Eyring et al. (2013) document, in greater detail than Table 12.1, the implementations of tropospheric and stratospheric ozone in CMIP5 models, including their ozone chemistry schemes and modifications applied to reference datasets in models driven by concentrations. In most models that prescribe ozone, concentrations are based on the original or slightly modified CMIP5 standard ozone dataset computed as part of the IGAC/SPARC activity (Cionni et al., 2011). In the stratosphere, this dataset is based on observations of the past (Randel and Wu, 2007) continued into the future with the multi-model mean of 13 chemistry-climate models (CCMs) projections following the SRES A1B (IPCC, 2000) and SRES A1 adjusted halogen scenario (WMO, 2007). The stratospheric zonal mean ozone field is merged with a 3-D tropospheric ozone time series generated as the mean of two CCMs (GISS-PUCCINI, Shindell et al., 2006; CAM3.5, Lamarque et al., 2010) in the past and continued by one CCM (CAM3.5) in the future. Some CMIP5 models (MIROC-ESM, MIROC4h, MIROC5 and GISS-E2-p1) prescribe ozone concentrations using different datasets but again following just one GHG scenario in the future for the projection of stratospheric ozone. In other models (e.g., IPSL-CM5, CCSM4) ozone is again prescribed, but supplied as concentrations from off-line computations using a related CCM. Some models determine ozone interactively from specified emissions via on-line atmospheric chemistry (CESM1(FASTCHEM), CESM1(WACCM), CNRM-CM5, GFDL-CM3, GISS-E2-p2, GISS-E2-p3, MIROC-ESM-CHEM, MRI-ESM1; and HadGEM2-ES for tropospheric ozone only). Computing ozone concentrations interactively allows the fast coupling between chemistry and climate to be captured, but modelling of chemistry processes is sometimes simplified (CNRM-CM5, CESM(FASTCHEM)) in comparison with full complexity CCMs to reduce the computational cost. Compared to CMIP3, in which all models prescribed ozone and around half of them used a fixed ozone climatology, this leads to substantial improvement to ozone forcings in CMIP5, although differences remain among the models with interactive chemistry.

For atmospheric aerosols, either aerosol precursor emissions-driven or concentration-driven forcings are applied depending on individual model characteristics (see Sections 7.3 and 7.4 for an assessment of aerosols processes including aerosol-radiation and aerosol-cloud interactions). A larger fraction of models in CMIP5 than CMIP3 prescribe aerosol precursor emissions rather than concentrations. Many still prescribe concentrations pre-computed either using a directly related aerosol CCM or from output of another, complex, emissions-driven aerosol chemistry model within the CMIP5 process. As for ozone, aerosol concentrations provided from off-line simulations help to reduce the computational burden of the projections themselves. For several of the concentration-driven models (CCSM4, IPSL-CM5A variants, MPI-ESM-LR, MPI-ESM-MR), additional emissions-driven simulations have been undertaken to tailor the prescribed concentrations closely to the model's individual aerosol-climate characteristics. Lamarque et al. (2010; 2011) provided the recommended CMIP5 aerosols dataset which has been used in several of the models driven by concentrations. Compared with the CMIP3 models, a much larger fraction of CMIP5 models now incorporate black and organic carbon aerosol forcings. Also, a larger fraction of CMIP5 than CMIP3 models now include a range of processes that combine in the effective radiative forcing from aerosol-cloud interactions (ERFaci; see Section 7.1.3 and Figure 7.3). Previously such processes were generally termed aerosol indirect effects, usually separated into cloud albedo (or first indirect) effect and cloud lifetime (or second indirect) effect. Many CMIP5 models only include the interaction between sulphate aerosol and cloud, and the majority of them only model the effect of aerosols on cloud albedo rather than cloud lifetime (Table 12.1). No CMIP5 models represent urban aerosol pollution explicitly so that is not listed in Table 12.1 (see Section 11.3.5.2 for discussion of future air-quality). Only one model (GISS-E2) explicitly includes

nitrate aerosol as a separate forcing, though it is also included within the total aerosol mixture in the MPI-ESM model versions.

Land-use change is typically applied by blending anthropogenic land surface disturbance via crop and pasture fraction changes with underlying land cover maps of natural vegetation, but model variations in the underlying land cover maps and biome modelling mean that the land-use forcing agent is impossible to impose in a completely common way at present (Pitman et al., 2009). Most CMIP5 models represent crop and pasture disturbance separately, while some (CanESM2, MIROC4h, MIROC5) represent crop but not pasture. Some models (e.g., HadGEM2-ES, MIROC-ESM and MPI-ESM versions) allow a dynamical representation of natural vegetation changes alongside anthropogenic disturbance (see also Sections 9.4.4.3 and 9.4.4.4).

Treatment of the CO₂ emissions associated with land cover changes is also model-dependent. Some models do not account for land cover changes at all, some simulate the biophysical effects but are still forced externally by land cover change induced CO₂ emissions (in emission driven simulations), while the most advanced ESMs simulate both biophysical effects of land cover changes and their associated CO₂ emissions.

12.3.3 Synthesis of Projected Global Mean Radiative Forcing for the 21st Century

Quantification of future global mean radiative forcing is of interest as it is directly related to changes in the global energy balance of the climate system and resultant climate change. Chapter 8 discusses RF concepts and methods for computing it that form the basis of analysis directly from the output of model projections.

We assess three related estimates of projected global mean forcing and its range through the 21st century in the context of forcing estimated for the recent past (Figure 12.4). The estimates used are: the total forcings for the defined RCP scenarios, harmonized to radiative forcing in the past (Meinshausen et al., 2011a; Meinshausen et al., 2011c); the total effective radiative forcing (ERF) estimated from CMIP5 models through the 21st century for the four RCP experiments (Forster et al., 2013); and that estimated from models in the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP; Lamarque et al., 2013—see Section 8.2.2 and Table 8.1) for RCP time-slice experiments (Shindell et al., 2013b). Methodological differences mean that whereas CMIP5 estimates include both natural and anthropogenic forcings based entirely on ERF, ACCMIP estimates anthropogenic composition forcing only (neglecting forcing changes due to natural, i.e., solar and volcanic, and land use factors) based on a combination of ERF for aerosols and RF for WMGHG (see Section 8.5.3). Note also that total forcing for the defined RCP scenarios is based on Meinshausen et al. (2011c) but combining total anthropogenic ERF (allowing for efficacies of the various anthropogenic forcings as in Figure 12.3) with natural (solar and volcanic) RF.

[INSERT FIGURE 12.4 HERE]

Figure 12.4: Global mean radiative forcing ($W m^{-2}$) between 1980 and 2100 estimated by alternative methods. The baseline is circa 1850 but dependent on the methods. Dashed lines indicate the total anthropogenic plus natural (solar and volcanic) RF for the RCP scenarios as defined by Meinshausen et al. (2011c), taking into account the efficacies of the various anthropogenic forcings (Meinshausen et al., 2011a), normalised by the mean between 1850 and 1859. Solid lines are multi-model mean ERF realised in a subset of CMIP5 models for the concentration-driven historical experiment and RCP scenarios, normalised either with respect to the 1850-1869 base period or with respect to the pre-industrial control simulation (Forster et al., 2013). (The subset of CMIP5 models included is defined by Table 1 of (Forster et al., 2013) but omitting the FGOALS-s2 model, the historical and RCP simulations of which were subsequently withdrawn from the CMIP5 archive.) This CMIP5-based estimate assumes each model has an invariant climate feedback parameter, calculated from abrupt $4 \times CO_2$ experiments using the method of Gregory et al. (2004). Each individual CMIP5 model's forcing estimate is an average over all available ensemble members, and a 1-sigma inter-model range around the multi-model mean is shaded in light colour. Grey or coloured vertical bars illustrate the 1-sigma range (68% confidence interval) of anthropogenic composition forcing (excluding natural and land-use change forcings, based on ERF for aerosols combined with RF for WMGHG) estimated in ACCMIP models (Shindell et al., 2013b) for time slice experiments at 1980, 2000, 2030 (RCP8.5 only) and 2100 (all RCPs). The ACCMIP ranges plotted have been converted from the 5–95% ranges given in Shindell et al. (2013b) (Table 8) to a 1-sigma range. Note that the ACCMIP bars at 1980 and 2100 are shifted slightly to aid clarity. The mean ERF diagnosed from 21 CMIP3 models for the SRES A1B scenario, as in Forster and Taylor (2006), is also shown (thick green line) with a 1-sigma range (thinner green lines). The number of models included in CMIP3 and CMIP5 ensemble means is shown colour coded. (See Tables AII.6.8-AII.6.10. Note that the CMIP5 model ranges given in Table AII.6.10 are based on decadal averages and therefore differ slightly from the ranges based on annual data shown in this Figure.)

The CMIP5 multi-model ensemble mean ERF at 2100 (relative to an 1850–1869 base period) is 2.2, 3.8, 4.8 and 7.6 W m^{-2} respectively for RCP2.6, RCP4.5, RCP6.0 and RCP8.5 concentration-driven projections, with a 1-sigma range based on annual mean data for year 2100 of about ± 0.5 to 1.0 W m^{-2} depending on scenario (lowest for RCP2.6 and highest for RCP8.5). The CMIP5-based ERF estimates are close to the total forcing at 2100 (relative to an 1850–1859 base period) of 2.4, 4.0, 5.2 and 8.0 W m^{-2} as defined for the four RCPs.

The spread in ERF indicated from CMIP5 model results with specified GHG concentration pathways is broadly consistent with that found for CMIP3 models for the A1B scenario using the corresponding method (Forster and Taylor, 2006). As for CMIP3 models, part of the forcing spread in CMIP5 models (Forster et al., 2013) is consistent with differences in GHG forcings arising from the radiative transfer codes (Collins et al., 2006b). Aerosol forcing implementations in CMIP5 models also vary considerably however (Section 12.3.2), leading to a spread in aerosol concentrations and forcings which contributes to the overall model spread. A further small source of spread in CMIP5 results possibly arises from an underlying ambiguity in the CMIP5 experimental design regarding the volcanic forcing offset between the historical experiment versus the pre-industrial control experiment. Most models implement zero volcanic forcing in the control experiment but some use constant negative forcing equal to the time-mean of historical volcanic forcing (see Table 12.1 and Section 12.3.2). The effect of this volcanic forcing offset persists into the future projections.

