large glacial ice sheets also deflect the path of the extratropical NH westerly winds (Cook and Held, 1988), generating anticyclonic circulation anomalies (Box 5.2, Figure 1), which tend to warm the western side of the ice sheet and cool the remainder (e.g., Roe and Lindzen, 2001). Furthermore, the orographic effects of ice sheets lead to reorganizations of the global atmosphere circulation by changing the major stationary wave patterns (e.g., Abe-Ouchi et al., 2007; Qiuzhen et al., 2008) and trade wind systems (Timmermann et al., 2004). This allows for a fast transmission of ice sheet signals to remote regions.

The enormous weight of ice sheets depresses the underlying bedrocks causing a drop in ice sheet height and a surface warming as a result of the lapse-rate effect. The lithospheric adjustment has been shown to play an important role in modulating the ice sheet response to orbital forcing (Birchfield et al., 1981; van den Berg et al., 2008). The presence of terrestrial sedimentary materials (regolith) on top of the unweathered bedrock affects the friction at the base of an ice sheet, and may further alter the response of continental ice sheets to external forcings, with impacts on the dominant periodicities of glacial cycles (Clark and Pollard, 1998).

An area of very active research is the interaction between ice sheets, ice shelves and the ocean (see Sections 4.4, 13.4.3, and 13.4.4). The mass balance of marine ice sheets is strongly determined by ocean temperatures

(Joughin and Alley, 2011). Advection of warmer waters below ice shelves can cause ice-shelf instabilities, reduced buttressing, accelerated ice stream flow (De Angelis and Skvarca, 2003) and grounding line retreat in regions with retrograde bedrock slopes (Schoof, 2012), such as West Antarctica. On orbital and millennial timescales such processes may have played an essential role in driving ice-volume changes of the West Antarctic ice sheet (Pollard and DeConto, 2009) and the Laurentide ice sheet (Alvarez-Solas et al., 2010). Massive freshwater release from retreating ice sheets, can feed back to the climate system by altering sea level, oceanic deep convection, ocean circulation, heat transport, sea ice and the global atmospheric circulation (Sections 5.6.3 and 5.7).

Whereas the initial response of ice sheets to external forcings can be quite fast, involving for instance ice-shelf processes and outlet glaciers ($10\text{--}10^3$ years), their long-term adjustment can take much longer ($10^4\text{--}10^5$ years) (see Section 12.5.5.3). As a result the climate-cryosphere system is not even in full equilibrium with the orbital forcing. This also implies that future anthropogenic radiative perturbations over the next century can determine the evolution of the Greenland (Charbit et al., 2008) and Antarctic ice sheets for centuries and millennia to come with a potential commitment to significant global sea level rise (Section 5.8).

5.3.3 Last Glacial Maximum (LGM) and Equilibrium Climate Sensitivity (ECS)

The LGM is characterized by a large temperature response (Section 5.3.3.1) to relatively well-defined radiative perturbations (Section 5.2), linked to atmospheric CO₂ concentration around 200 ppm (Section 5.2.2) and large ice sheets covering northern Europe and North America. This can be used to evaluate climate models (Braconnot et al. (2012b), see Sections 9.7 and 10.8) and to estimate ECS from the combined use of proxy information and simulations (Section 5.3.3.2).

5.3.3.1 LGM Climate

Since AR4, synthesis of proxy LGM temperature estimates was completed for SST (MARGO Project Members, 2009), and for land SAT (Bartlein et al., 2011) (Box 5.1, Figure 1). The MARGO SST synthesis expanded earlier work (CLIMAP Project Members, 1976, 1981; Sarnthein et al., 2003a; Sarnthein et al., 2003b) by using multiple proxies (Table 5.2). The land SAT synthesis is based on pollen data, following COHMAP (COHMAP Members, 1988).

Climate models and proxy data consistently show that mean annual SST change (relative to pre-industrial) is largest in the mid-latitude North Atlantic (up to -10°C), and the Mediterranean (about -6°C) (MARGO Project Members, 2009, Box 5.1, Table 5.2). Warming and seasonally ice-free conditions are reconstructed, however, in the northeastern North Atlantic, in the eastern Nordic Seas and north Pacific; albeit with large uncertainty because of the different interpretation of proxy data (de Vernal et al., 2006). SAT reconstructions generally shows year-round cooling, with regional exceptions such as Alaska (Bartlein et al., 2011). Modelling studies show how atmospheric dynamics influenced by ice-sheets affect regional temperature patterns in the North Atlantic region (Lainé et al., 2009; Pausata et al., 2011; Unterman et al., 2011; Hofer et al., 2013), and in the north Pacific region (Yanase and Abe-Ouchi, 2010). Larger cooling over land compared to ocean is a robust feature of observations and multiple atmosphere-ocean general circulation models (AOGCM) (Izumi et al., 2013). As in AR4, central Greenland temperature change during the LGM is underestimated by PMIP3/CMIP5 simulations, which show $2^{\circ}\text{C}\text{--}18^{\circ}\text{C}$ cooling, compared to $21^{\circ}\text{C}\text{--}25^{\circ}\text{C}$ cooling reconstructed from ice-core data (Table 5.2). A mismatch between reconstructions and model results may arise because of missing Earth-system feedbacks (dust, vegetation) (see Section 5.2.2.3) or insufficient integration time to reach an equilibrium for LGM boundary conditions.