ACCMIP projected forcing at 2030 (for RCP8.5) and 2100 (all RCPs) is systematically higher than corresponding CMIP5 ERF, although with some overlap between 1 sigma ranges. CMIP5 and ACCMIP comprise different sets of models and they are related in many but not all cases (Section 8.2.2). Confining analysis to a subset of closely related models also gives higher forcing estimates from ACCMIP compared to CMIP5 so the discrepancy in multi-model ensemble mean forcings appears unrelated to the different model samples associated with the two methods of estimation. The discrepancy is thought to originate mostly from differences in the underlying methodologies used to estimate RF, but is not yet well understood (see also Section 8.5.3).

There is *high confidence* in projections from ACCMIP models (Shindell et al., 2013b) based on the GISS-E2 CMIP5 simulations (Shindell et al., 2013a) and an earlier study with a version of the HadGEM2-ES model related to that used in CMIP5 (Bellouin et al., 2011), consistent with understanding of the processes controlling nitrate formation (Adams et al., 2001), that nitrate aerosols (which provide a negative forcing) will increase substantially over the 21st century under the RCPs (Section 8.5.3, Figure 8.20). The magnitude of total aerosol-related forcing (also negative in sign) will therefore tend to be underestimated in the CMIP5 multi-model mean ERF, as nitrate aerosol has been omitted as a forcing from almost all CMIP5 models.

Natural radiative forcing variations are, by their nature, difficult to project reliably (see Section 8.4). There is *very high confidence* that industrial-era natural forcing has been a small fraction of the (positive) anthropogenic forcing except for brief periods following large volcanic eruptions (Sections 8.5.1 and 8.5.2). Based on that assessment and the assumption that variability in natural forcing remains of a similar magnitude and character to that over the industrial-era, total anthropogenic forcing relative to pre-industrial, for any of the RCP scenarios through the 21st century, is *very likely* to be greater in magnitude than changes in natural (solar plus volcanic) forcing on decadal time scales.

In summary, global mean forcing projections derived from climate models exhibit a substantial range for the given RCP scenarios in concentration-driven experiments, contributing to the projected global mean temperature range (Section 12.4.1). Forcings derived from ACCMIP models for 2100 are systematically higher than those estimated from CMIP5 models for reasons that are not fully understood but are partly due to methodological differences. The multi-model mean estimate of combined anthropogenic plus natural forcing from CMIP5 is consistent with indicative RCP forcing values at 2100 to within $0.2\text{--}0.4 \text{ W m}^{-2}$.

12.4 Projected Climate Change over the 21st Century

12.4.1 Time-Evolving Global Quantities

12.4.1.1 Projected Changes in Global Mean Temperature and Precipitation

A consistent and robust feature across climate models is a continuation of global warming in the 21st century for all the RCP scenarios (Figure 12.5 showing changes in concentration-driven model simulations). Temperature increases are almost the same for all the RCP scenarios during the first two decades after 2005 (see Figure 11.25). At longer time scales, the warming rate begins to depend more on the specified GHG concentration pathway, being highest ($>0.3^{\circ}\text{C}$ per decade) in the highest RCP8.5 and significantly lower in RCP2.6, particularly after ~ 2050 when global surface temperature response stabilizes (and declines thereafter). The dependence of global temperature rise on GHG forcing at longer timescales has been confirmed by several studies (Meehl et al., 2007b). In the CMIP5 ensemble mean, global warming under RCP2.6 stays below 2°C above pre-industrial levels throughout the 21st century, clearly demonstrating the potential of mitigation policies (note that to translate the anomalies in Figure 12.5 into anomalies with respect to the pre-industrial period, an assumed 0.61°C of observed warming since 1850–1900, as discussed in Section 2.4.3, should be added). This is in agreement with previous studies of aggressive mitigation scenarios (Johns et al., 2011; Meehl et al., 2012). Note, however, that some individual ensemble members do show warming exceeding 2°C above pre-industrial (see Table 12.3). As for the non-mitigation pathways, global warming exceeds 2°C within the 21st century under RCP4.5, RCP6.0 and RCP8.5, in qualitative agreement with previous studies using the SRES A1B and A2 scenarios (Joshi et al., 2011). Global mean temperature increase exceeds 4°C under RCP8.5 by 2100. The CMIP5 concentration-driven global temperature projections are broadly similar to CMIP3 SRES scenarios discussed in AR4 (Meehl et al., 2007b) and Section 12.4.9, although the overall range of the former is larger primarily because of the low-emission mitigation pathway RCP2.6 (Knutti and Sedláček, 2013).

[INSERT FIGURE 12.5 HERE]

Figure 12.5: Time series of global annual mean surface air temperature anomalies (relative to 1986–2005) from CMIP5 concentration-driven experiments. Projections are shown for each RCP for the multi model mean (solid lines) and the 5–95% range (± 1.64 standard deviation) across the distribution of individual models (shading). Discontinuities at 2100 are due to different numbers of models performing the extension runs beyond the 21st century and have no physical meaning. Only one ensemble member is used from each model and numbers in the figure indicate the number of different models contributing to the different time periods. No ranges are given for the RCP6.0 projections beyond 2100 as only two models are available.

The multi model global mean temperature changes under different RCPs are summarized in Table 12.2. The relationship between cumulative anthropogenic carbon emissions and global temperature is assessed in Section 12.5 and only concentration-driven models are included here. Warming in 2046–2065 is slightly larger under RCP4.5 compared to RCP6.0, consistent with its greater total anthropogenic forcing at that time (see Table A.II.6.12). For all other periods the magnitude of global temperature change increases from RCP2.6 to RCP8.5. Beyond 2100, RCP2.6 shows a decreasing trend whereas under all other RCPs warming continues to increase. Also shown in Table 12.2 are projected changes at 2081–2100 averaged over land and ocean separately as well as area-weighted averages over the Tropics (30°S – 30°N), Arctic (67.5°N – 90°N) and Antarctic (90°S – 55°S) regions. Surface air temperatures over land warm more than over the ocean and northern polar regions warm more than the tropics. The excess of land mass in the Northern Hemisphere in comparison with the Southern Hemisphere, coupled with the greater uptake of heat by the Southern Ocean in comparison with northern ocean basins means that the Northern Hemisphere generally warms more than the Southern. Arctic warming is much greater than in the Antarctic, due to the presence of the Antarctic ice sheet and differences in local responses in snow and ice. Mechanisms behind these features of warming are discussed in Section 12.4.3. Maps and time series of regional temperature changes are displayed in Annex I and regional averages are presented in Table 14.8a.

Table 12.2: CMIP5 annual mean surface air temperature anomalies ($^{\circ}\text{C}$) from the 1986–2005 reference period for selected time periods, regions and RCPs. The multi model mean ± 1 standard deviation ranges across the individual models are listed and the 5–95% ranges from the models' distribution (based on a Gaussian assumption and obtained by multiplying the CMIP5 ensemble standard deviation by 1.64) are given in brackets. Only one ensemble member is used from each model and the number of models differs for each RCP (see Figure 12.5) and becomes significantly smaller after 2100. No ranges are given for the RCP6.0 projections beyond 2100 as only two models are available. Using HadCRUT4 and its uncertainty estimate (5–95% confidence interval), the observed warming to the 1986–2005 reference period (see Section 2.4.3) is 0.61 ± 0.06 (1850–1900), 0.30 ± 0.03 (1961–1990), 0.11 ± 0.02 (1980–1999). Decadal values are provided in Table AII.7.5, but note that percentiles of the CMIP5 distributions cannot directly be interpreted in terms of calibrated language.

	RCP2.6	RCP4.5	RCP6.0	RCP8.5
Global: 2046–2065	1.0 ± 0.3 (0.4,1.6)	1.4 ± 0.3 (0.9,2.0)	1.3 ± 0.3 (0.8,1.8)	2.0 ± 0.4 (1.4,2.6)
2081–2100	1.0 ± 0.4 (0.3,1.7)	1.8 ± 0.5 (1.1,2.6)	2.2 ± 0.5 (1.4,3.1)	3.7 ± 0.7 (2.6,4.8)
2181–2200	0.7 ± 0.4 (0.1,1.3)	2.3 ± 0.5 (1.4,3.1)	3.7 ± 0.7 (-,-)	6.5 ± 2.0 (3.3,9.8)
2281–2300	0.6 ± 0.3 (0.0,1.2)	2.5 ± 0.6 (1.5,3.5)	4.2 ± 1.0 (-,-)	7.8 ± 2.9 (3.0,12.6)
Land: 2081–2100	1.2 ± 0.6 (0.3,2.2)	2.4 ± 0.6 (1.3,3.4)	3.0 ± 0.7 (1.8,4.1)	4.8 ± 0.9 (3.4,6.2)
Ocean: 2081–2100	0.8 ± 0.4 (0.2,1.4)	1.5 ± 0.4 (0.9,2.2)	1.9 ± 0.4 (1.1,2.6)	3.1 ± 0.6 (2.1,4.0)
Tropics: 2081–2100	0.9 ± 0.3 (0.3,1.4)	1.6 ± 0.4 (0.9,2.3)	2.0 ± 0.4 (1.3,2.7)	3.3 ± 0.6 (2.2,4.4)
Polar: Arctic: 2081–2100	2.2 ± 1.7 (-0.5,5.0)	4.2 ± 1.6 (1.6,6.9)	5.2 ± 1.9 (2.1,8.3)	8.3 ± 1.9 (5.2,11.4)
Polar: Antarctic: 2081–2100	0.8 ± 0.6 (-0.2,1.8)	1.5 ± 0.7 (0.3,2.7)	1.7 ± 0.9 (0.2,3.2)	3.1 ± 1.2 (1.1,5.1)

Global annual multi model mean temperature changes above pre-industrial are listed in Table 12.3 for the 2081–2100 period (assuming 0.61°C warming since 1850–1900 as discussed in Section 2.4.3) along with the percentage of 2081–2100 projections from the CMIP5 models exceeding policy-relevant temperature levels under each RCP. These complement a similar discussion for the near-term projections in Table 11.3 which are based on the CMIP5 ensemble as well as evidence (discussed in Sections 10.3.1, 11.3.2.1.1 and 11.3.6.3) that some CMIP5 models have a higher sensitivity to greenhouse gases and a larger response to other anthropogenic forcings (dominated by the effects of aerosols) than the real world (*medium confidence*). The percentage calculations for the long-term projections in Table 12.3 are based solely on the CMIP5 ensemble, using one ensemble member for each model. For these long-term projections, the 5–95% ranges of the CMIP5 model ensemble are considered the *likely* range, an assessment based on the fact that the 5–95% range of CMIP5 models' TCR coincides with the assessed *likely* range of the TCR (see Section 12.4.1.2 below and Box 12.2). Based on this assessment, global mean temperatures averaged in the period 2081–2100 are projected to *likely* exceed 1.5°C above preindustrial for RCP4.5, RCP6.0 and RCP8.5 (*high confidence*). They are also *likely* to exceed 2°C above preindustrial for RCP6.0 and RCP8.5 (*high confidence*). Temperature change above 2°C under RCP2.6 is *unlikely* but is assessed only with *medium confidence* as some CMIP5 ensemble members do produce a global mean temperature change above 2°C. Warming above 4°C by 2081–2100 is *unlikely* in all RCPs (*high confidence*) except RCP8.5. Under the latter, the 4°C global temperature level is exceeded in more than half of ensemble members, so is assessed to be *as likely as not* (*medium confidence*). Note that the likelihoods of exceeding specific temperature levels show some sensitivity to the choice of reference period (see Section 11.3.6.3).

Table 12.3: CMIP5 global annual mean temperature changes above pre-industrial for the 2081–2100 period of each RCP scenario (mean, ±1 standard deviation and 5–95% ranges based on a Gaussian assumption and obtained by multiplying the CMIP5 ensemble standard deviation by 1.64), assuming 0.61°C warming has occurred prior to 1986–2005 (second column). For a number of temperature levels (1°C, 1.5°C, 2°C, 3°C and 4°C), the proportion of CMIP5 model projections for 2081–2100 above those levels under each RCP scenario are listed. Only one ensemble member is used for each model.

	ΔT 2081–2100	$\Delta T > +1.0^\circ\text{C}$	$\Delta T > +1.5^\circ\text{C}$	$\Delta T > +2.0^\circ\text{C}$	$\Delta T > +3.0^\circ\text{C}$	$\Delta T > +4.0^\circ\text{C}$
RCP2.6	1.6 ± 0.4 (0.9, 2.3)	94%	56%	22%	0%	0%
RCP4.5	2.4 ± 0.5 (1.7, 3.2)	100%	100%	79%	12%	0%
RCP6.0	2.8 ± 0.5 (2.0, 3.7)	100%	100%	100%	36%	0%
RCP8.5	4.3 ± 0.7 (3.2, 5.4)	100%	100%	100%	100%	62%

CMIP5 models on average project a gradual increase in global precipitation over the 21st century: change exceeds 0.05 mm day⁻¹ (~2% of global precipitation) and 0.15 mm day⁻¹ (~5% of global precipitation) by 2100 in RCP2.6 and RCP8.5, respectively. The relationship between global precipitation and global temperature is approximately linear (Figure 12.6). The precipitation sensitivity, i.e., the change of global precipitation with temperature, is about 1–3% °C⁻¹ in most models, tending to be highest for RCP2.6 and RCP4.5 (Figure 12.7; Note that only global values are discussed in this section, ocean and land changes are

discussed in Section 12.4.5.2). These behaviours are consistent with previous studies, including CMIP3 model projections for SRES scenarios and AR4 constant composition commitment experiments (Meehl et al., 2007b), and ENSEMBLES multi-model results for SRES A1B and E1 scenarios (Johns et al., 2011).

[INSERT FIGURE 12.6 HERE]

Figure 12.6: Global mean precipitation (mm day^{-1}) versus temperature ($^{\circ}\text{C}$) changes relative to 1986–2005 baseline period in CMIP5 model concentrations-driven projections for the four RCPs for a) means over decadal periods starting in 2006 and overlapped by 5 years (2006–2015, 2011–2020, up to 2091–2100), each line representing a different model (one ensemble member per model) and b) corresponding multi-model means for each RCP.

The processes that govern global precipitation changes are now well understood and have been presented in Section 7.6. They are briefly summarized here and used to interpret the long term projected changes. The precipitation sensitivity (about $\sim 1\text{--}3\% \text{ }^{\circ}\text{C}^{-1}$) is very different from the water vapour sensitivity ($\sim 7\% \text{ }^{\circ}\text{C}^{-1}$) as the main physical laws that drive these changes also differ. Water vapour increases are primarily a consequence of the Clausius-Clapeyron relationship associated with increasing temperatures in the lower troposphere (where most atmospheric water vapour resides). In contrast, future precipitation changes are primarily the result of changes in the energy balance of the atmosphere and the way that these later interact with circulation, moisture and temperature (Mitchell et al., 1987; Boer, 1993; Vecchi and Soden, 2007; Previdi, 2010; O’Gorman et al., 2012). Indeed, the radiative cooling of the atmosphere is balanced by latent heating (associated with precipitation) and sensible heating. Since AR4, the changes in heat balance and their effects on precipitation have been analyzed in detail for a large variety of forcings, simulations and models (Takahashi, 2009a; Andrews et al., 2010; Bala et al., 2010; Ming et al., 2010; O’Gorman et al., 2012; Bony et al., 2013).

An increase of CO_2 decreases the radiative cooling of the troposphere and reduces precipitation (Andrews et al., 2010; Bala et al., 2010). On longer time scales than the fast hydrological adjustment timescale (Andrews et al., 2010; Bala et al., 2010; Cao et al., 2012; Bony et al., 2013), the increase of CO_2 induces a slow increase of temperature and water vapour, thereby enhancing the radiative cooling of atmosphere and increasing global precipitation (Allen and Ingram, 2002; Yang et al., 2003; Held and Soden, 2006). Even after the CO_2 forcing stabilises or begins to decrease, the ocean continues to warm, which then drives up global temperature, evaporation and precipitation. In addition, non-linear effects also affect precipitation changes (Good et al., 2012). These different effects explain the steepening of the precipitation versus temperature relationship in RCP2.6 and RCP4.5 scenarios (Figure 12.6), as radiative forcing stabilises and/or declines from the mid-century (Figure 12.4). In idealized CO_2 ramp-up/ramp-down experiments, this effect produces an hydrological response overshoot (Wu et al., 2010). An increase of absorbing aerosols warms the atmosphere and reduces precipitation, and the surface temperature response may be too small to compensate this decrease (Andrews et al., 2010; Ming et al., 2010; Shiogama et al., 2010a). Change in scattering aerosols or incoming solar radiation modify global precipitation mainly via the response of the surface temperature (Andrews et al., 2009; Bala et al., 2010).

The main reasons for the inter-model spread of the precipitation sensitivity estimate amongst GCMs have not been fully understood. Nevertheless, spread in the changes of the cloud radiative effect have been shown to have an impact (Previdi, 2010), although the effect is less important for precipitation than it is for the climate sensitivity estimate (Lambert and Webb, 2008). The lapse rate plus water vapour feedback and the response of the surface heat flux (Previdi, 2010; O’Gorman et al., 2012), the shortwave absorption by water vapor (Takahashi, 2009b) or by aerosols have been also identified as important factors.

Global precipitation sensitivity estimates from observation are very sensitive to the data and the time period considered. Some observational studies suggest precipitation sensitivity values higher than model estimates (Wentz et al., 2007; Zhang et al., 2007) although more recent studies suggest consistent values (Adler et al., 2008; Li et al., 2011b).

[INSERT FIGURE 12.7 HERE]

Figure 12.7: Percentage changes over the 21st century in global, land and ocean precipitation per $^{\circ}\text{C}$ of global warming in CMIP5 model concentration-driven projections for the four RCP scenarios. Annual mean changes are calculated for each year between 2006 and 2100 from one ensemble member per model relative to its mean precipitation and temperature for the 1986–2005 baseline period, and the gradient of a least-squares fit through the annual data is derived. Land and ocean derived values use global mean temperature in the denominator of dP/dT . Each coloured symbol

represents a different model, the same symbol being used for the same model for different RCPs and larger black squares being the multi-model mean. Also shown for comparison are global mean results for ENSEMBLES model concentrations-driven projections for the E1 and A1B scenarios (Johns et al., 2011), in this case using a least-squares fit derived over the period 2000–2099 and taking percentage changes relative to the 1980–1999 baseline period. Changes of precipitation over land and ocean are discussed in Section 12.4.5.2.

12.4.1.2 Uncertainties in Global Quantities

Uncertainties in global mean quantities arise from variations in internal natural variability, model response and forcing pathways. Table 12.2 gives two measures of uncertainty in the CMIP5 model projections, the standard deviation and the 5–95% range across the ensemble's distribution. Because CMIP5 was not designed to explore fully the uncertainty range in projections (see Section 12.2), neither its standard deviation nor its range can be interpreted directly as an uncertainty statement about the corresponding real quantities, and other techniques and arguments to assess uncertainty in future projections must be considered. Figure 12.8 summarises the uncertainty ranges in global mean temperature changes at the end of the 21st century under the various scenarios quantified by various methods. Individual CMIP5 models are shown by red crosses. Red bars indicate mean and 5–95% percentiles based on assuming a normal distribution for the CMIP5 sample (i.e., ± 1.64 standard deviations). Estimates from the simple climate carbon cycle model MAGICC (Meinshausen et al., 2011a; Meinshausen et al., 2011b) calibrated to C⁴MIP (Friedlingstein et al., 2006) carbon cycle models, assuming a PDF for climate sensitivity that corresponds to the assessment of IPCC AR4 (Meehl et al., 2007b, Box 10.2), are given as yellow bars (Rogelj et al., 2012). Note that not all models have simulated all scenarios. To test the effect of undersampling, and to generate a consistent set of uncertainties across scenarios, a step response method that estimates the total warming as sum of responses to small forcing steps (Good et al., 2011a) is used to emulate 23 CMIP5 models under the different scenarios (those 23 models that supplied the necessary simulations to compute the emulators, i.e., CO₂ step change experiments). This provides means and ranges (5–95%) that are comparable across scenarios (blue). See also Section 12.4.9 for a discussion focused on the differences between CMIP3 and CMIP5 projections of global average temperature changes.