Uncertainties remain on the magnitude of tropical SST cooling during the LGM. Previous estimates of tropical cooling ($2.7^{\circ}\text{C} \pm 0.5^{\circ}\text{C}$, Ballantyne et al., 2005) are greater than more recent estimates ($1.5^{\circ}\text{C} \pm$

1.2°C, MARGO Project Members, 2009). Such discrepancies may arise from seasonal productivity (Leduc et al., 2010) and habitat depth (Telford et al., 2013) biases. In the western and eastern tropical Pacific, many proxy records show 2–3°C cooling relative to the pre-industrial period (Lea et al., 2000; Lea et al., 2006; de Garidel-Thoron et al., 2007; Leduc et al., 2007; Pahnke et al., 2007; Stott et al., 2007; Koutavas and Sachs, 2008; Steinke et al., 2008; Linsley et al., 2010). AOGCMs tend to underestimate longitudinal patterns of tropical SST (Otto-Bliesner et al., 2009) and atmospheric circulation (DiNezio et al., 2011).

Larger sea-ice seasonality is reconstructed for the LGM compared to the pre-industrial period around Antarctica (Gersonde et al., 2005). Climate models underestimate this feature, as well as the magnitude of Southern Ocean cooling (Roche et al., 2012) (see Box 5.1, Figure 1). In Antarctica 7°C–10°C cooling relative to the pre-industrial period is reconstructed from ice cores (Stenni et al., 2010; Uemura et al., 2012) and captured in most PMIP3/CMIP5 simulations (Figure 5.5 d).

The combined use of proxy reconstructions, with incomplete spatial coverage, and model simulations is used to estimate LGM global mean temperature change (Table 5.2). One recent such study, combining multi-proxy data with multiple AOGCMs, estimates LGM global cooling at $4.0^{\circ}\text{C} \pm 0.8^{\circ}\text{C}$ (95% confidence interval) (Annan and Hargreaves, 2013). This result contrasts with the wider range of global cooling (1.7–8.3°C) obtained using Earth-system models of intermediate complexity (EMIC) (Schneider von Deimling et al., 2006; Holden et al., 2010b; Schmittner et al., 2011). The source of these differences in the estimate of LGM cooling may be the result of: (i) the proxy data used to constrain the simulations, such as datasets associated with mild cooling in the tropics and the North Atlantic; (ii) model resolution and structure, which affects their ability to resolve the land-sea contrast (Annan and Hargreaves, 2013) and polar amplification (Fyke and Eby, 2012); (iii) the experimental design of the simulations, where the lack of dust and vegetation feedbacks (Section 5.2.2.3) and insufficient integration time. Based on the results and the caveats in the studies assessed here (Table 5.2), it is *very likely* that global-mean surface temperature during the LGM was cooler than pre-industrial by 3°C–8°C.

Some recent AOGCM simulations produce a stronger AMOC under LGM conditions, leading to mild cooling over the North Atlantic and GIS (Otto-Bliesner et al., 2007; Weber et al., 2007). This finding contrasts with proxy-based information (Lynch-Stieglitz et al., 2007; Hesse et al., 2011). Changes in deep-ocean temperature and salinity during the LGM have been constrained by pore-water chemistry in deep-sea sediments. For example, pore-water data indicate that deep water in the Atlantic Ocean cooled by between $-1.7^{\circ}\text{C} \pm 0.9^{\circ}\text{C}$ and $-4.5^{\circ}\text{C} \pm 0.2^{\circ}\text{C}$, and became saltier by up to 2.4 ± 0.2 psu in the South Atlantic and at least 0.95 ± 0.07 psu in the North Atlantic (cf. Adkins et al., 2002). The magnitude of deep-water cooling is supported by other marine proxy data (e.g., (Dwyer et al., 2000; Martin et al., 2002; Elderfield et al., 2010), while the increase in salinity is consistent with independent estimates based on $\delta^{18}\text{O}$ (Duplessy et al., 2002; Waelbroeck et al., 2002). Average salinity increased due to storage of freshwater in ice sheets. The much larger than average salinity increase in deep Southern Ocean compared to the North Atlantic is probably due to increased salt rejection through sea ice freezing processes around Antarctica (Miller et al., 2012b) (see also Section 9.4.2.3.2).

As a result of prevailing LGM modelling uncertainties (Chavaillaz et al., 2013; Rojas, 2013) and ambiguities in proxy interpretations (Kohfeld et al., 2013), it cannot be determined robustly whether LGM SH westerlies changed in amplitude and position relative to today.

Table 5.2 Summary of LGM SST and SAT reconstructions (anomalies with respect to pre-industrial climate) using proxy data and model ensemble constrained by proxy data. Cooling ranges indicate 90% confidence intervals (C.I., where available).