For the CO₂ concentration-driven simulations (Figure 12.8a), the dominant driver of uncertainty in projections of global temperature for the higher RCPs beyond 2050 is the transient climate response (TCR), for RCP2.6, which is closer to equilibrium by the end of the century, it is both the TCR and the equilibrium climate sensitivity (ECS). In a transient situation, the ratio of temperature to forcing is approximately constant and scenario independent (Meehl et al., 2007b, Appendix 10.A.1; Gregory and Forster, 2008; Knutti et al., 2008b; Good et al., 2013). Therefore, the uncertainty in TCR maps directly into the uncertainty in global temperature projections for the RCPs other than RCP2.6. The assessed *likely* range of TCR based on various lines of evidence, (see Box 12.2) is similar to the 5–95% percentile range of TCR in CMIP5. In addition, the assessed *likely* range of ECS is also close to the CMIP5 range (see Box 12.2). There is little evidence that the CMIP5 models are significantly over- or underestimating the radiative forcing. The radiative forcing uncertainty is small compared to response uncertainty (see Figure 12.4), and is considered by treating the 5–95% as a *likely* rather than *very likely* range. Kuhlbrodt and Gregory (2012) suggest that models might be overestimating ocean heat uptake, as previously suggested by Forest et al. (2006), but observationally constrained estimates of TCR are unaffected by that. The ocean heat uptake efficiency does not contribute much to the spread of TCR (Knutti and Tomassini, 2008; Kuhlbrodt and Gregory, 2012).

Therefore, for global mean temperature projections only, the 5–95% range (estimated as 1.64 times the sample standard deviation) of the CMIP5 projections can also be interpreted as a *likely* range for future temperature change between about 2050 and 2100. *Confidence* in this assessment is *high* for the end of the century because the warming then is dominated by CO₂ and the TCR. *Confidence* is only *medium* for mid-century when the contributions of radiative forcing and initial conditions to the total temperature response uncertainty are larger. The *likely* ranges are an expert assessment, taking into account many lines of evidence, in much the same way as in AR4 (Figure SPM.5), and are not probabilistic. The *likely* ranges for 2046–2065 do not take into account the possible influence of factors that lead to near-term (2016–2035) projections of GMST that are somewhat cooler than the 5–95% model ranges (see Section 11.3.6), because the influence of these factors on longer term projections cannot be quantified. A few recent studies indicate that some of the models with the strongest transient climate response might overestimate the near term warming (Otto et al., 2013; Stott et al., 2013) (see Sections 10.8.1, 11.3.2.1.1), but there is little evidence of whether and how much that affects the long term warming response. One perturbed physics ensemble

combined with observations indicates warming that exceeds the AR4 at the top end but used a relatively short time period of warming (50 years) to constrain the models' projections (Rowlands et al., 2012) (see Sections 11.3.2.1.1 and 11.3.6.3). Global-mean surface temperatures for 2081–2100 (relative to 1986–2005) for the CO₂ concentration driven RCPs is therefore assessed to *likely* fall in the range 0.3°C–1.7°C (RCP2.6), 1.1°C–2.6°C (RCP4.5), 1.4°C–3.1°C (RCP6.0), and 2.6°C–4.8°C (RCP8.5) estimated from CMIP5. Beyond 2100, the number of CMIP5 simulations is insufficient to estimate a *likely* range. Uncertainties before 2050 are assessed in Section 11.3.2.1.1. The assessed *likely* range is very similar to the range estimated by the pulse response model, suggesting that the different sample of models for the different RCPs are not strongly affecting the result, and providing further support that this pulse response technique can be used to emulate temperature and ocean heat uptake in Chapter 13 and Section 12.4.9 below. The results are consistent with the probabilistic results from MAGICC, which for the lower RCPs have a slightly narrower range due to the lack of internal variability in the simple model, and the fact that non-CO₂ forcings are treated more homogeneously than in CMIP5 (Meinshausen et al., 2011a; Meinshausen et al., 2011b). This is particularly pronounced for RCP2.6 where the CMIP5 range is substantially larger, partly due to the larger fraction of non-CO₂ forcings in that scenario.

The uncertainty estimate in AR4 for the SRES scenarios was –40% to +60% around the CMIP3 means (shown here in grey for comparison). That range was asymmetric and wider for the higher scenarios because it included the uncertainty in carbon cycle climate feedbacks. The SRES scenarios are based on the assumption of prescribed emissions, which then translates to uncertainties in concentrations that propagate through to uncertainties in the temperature response. The RCP scenarios assume prescribed concentrations. For scenarios that stabilize (RCP2.6) that approach of constant fractional uncertainty underestimates the uncertainty and is no longer applicable, mainly because internal variability has a larger relative contribution to the total uncertainty (Good et al., 2013; Knutti and Sedláček, 2013). For the RCPs, the carbon cycle climate feedback uncertainty is not included because the simulations are driven by concentrations. Furthermore, there is no clear evidence that distribution of CMIP5 global temperature changes deviates from a normal distribution. For most other variables the shape of the distribution is unclear, and standard deviations are simply used as an indication of model spread, not representing a formal uncertainty assessment.

Simulations with prescribed CO₂ emissions rather than concentrations are only available for RCP8.5 (Figure 12.8b) and from MAGICC. The projected temperature change in 2100 is slightly higher and the uncertainty range is wider as a result of uncertainties in the carbon cycle climate feedbacks. The CMIP5 range is consistent with the uncertainty range given in AR4 for SRES A2 in 2100. Further details about emission vs. concentration driven simulations are given in Section 12.4.8.

In summary, the projected changes in global temperature for 2100 in the RCP scenarios are very consistent with those obtained by CMIP3 for SRES in IPCC AR4 (see Section 12.4.9) when taking into account the differences in scenarios. The *likely* uncertainty ranges provided here are similar for RCP4.5 and RCP6.0 but narrower for RCP8.5 compared to AR4. There was no scenario as low as RCP2.6 in AR4. The uncertainties in global temperature projections have not decreased significantly in CMIP5 (Knutti and Sedláček, 2013), but the assessed ranges cannot be compared between AR4 and AR5. The main reason is that uncertainties in carbon cycle feedbacks are not considered in the concentration driven RCPs. In contrast, the *likely* range in AR4 included those. The assessed *likely* ranges are therefore narrower for the high RCPs. The differences in the projected warming are largely attributable to the difference in scenarios (Knutti and Sedláček, 2013), and the change in the future and reference period, rather than to developments in modeling since AR4. A detailed comparison between the SRES and RCP scenarios and the CMIP3 and CMIP5 models is given in Section 12.4.9.

[INSERT FIGURE 12.8 HERE]

Figure 12.8: Uncertainty estimates for global mean temperature change in 2081–2100 with respect to 1986–2005. Red crosses mark projections from individual CMIP5 models. Red bars indicate mean and 5–95% ranges based on CMIP5 (1.64 standard deviations), which are considered as a *likely range*. Blue bars indicate 5–95% ranges from the pulse response emulation of 21 models (Good et al., 2011a). Grey bars mark the range from the mean of CMIP5 minus 40% mean to the mean +60%, assessed as *likely* in AR4 for the SRES scenarios. The yellow bars show the median, 17–83% range and 5–95% range based on Rogelj et al. (2012). See also Figure 12.39 and 12.40.

12.4.2 Pattern Scaling

12.4.2.1 Definition and Use

In this chapter we show geographical patterns of projected changes in climate variables according to specific scenarios and time horizons. Alternative scenarios and projection times can be inferred from those shown by using some established approximation methods. This is especially the case for large-scale regional patterns of average temperature and—with additional caveats—precipitation changes. In fact, “pattern scaling” is an approximation that has been explicitly suggested in the description of the RCPs (Moss et al., 2010) as a method for deriving impact-relevant regional projections for scenarios that have not been simulated by global and regional climate models. It was first proposed by Santer et al. (1990) and revisited later by numerous studies (e.g., Huntingford and Cox, 2000). It relies on the existence of robust geographical patterns of change, emerging at the time when the signal of external forcings emerges from the noise, and persisting across the length of the simulation, across different scenarios, and even across models, modulated by the corresponding changes in global average temperature. The robustness of temperature change pattern has been amply documented from the original paper onward. An example is given in Figure 12.9 for surface air temperature from each of the CMIP5 models highlighting both similarities and differences between the responses of different models. The precipitation pattern was shown to scale linearly with global average temperature to a sufficient accuracy in CMIP3 models (Neelin et al., 2006) for this to be useful for projections related to the hydrological cycle. Shiogama et al. (2010b) find similar results with the caution that in the early stages of warming aerosols modify the pattern. A more mixed evaluation can be found in Good et al. (2012), where some land areas in the low latitudes exhibit a non-linear relation to global average temperature, but, largely, average precipitation change over the remaining regions can be well approximated by a grid-point specific linear function of global average temperature change. It is in the latter quantity that the dependence of the evolution of the change in time on the model (e.g., its climate sensitivity) and the forcing (e.g., the emission scenario) is encapsulated.

[INSERT FIGURE 12.9 HERE]

Figure 12.9: Surface air temperature change in 2081–2100 displayed as anomalies with respect to 1986–2005 for RCP4.5 from one ensemble member of each of the concentration-driven models available in the CMIP5 archive.

In analytical terms, it is assumed that the following relation holds

$$C(t, \xi) = T_G(t) \chi(\xi) + R(t, \xi)$$

where the symbol ξ identifies the geographic location (model grid point or other spatial coordinates) and possibly the time of year (for example a June-July-August average). The index t runs along the length of the forcing scenario of interest. $T_G(t)$ indicates global average temperature change at time t under this scenario; $\chi(\xi)$ is the time-invariant geographic pattern of change per 1°C global surface temperature change for the variable of interest (which represents the forced component of the change) and $C(t, \xi)$ is the actual field of change for that variable at the specific time t under this scenario. The $R(t, \xi)$ is a residual term and highlights the fact that pattern scaling cannot reconstruct model behaviour with complete accuracy due to both natural variability and because of limitations of the methodology discussed below. This way, regionally and temporally differentiated results under different scenarios or climate sensitivities can be approximated by the product of a spatial pattern, constant over time, scenario and model characteristics, and a time evolving global mean change in temperature. Model and scenario dependence are thus captured through the global mean temperature response, and simple climate models calibrated against fully coupled climate models can be used to simulate the latter, at a great saving in computational cost. The spatial pattern can be estimated through the available coupled models simulations under the assumption that it does not depend on the specific scenario(s) used.

The choice of the pattern in the studies available in the literature can be as simple as the ensemble average field of change (across models and/or across scenarios, for the coupled experiments available), normalized by the corresponding change in global average temperature, choosing a segment of the simulations when the signal has emerged from the noise of natural variability from a baseline of reference (e.g., the last 20 years of the 21st century compared to pre-industrial or current climate) and taking the difference of two multidecadal means. Similar properties and results have been obtained using more sophisticated multivariate procedures

that optimize the variance explained by the pattern (Holden and Edwards, 2010). The validity of this approximation is discussed by Mitchell et al. (1999) and Mitchell (2003). Huntingford and Cox (2000) evaluate the quality of the approximation for numerous variables, showing that the technique performs best for temperature, downward longwave radiation, relative humidity, wind speeds and surface pressure while showing relatively larger limitations for rainfall rate anomalies. Joshi et al. (2013) have recently shown that the accuracy of the approximation, especially across models, is improved by adding a second term, linear in the land-sea surface warming ratio, another quantity that can be easily estimated from existing coupled climate model simulations. There exist of course differences between the patterns generated by different GCMs (documented for example for CMIP3 in Watterson and Whetton, 2011b), but uncertainty can be characterized, for example, by the inter-model spread in the pattern $\chi(\xi)$. Recent applications of the methodology to probabilistic future projections have in fact sought to fully quantify errors introduced by the approximation, on the basis of the available coupled model runs (Harris et al., 2006).

Pattern scaling and its applications have been documented in IPCC WG1 Reports before (IPCC, 2001, Section 13.5.2.1; Meehl et al., 2007b, Section 10.3.2). It has been used extensively for regional temperature and precipitation change projections, e.g., Murphy et al. (2007), (Watterson, 2008), Giorgi (2008), Harris et al. (2006) and Harris et al. (2010), May (2008a), Ruosteenoja et al. (2007), Räisänen and Ruokolainen (2006), Cabre et al. (2010) and impacts studies, e.g., as described in Dessai et al. (2005) and Fowler et al. (2007b). Recent studies have focused on patterns linked to warming at certain global average temperature change thresholds (e.g., May, 2008a; Sanderson et al., 2011) and patterns derived under the RCPs (Ishizaki et al., 2012).

There are basic limitations to this approach, besides a degradation of its performance as the regional scale of interest becomes finer and in the presence of regionally specific forcings. Recent work with MIROC3.2 (Shiogama et al., 2010a; Shiogama et al., 2010b) has revealed a dependence of the precipitation sensitivity (global average precipitation change per 1°C of global warming—see Figure 12.6) on the scenario, due to the precipitation being more sensitive to carbon aerosols than well-mixed greenhouse gases. In fact, there are significant differences in black and organic carbon aerosol forcing between the emission scenarios investigated by Shiogama et al. (2010a; 2010b). Levy II et al. (2013) confirm that patterns of precipitation change are spatially correlated with the sources of aerosol emissions, in simulations where the indirect effect is represented. This is a behaviour that is linked to a more general limitation of pattern scaling, which breaks down if aerosol forcing is significant. The effects of aerosols have a regional nature and are thus dependent on the future sources of pollution which are likely to vary geographically in the future and be difficult to predict (May, 2008a). For example, Asian and North American aerosol production are likely to have different time histories and future projections. Schlesinger et al. (2000) extended the methodology of pattern scaling by isolating and recombining patterns derived by dedicated experiments with a coupled climate model where sulfate aerosols were increased for various regions in turn. More recently, in an extension of pattern scaling into a probabilistic treatment of model, scenario and initial condition uncertainties, Frieler et al. (2012) derived joint probability distributions for regionally averaged temperature and precipitation changes as linear functions of global average temperature and additional predictors including regionally specific SO_x and black carbon emissions.

Pattern scaling is less accurate for strongly mitigated stabilization scenarios. This has been shown recently by May (2012), comparing patterns of temperature change under a scenario limiting global warming since pre-industrial times to 2°C and patterns produced by a scenario that reaches 4.5°C of global average temperature change. The limitations of pattern scaling in approximating changes while the climate system approaches equilibrium have found their explanation in Manabe and Wetherald (1980) and Mitchell et al. (1999). Both studies point out that as the temperatures of the deep oceans reach equilibrium (over multiple centuries) the geographical distribution of warming changes as well, for example showing a larger warming of the high latitudes in the Southern hemisphere than in the earlier periods of the transient response, relative to the global mean warming. More recently Held et al. (2010) showed how this slow warming pattern is in fact present during the initial transient response of the system as well, albeit with much smaller amplitude. Further, Gillett et al. (2011) show how in a simulation in which emissions cease, regional temperatures and precipitation patterns exhibit ongoing changes, even though global mean temperature remains almost constant. Wu et al. (2010) showed that the global precipitation response shows a non-linear response to strong mitigation scenarios, with the hydrological cycle continuing to intensify even after atmospheric CO₂

concentration, and thus global average temperature, start decreasing. Regional non-linear responses to mitigation scenarios of precipitation and sea surface temperatures are shown by Chadwick et al. (2013).

Other areas where pattern scaling shows a lack of robustness are the edges of polar ice caps and sea ice extent, where at an earlier time in the simulation ice melts and regions of sharp gradient surface, while later in the simulation, in the absence of ice, the gradient will become less steep. Different sea-ice representations in models also make the location of such regions much less robust across the model ensembles and the scenarios.

Pattern scaling has not been as thoroughly explored for quantities other than average temperature and precipitation. Impact relevant extremes, for example, seem to indicate a critical dependence on the scale at which their changes are evaluated, with studies showing that some aspects of their statistics change in a close-to-linear way with mean temperature (Kharin et al., 2007; Lustenberger et al., 2013) while others have documented the dependence of their changes on moments of their statistical distribution other than the mean (Ballester et al., 2010a), which would make pattern scaling inadequate.

12.4.2.2 CMIP5 Patterns Scaled by Global Average Temperature Change

On the basis of CMIP5 simulations, we show geographical patterns (Figure 12.10) of warming and precipitation change and indicate measures of their variability across models and across RCPs. The patterns are scaled to 1°C global mean surface temperature change above the reference period 1986–2005 for 2081–2100 (first row) and for the constant composition commitment runs at a time of stabilization, 2181–2200 (thus excluding RCP8.5, which does not stabilize by that time) (second row). Spatial correlation of fields of temperature and precipitation change range from 0.93 to 0.99 when considering ensemble means under different RCPs. The lower values are found when computing correlation between RCP2.6 and the higher RCPs, and may be related to the high mitigation enacted under RCP2.6 from early in the 21st century. Pattern correlation varies between 0.91 and 0.98 for temperature and between 0.91 and 0.96 for precipitation when comparing patterns computed by averaging and normalizing changes at the end of the 21st, 22nd and 23rd century, with the largest value representing the correlation between the patterns at the end of the 22nd and 23rd century, the lowest representing the correlation between the pattern at the end of the 21st and the pattern at the end of the 23rd century. The zonal means shown to the side of each plot represent each model by one line, colour coding the four different scenarios. They show good agreement of models and scenarios over low and mid-latitudes for temperature, but higher spread across models and especially across scenarios for the areas subject to polar amplification, for which the previous discussion about the sensitivity of the patterns to the sea-ice edge may be relevant. A comparison of the mean of the lines to their spread indicates overall the presence of a strong mean signal with respect to the spread of the ensemble. Precipitation shows an opposite pattern of inter-model spread, with larger variations in the low latitudes and around the equator, and smaller around the high latitudes. Precipitation has also a lower signal-to-noise ratio (measured as above by comparing the ensemble mean change magnitude to the spread across models and scenarios of these zonal mean averages).

As already mentioned, while we do not explicitly use pattern scaling in the sections that follow, we consider it a useful approximation when the need emerges to interpolate or extrapolate results to different scenarios or time periods, noting the possibility that the scaling may break down at higher levels of global warming, and that the validity of the approximation is limited to broad patterns of change, as opposed to local scales. An important caveat is that pattern scaling only applies to the climate response that is externally forced. The actual response is a combination of forced change and natural variability, which is not and should not be scaled up or down by the application of this technique, which becomes important on small spatial scales and shorter timescales, and whose relative magnitude compared to the forced component also depends on the variable (Hawkins and Sutton, 2009; Hawkins and Sutton, 2011; Mahlstein et al., 2011; Deser et al., 2012b; Deser et al., 2012a; Mahlstein et al., 2012) (see 11.2). One approach to produce projections that include both components is to estimate natural variability separately, scale the forced response and add the two.

[INSERT FIGURE 12.10 HERE]

Figure 12.10: Temperature (left) and precipitation (right) change patterns derived from transient simulations from the CMIP5 ensembles, scaled to 1°C of global mean surface temperature change. The patterns have been calculated by computing 20-year averages at the end of the 21st (top) and 22nd (bottom) century and over the period 1986–2005 for

the available simulations under all RCPs, taking their difference (percentage difference in the case of precipitation) and normalizing it, grid-point by grid-point, by the corresponding value of global average temperature change for each model and scenario. The normalized patterns have then been averaged across models and scenarios. The colour scale represents °C (in the case of temperature) and % (in the case of precipitation) per 1°C of global average temperature change. Stippling indicates where the mean change averaged over all realisations is larger than the 95% percentile of the distribution of models. Zonal means of the geographical patterns are shown for each individual model for RCP2.6 (blue), 4.5 (light blue), 6.0 (orange) and 8.5 (red). RCP8.5 is excluded from the stabilisation figures. The RCP2.6 simulation of the FIO-ESM model was excluded because it did not show any warming by the end of the 21st century, thus not complying with the method requirement that the pattern be estimated at a time when the temperature change signal from CO₂ increase has emerged.

12.4.3 Changes in Temperature and Energy Budget

12.4.3.1 Patterns of Surface Warming: Land-Sea Contrast, Polar Amplification and SSTs

Patterns of surface air temperature change for various RCPs show widespread warming during the 21st century (Figure 12.11; see Annex I for seasonal patterns). A key feature that has been present throughout the history of coupled modelling is the larger warming over land compared to oceans, which occurs in both transient and equilibrium climate change (e.g., Manabe et al., 1990). The degree to which warming is larger over land than ocean is remarkably constant over time under transient warming due to well-mixed greenhouse gases (Lambert and Chiang, 2007; Boer, 2011; Lambert et al., 2011) suggesting that heat capacity differences between land and ocean do not play a major role in the land-sea warming contrast (Sutton et al., 2007; Joshi et al., 2008; Joshi et al., 2013). The phenomenon is predominantly a feature of the surface and lower atmosphere (Joshi et al., 2008). Studies have found it occurs due to contrasts in surface sensible and latent fluxes over land (Sutton et al., 2007), land-ocean contrasts in boundary layer lapse rate changes (Joshi et al., 2008), boundary layer relative humidity and associated low-level cloud cover changes over land (Doutriaux-Boucher et al., 2009; Fasullo, 2010) and soil moisture reductions (Dong et al., 2009; Clark et al., 2010) under climate change. The land-sea warming contrast is also sensitive to aerosol forcing (Allen and Sherwood, 2010; Joshi et al., 2013). Globally-averaged warming over land and ocean is identified separately in Table 12.2 for the CMIP5 models and the ratio of land to ocean warming is *likely* in the range of 1.4–1.7, consistent with previous studies (Lambert et al., 2011). The CMIP5 multi model mean ratio is approximately constant from 2020 through to 2100 (based on an update of Joshi et al., 2008 from available CMIP5 models).

[INSERT FIGURE 12.11 HERE]

Figure 12.11: Multi model ensemble average of surface air temperature change (compared to 1986–2005 base period) for 2046–2065, 2081–2100, 2181–2200 for RCP2.6, 4.5, 6.0 and 8.5. Hatching indicates regions where the multi model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean change is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

Amplified surface warming in Arctic latitudes is also a consistent feature in climate model integrations (e.g., Manabe and Stouffer, 1980). This is often referred to as polar amplification, although as numerous studies have shown that under transient forcing, this is primarily an Arctic phenomenon (Manabe et al., 1991; Meehl et al., 2007b). The lack of an amplified transient warming response in high Southern latitudes has been associated with deep ocean mixing, strong ocean heat uptake and the persistence of the vast Antarctic ice sheet. In equilibrium simulations, amplified warming occurs in both polar regions.

On an annual average, and depending on the forcing scenario (see Table 12.2), the CMIP5 models show a mean Arctic (67.5°–90°N) warming between 2.2 and 2.4 times the global average warming for 2081–2100 compared to 1986–2005. Similar polar amplification factors occurred in earlier coupled model simulations (e.g., Holland and Bitz, 2003; Winton, 2006a). This factor in models is slightly higher than the observed central value, but it is within the uncertainty of the best estimate from observations of the recent past (Bekryaev et al., 2010). The uncertainty is large in the observed factor because station records are short and sparse (Serreze and Francis, 2006) and the forced signal is contaminated by the noise of internal variability. By contrast, model trends in surface air temperature are 2.5 to 5 times higher than observed over Antarctica, but here also the observational estimates have a very large uncertainty, so, for example, the CMIP3 ensemble mean is consistent with observations within error estimates (Monaghan et al., 2008). Moreover, recent work

suggests more widespread current West Antarctic surface warming than previously estimated (Bromwich et al., 2013).

The amplified Arctic warming in models has a distinct seasonal character (Manabe and Stouffer, 1980; Rind, 1987; Holland and Bitz, 2003; Lu and Cai, 2009; Kumar et al., 2010). Arctic amplification (defined as the 67.5°N–90°N warming compared to the global average warming for 2081–2100 versus 1986–2005) peaks in early winter (November–December) with a CMIP5 RCP4.5 multi-model mean warming for 67.5°N–90°N exceeding the global average by a factor of more than 4. The warming is smallest in summer when excess heat at the Arctic surface goes into melting ice or is absorbed by the ocean, which has a relatively large thermal inertia. Simulated Arctic warming also has a consistent vertical structure that is largest in the lower troposphere (e.g., Manabe et al., 1991; Kay et al., 2012). This is in agreement with recent observations (Serreze et al., 2009; Screen and Simmonds, 2010) but contrary to an earlier study which suggested a larger warming aloft (Graversen et al., 2008). The discrepancy in observed vertical structure may reflect inadequacies in datasets (Bitz and Fu, 2008; Grant et al., 2008; Thorne, 2008) and sensitivity to the time period used for averaging (see also Box 2.3).

As also discussed in Box 5.1, there are many mechanisms that contribute to Arctic amplification, some of which were identified in early modelling studies (Manabe and Stouffer, 1980). Feedbacks associated with changes in sea ice and snow amplify surface warming near the poles (Hall, 2004; Soden et al., 2008; Graversen and Wang, 2009; Kumar et al., 2010). The longwave radiation changes in the top of the atmosphere associated with surface warming opposes surface warming at all latitudes, but less so in the Arctic (Winton, 2006a; Soden et al., 2008). Rising temperature globally is expected to increase the horizontal latent heat transport by the atmosphere into the Arctic (Flannery, 1984; Alexeev et al., 2005; Cai, 2005; Langen and Alexeev, 2007; Kug et al., 2010), which warms primarily the lower troposphere. On average, CMIP3 models simulate enhanced latent heat transport (Held and Soden, 2006), but north of about 65°N, the sensible heat transport declines enough to more than offset the latent heat transport increase (Hwang et al., 2011). Increased atmospheric heat transport into the Arctic and subsidence warming has been associated with a teleconnection driven by enhanced convection in the tropical western Pacific (Lee et al., 2011). Ocean heat transport plays a role in the simulated Arctic amplification, with both large late 20th century transport (Mahlstein and Knutti, 2011) and increases over the 21st century (Hwang et al., 2011; Bitz et al., 2012) associated with higher amplification. As noted by Held and Soden (2006), Kay et al. (2012), and Alexeev and Jackson (2012), diagnosing the role of various factors in amplified warming is complicated by coupling in the system in which local feedbacks interact with poleward heat transports.

While models consistently exhibit Arctic amplification as global mean temperatures rise, the multitude of physical processes described above mean that they differ considerably in the magnitude. Previous work has implicated variations across climate models in numerous factors including inversion strength (Boé et al., 2009a), ocean heat transport (Holland and Bitz, 2003; Mahlstein and Knutti, 2011), albedo feedback (Winton, 2006a), longwave radiative feedbacks (Winton, 2006a), and shortwave cloud feedback (Crook et al., 2011; Kay et al., 2012) as playing a role in the across-model scatter in polar amplification. The magnitude of amplification is generally higher in models with less extensive late 20th century sea ice in June suggesting that the initial ice state influences the 21st century Arctic amplification. The pattern of simulated Arctic warming is also associated with the initial ice state, and in particular with the location of the winter sea ice edge (Holland and Bitz, 2003; Räisänen, 2007; Bracegirdle and Stephenson, 2012). This relationship has been suggested as a constraint on projected Arctic warming (Abe et al., 2011; Bracegirdle and Stephenson, 2012), although, in general, the ability of models to reproduce observed climate and its trends is not a sufficient condition for attributing *high confidence* to the projection of future trends (see Section 9.8).

Minima in surface warming occur in the North Atlantic and Southern Oceans under transient forcing in part due to deep ocean mixed layers in those regions (Manabe et al., 1990; Xie et al., 2010). Trenberth and Fasullo (2010) find that the large biases in the Southern Ocean energy budget in CMIP3 coupled models are negatively correlated with equilibrium climate sensitivity (see Section 12.5.3), suggesting that an improved mean state in the Southern Ocean is needed before warming there can be understood. In the equatorial Pacific, warming is enhanced in a narrow band which previous assessments have described as ‘El Niño-like’, as may be expected from the projected decrease in atmospheric tropical circulations (see Section 12.4.4). However, DiNezio et al. (2009) highlight that the tropical Pacific warming in the CMIP3 models is not ‘El Niño-like’ as the pattern of warming and associated teleconnections (Xie et al., 2010; Section 12.4.5.2) is

quite distinct from that of an El Niño event. Instead the pattern is of enhanced equatorial warming and is due to a meridional minimum in evaporative damping on the equator (Liu et al., 2005) and ocean dynamical changes that can be decoupled from atmospheric changes (DiNezio et al., 2009) (see also further discussion in Section 12.4.7).

In summary, there is robust evidence over multiple generations of models and *high confidence* in these large-scale warming patterns. In the absence of a strong reduction in the Atlantic Meridional Overturning Circulation, there is *very high confidence* that the Arctic region is projected to warm most.

12.4.3.2 Zonal Average Atmospheric Temperature

Zonal temperature changes at the end of the 21st century show warming throughout the troposphere and, depending on the scenario, a mix of warming and cooling in the stratosphere (Figure 12.12). The maximum warming in the tropical upper troposphere is consistent with theoretical explanations and associated with a decline in the moist adiabatic lapse rate of temperature in the tropics as the climate warms (Bony et al., 2006). The northern polar regions also experience large warming in the lower atmosphere, consistent with the mechanisms discussed in Section 12.4.3.1. The tropospheric patterns are similar to those in the TAR and AR4 with the RCP8.5 changes being up to several degrees warmer in the tropics compared to the A1B changes appearing in the AR4. Similar tropospheric patterns appear in the RCP 2.6 and 4.5 changes, but with reduced magnitudes, suggesting some degree of scaling with forcing change in the troposphere, similar to behaviour discussed in the AR4 and Section 12.4.2. The consistency of tropospheric patterns over multiple generations of models indicates *high confidence* in these projected changes.

In the stratosphere, the models show similar tropical patterns of change, with magnitudes differing according to degree of climate forcing. Substantial differences appear in polar regions. In the north, RCP8.5 and 4.5 yield cooling, though it is more significant in the RCP8.5 ensemble. In contrast, RCP2.6 shows warming, albeit weak and with little significance. In the southern polar region, RCP 2.6 and 4.5 both show significant warming, and RCP8.5 is the outlier, with significant cooling. The polar stratospheric warming, especially in the southern hemisphere, is similar to that found by Butchart et al. (2010) and Meehl et al. (2012) in GCM simulations that showed effects of ozone recovery in determining the patterns (Baldwin et al., 2007; Son et al., 2010). Eyring et al. (2013) find behaviour in the CMIP5 ensemble both for models with and without interactive chemistry that supports the contention that the polar stratospheric changes in Figure 12.12 are strongly influenced by ozone recovery. Overall, the stratospheric temperature changes do not exhibit pattern scaling with global temperature change and are dependent on ozone recovery.

Away from the polar stratosphere, there is physical and pattern consistency in temperature changes between different generations of models assessed here and in the TAR and AR4. The consistency is especially clear in the northern high latitudes and, coupled with physical understanding, indicates that some of the greatest warming is *very likely* to occur here. There is also consistency across generations of models in relatively large warming in the tropical upper troposphere. Allen and Sherwood (2008) and Johnson and Xie (2010) have presented dynamic and thermodynamic arguments, respectively, for the physical robustness of the tropical behaviour. However, there remains uncertainty about the magnitude of warming simulated in the tropical upper troposphere because large observational uncertainties and contradictory analyses limit a confident assessment of model accuracy in simulating temperature trends in the tropical upper troposphere (Section 9.4.1.4.3). The combined evidence indicates that relatively large warming in the tropical upper troposphere is *likely*, but with *medium confidence*.

[INSERT FIGURE 12.12 HERE]

Figure 12.12: CMIP5 multi-model changes in annual mean zonal mean temperature in the atmosphere and ocean relative to 1986–2005 for 2081–2100 under the RCP2.6 (left), RCP4.5 (centre) and RCP8.5 (right) forcing scenarios. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1).

12.4.3.3 Temperature Extremes

As the climate continues to warm, changes in several types of temperature extremes have been observed (Donat et al., 2013), and are expected to continue in the future in concert with global warming (Seneviratne

et al., 2012). Extremes occur on multiple time scales, from a single day or a few consecutive days (a heat wave) to monthly and seasonal events. Extreme temperature events are often defined by indices (see Box 2.4 for the common definitions used) e.g., percentage of days in a year when maximum temperature is above the 90th percentile of a present day distribution or by long period return values. While changes in temperature extremes are a very robust signature of anthropogenic climate change (Seneviratne et al., 2012), the magnitude of change and consensus among models varies with the characteristics of the event being considered (e.g., timescale, magnitude, duration and spatial extent) as well as the definition used to describe the extreme.

Since the AR4 many advances have been made in establishing global observed records of extremes (Alexander et al., 2006; Perkins et al., 2012; Donat et al., 2013) against which models can be evaluated to give context to future projections (Sillmann and Roeckner, 2008; Alexander and Arblaster, 2009). Numerous regional assessments of future changes in extremes have also been performed and a comprehensive summary of these is given in (Seneviratne et al., 2012). Here we summarise the key findings from this report and assess updates since then.

It is *virtually certain* that there will be more hot and fewer cold extremes as global temperature increases (Caesar and Lowe, 2012; Orłowsky and Seneviratne, 2012; Sillmann et al., 2013), consistent with previous assessments (Solomon et al., 2007; Seneviratne et al., 2012). Figure 12.13 shows multi model mean changes in the absolute temperature indices of the coldest day of the year and the hottest day of the year and the threshold-based indices of frost days and tropical nights from the CMIP5 ensemble (Sillmann et al., 2013). A robust increase in warm temperature extremes and decrease in cold temperature extremes is found at the end of the 21st century, with the magnitude of the changes increasing with increased anthropogenic forcing. The coldest day of the year undergoes larger increases than the hottest day in the globally averaged time series (Figure 12.13b and d). This tendency is consistent with the CMIP3 model results shown in Figure 12.13, which use different models and the SRES scenarios (see Section 12.3.4.1 for a comparison of RCP and SRES scenarios and Seneviratne et al. (2012) for earlier CMIP3 results). Similarly, increases in the frequency of warm nights are greater than increases in the frequency of warm days (Sillmann et al., 2013). Regionally, the largest increases in the coldest day of the year are projected in the high latitudes of the Northern Hemisphere under the RCP8.5 scenario (Figure 12.13a). The subtropics and mid-latitudes exhibit the greatest projected changes in the hottest day of the year, whereas changes in tropical nights and the frequency of warm days and warm nights are largest in the tropics (Sillmann et al., 2013). The number of frost days declines in all regions while significant increases in tropical nights are seen in south-eastern North America, the Mediterranean and central Asia.

It is *very likely* that, on average, there will be more record high than record cold temperatures in a warmer average climate. For example, Meehl et al. (2009) find that the current ratio of 2 to 1 for record daily high maxima to low minima over the United States becomes approximately 20 to 1 by the mid 21st century and 50 to 1 by late century in their model simulation of the SRES A1B scenario. However, even at the end of the century daily record low minima continue to be broken, if in a small number, consistent with Kodra et al. (2011) who conclude that cold extremes will continue to occur in a warmer climate, even though their frequency declines.

It is also *very likely* that heat waves, defined as spells of days with temperature above a threshold determined from historical climatology, will occur with a higher frequency and duration, mainly as a direct consequence of the increase in seasonal mean temperatures (Barnett et al., 2006; Ballester et al., 2010a; Ballester et al., 2010b; Fischer and Schär, 2010). Changes in the absolute value of temperature extremes are also *very likely* and expected to regionally exceed global temperature increases by far, with substantial changes in hot extremes projected even for moderate (<2.5°C above present day) average warming levels (Clark et al., 2010; Diffenbaugh and Ashfaq, 2010). These changes often differ from the mean temperature increase, as a result of changes in variability and shape of the temperature distribution (Hegerl et al., 2004; Meehl and Tebaldi, 2004; Clark et al., 2006). For example, summer temperature extremes over central and southern Europe are projected to warm substantially more than the corresponding mean local temperatures as a result of enhanced temperature variability at interannual to intraseasonal time scales (Schär et al., 2004; Clark et al., 2006; Kjellstrom et al., 2007; Vidale et al., 2007; Fischer and Schär, 2009, 2010; Nikulin et al., 2011; Fischer et al., 2012a). Several recent studies have also argued that the probability of occurrence of a Russian heat wave at least as severe as the one in 2010 increases substantially (by a factor of 5 to 10 by the mid-

century) along with increasing mean temperatures and enhanced temperature variability (Barriopedro et al., 2011; Dole et al., 2011).

[INSERT FIGURE 12.13 HERE]

Figure 12.13: CMIP5 multi model mean geographical changes (relative to a 1981–2000 reference period in common with CMIP3) under RCP8.5 and 20-year smoothed time series for RCP2.6, RCP4.5 and RCP8.5 in the (a,b) annual minimum of minimum daily temperature, (c,d) annual maximum of maximum daily temperature, (e,f) frost days (number of days below 0°C) and (g,h) tropical nights (number of days above 20°C). White areas over land indicate regions where the index is not valid. Shading in the time series represents the interquartile ensemble spread (25th and 75th quantiles). The box-and-whisker plots show the interquartile ensemble spread (box) and outliers (whiskers) for 11 CMIP3 model simulations of the SRES scenarios A2 (orange), A1B (cyan), and B1 (purple) globally averaged over the respective future time periods (2046–2065 and 2081–2100) as anomalies from the 1981–2000 reference period. Stippling indicates grid points with changes that are significant at the 5% level using a Wilcoxon signed-ranked test. Updated from Sillmann et al. (2013), excluding the FGOALS-s2 model.

Since the AR4, an increased understanding of mechanisms and feedbacks leading to projected changes in extremes has been gained (Seneviratne et al., 2012). Climate models suggest that hot extremes are amplified by soil moisture-temperature feedbacks (Seneviratne et al., 2006; Diffenbaugh et al., 2007; Lenderink et al., 2007; Vidale et al., 2007; Fischer and Schär, 2009; Fischer et al., 2012a) in northern mid-latitudes regions as the climate warms, consistent with previous assessments. Changes in temperature extremes may also be impacted by changes in land-sea contrast, with Watterson et al. (2008) showing an amplification of southern Australian summer warm extremes over the mean due to anomalous temperature advection from warmer continental interiors. The largest increases in the magnitude of warm extremes are simulated over mid-latitude continental areas, consistent with the drier conditions, and the associated reduction in evaporative cooling from the land surface projected over these areas (Kharin et al., 2007). The representation of the latter constitutes a major source of model uncertainty for projections of the absolute magnitude of temperature extremes (Clark et al., 2010; Fischer et al., 2011).

Winter cold extremes also warm more than the local mean temperature over northern high latitudes (Orlowsky and Seneviratne, 2012; Sillmann et al., 2013) as a result of reduced temperature variability related to declining snow cover (Gregory and Mitchell, 1995; Kjellstrom et al., 2007; Fischer et al., 2011) and decreases in land-sea contrast (de Vries et al., 2012). Changes in atmospheric circulation, induced by remote surface heating can also modify the temperature distribution (Haarsma et al., 2009). Sillmann and Croci-Maspoli (2009) note that cold winter extremes over Europe are in part driven by atmospheric blocking and changes to these blocking patterns in the future lead to changes in the frequency and spatial distribution of cold temperature extremes as global temperatures increase. Occasional cold winters will continue to occur (Räsänen and Ylhäisi, 2011).

Human discomfort, morbidity and mortality during heat waves depend not only on temperature but also specific humidity. Heat stress, defined as the combined effect of temperature and humidity, is expected to increase along with warming temperatures and dominates the local decrease in summer relative humidity due to soil drying (Diffenbaugh et al., 2007; Fischer et al., 2012b; Dunne et al., 2013). Areas with abundant atmospheric moisture availability and high present-day temperatures such as Mediterranean coastal regions are expected to experience the greatest heat stress changes because the heat stress response scales with humidity which thus becomes increasingly important to heat stress at higher temperatures (Fischer and Schär, 2010; Sherwood and Huber, 2010; Willett and Sherwood, 2012). For some regions, simulated heat stress indicators are remarkably robust, because those models with stronger warming simulate a stronger decrease in atmospheric relative humidity (Fischer and Knutti, 2013).

Changes in rare temperature extremes can be assessed using extreme value theory based techniques (Seneviratne et al., 2012). Kharin et al. (2007), in an analysis of CMIP3 models, found large increases in the 20 year return values of the annual maximum and minimum daily averaged surface air temperatures (i.e., the size of an event that would be expected on average once every 20 years, or with a 5% chance every year) with larger changes over land than ocean. Figure 12.14 displays the end of 21st century change in the magnitude of these rare events from the CMIP5 models in the RCP2.6, 4.5 and 8.5 scenarios (Kharin et al., 2013). Comparison to the changes in summer mean temperature shown in Figure AI.5 and A1.7 of Annex I reveals that rare high temperature events are projected to change at rates similar to or slightly larger than the summertime mean temperature in many land areas. However, in much of Northern Europe 20 year return

values of daily high temperatures are projected to increase 2°C or more than JJA mean temperatures under RCP8.5, consistent with previous studies (Sterl et al., 2008; Orłowsky and Seneviratne, 2012). Rare low temperature events are projected to experience significantly larger increases than the mean in most land regions, with a pronounced effect at high latitudes. Twenty year return values of cold extremes increase significantly more than winter mean temperature changes, particularly over parts of North America and Europe. Kharin et al. (2013) concluded from the CMIP5 models that it is *likely* that in most land regions a current 20 year maximum temperature event is projected to become a one-in-two year event by the end of the 21st century under the RCP4.5 and RCP8.5 scenarios, except for some regions of the high latitudes of the Northern Hemisphere where it is *likely* to become a one-in-five year event (see also Seneviratne et al. (2012) SREX Figure 3.5). Current 20 year minimum temperature events are projected to become exceedingly rare, with return periods *likely* increasing to more than 100 years in almost all locations under RCP8.5 (Kharin et al., 2013). Section 10.6.1.1 notes that a number of detection and attribution studies since SREX suggest that the model changes may tend to be too large for warm extremes and too small for cold extremes and thus these likelihood statements are somewhat less strongly stated than a direct interpretation of model output and its ranges. The CMIP5 analysis shown in Figure 12.14 reinforces this assessment of large changes in the frequency of rare events, particularly in the RCP8.5 scenario (Kharin et al., 2013).

[INSERT FIGURE 12.14 HERE]

Figure 12.14: The CMIP5 multi-model median change in 20-year return values of annual warm temperature extremes (left hand panels) and cold temperature extremes (right hand panels) as simulated by CMIP5 models in 2081–2100 relative to 1986–2005 in the RCP2.6 (top panels), RCP4.5 (middle panels), and RCP8.5 (bottom panels) experiments.

There is high consensus amongst models in the sign of the future change in temperature extremes, with recent studies confirming this conclusion from the previous assessments (Tebaldi et al., 2006; Meehl et al., 2007b; Orłowsky and Seneviratne, 2012; Seneviratne et al., 2012; Sillmann et al., 2013). However, the magnitude of the change remains uncertain due to scenario and model (both structural and parameter) uncertainty (Clark et al., 2010) as well as internal variability. These uncertainties are much larger than corresponding uncertainties in the magnitude of mean temperature change (Barnett et al., 2006; Clark et al., 2006; Fischer and Schär, 2010; Fischer et al., 2011).

12.4.3.4 Energy Budget

Anthropogenic or natural perturbations to the climate system produce radiative forcings that result in an imbalance in the global energy budget at the top of the atmosphere (TOA) and affect the global mean temperature (Section 12.3.3). The climate responds to a change in radiative forcing on multiple timescales and at multiyear timescales, the energy imbalance (i.e., the energy heating or cooling the Earth) is very close to the ocean heat uptake due to the much lower thermal inertia of the atmosphere and the continental surfaces (Levitus et al., 2005; Knutti et al., 2008a; Murphy et al., 2009; Hansen et al., 2011). The radiative responses of the fluxes at TOA are generally analysed using the forcing-feedback framework and are presented in Section 9.7.2.

CMIP5 models simulate a small increase of the energy imbalance at the TOA over the 20th century (see Box 3.1, Section 9.4.2, Box 13.1). The future evolution of the imbalance is very different depending on the scenario (Figure 12.15a): for RCP8.5 it continues to increase rapidly, much less for RCP6.0, is almost constant for RCP4.5 and decreases for RCP2.6. This latter negative trend reveals the quasi-stabilisation characteristic of RCP2.6. (In a transient scenario simulation, the TOA imbalance is always less than the radiative forcing because of the slow rate of ocean heat uptake.)

The rapid fluctuations that are simulated during the 20th century originate from volcanic eruptions that are prescribed in the models (see Section 12.3.2). These aerosols reflect solar radiation and thus decrease the amount of SW radiation absorbed by the Earth (Figure 12.15c). The minimum of shortwave (SW) radiation absorbed by the Earth during the period 1960–2000 is mainly due to two factors: a sequence of volcanic eruptions and an increase of the reflecting aerosol burden due to human activities (see Sections 7.5, 8.5 and 9.4.6). During the 21st century, the absorbed SW radiation monotonically increases for the RCP8.5 scenario, and increases and subsequently stabilizes for the other scenarios, consistent with what has been previously obtained with CMIP3 models and SRES scenarios (Trenberth and Fasullo, 2009). The two main contributions to the SW changes are the change of clouds (see Section 12.4.3.5) and the change of the

cryosphere (see Section 12.4.6) at high latitudes. In the longwave (LW) domain (Figure 12.15b), the net flux at TOA represent the opposite of the flux that is emitted by the Earth's surface and atmosphere toward space, i.e., a negative anomaly represents an increase of the emitted LW radiation. The LW net flux depends mainly on two factors: the surface temperature and the magnitude of the greenhouse effect of the atmosphere. During the 20th century, the rapid fluctuations of LW radiation are driven by volcanic forcings, which decrease the absorbed SW radiation, surface temperature, and the LW radiation emitted by the Earth toward space. During the period 1960–2000, the fast increase of greenhouse gas concentrations also decreases the radiation emitted by the Earth. In response to this net heating of Earth, temperatures warm and thereby increase emitted LW radiation although the change of the temperature vertical profile, water vapour, and cloud properties modulate this response (e.g., Bony et al., 2006; Randall et al., 2007).

[INSERT FIGURE 12.15 HERE]

Figure 12.15: Time series of global and annual multi model mean (a) net total radiation anomaly at the TOA, (b) net longwave radiation anomaly at the TOA and (c) net shortwave radiation anomaly at the TOA from the CMIP5 concentration-driven experiments for the historical period (black) and the four RCP scenarios. All the fluxes are positive downward and units are W m^{-2} . The anomalies are calculated relative to the 1900–1950 base period as this is a common period to all model experiments with few volcanic eruptions and relatively small trends. One ensemble member is used for each individual CMIP5 model and the \pm standard deviation across the distribution of individual models is shaded.

[INSERT FIGURE 12.16 HERE]

Figure 12.16: Multi-model CMIP5 average changes in annual mean (left) net total radiation anomaly at the TOA, (middle) net longwave radiation anomaly at the TOA and (right) net shortwave radiation anomaly at the TOA for the RCP4.5 scenario averaged over the periods 2081–2100. All fluxes are positive downward, units are W m^{-2} . The net radiation anomalies are computed with respect to the 1900–1950 base period. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

12.4.3.5 Clouds

This section provides a summary description of future changes in clouds and their feedbacks on climate. A more general and more precise description and assessment of the role of clouds in the climate system is provided in Chapter 7, in particular Section 7.2 for cloud processes and feedbacks and Section 7.4 for aerosol-cloud interactions. Cloud feedbacks and adjustments are presented in Section 7.2.5 and a synthesis is provided in Section 7.2.6. Clouds are a major component of the climate system and play an important role in climate sensitivity (Cess et al., 1990; Randall et al., 2007), the diurnal temperature range (DTR) over land (Zhou et al., 2009), and land-sea contrast (see Section 12.4.3.1). The observed global mean cloud radiative forcing is about -20 W m^{-2} (Loeb et al., 2009) (see Section 7.2.1), i.e., clouds have a net cooling effect. Current GCMs simulate clouds through various complex parameterizations (see Section 7.2.3), and cloud feedback is a major source of the spread of the climate sensitivity estimate (Soden and Held, 2006; Randall et al., 2007; Dufresne and Bony, 2008) (see Section 9.7.2).

Under future projections the multi model pattern of total cloud amount shows consistent decreases in the subtropics, in conjunction with a decrease of the relative humidity there, and increases at high latitudes. Another robust pattern is an increase in cloud cover at all latitudes in the vicinity of the tropopause, a signature of the increase of the altitude of high level clouds in convective regions (Wetherald and Manabe, 1988; Meehl et al., 2007b; Soden and Vecchi, 2011; Zelinka et al., 2012). Low level clouds were identified as a primary cause of inter-model spread in cloud feedbacks in CMIP3 models (Bony and Dufresne, 2005; Webb et al., 2006; Wyant et al., 2006). Since AR4, these results have been confirmed along with the positive feedbacks due to high level clouds in the CMIP3 or CFMIP models (Zelinka and Hartmann, 2010; Soden and Vecchi, 2011; Webb et al., 2013) and CMIP5 models (Vial et al., 2013). Since AR4, the response of clouds has been partitioned in a direct or 'rapid' response of clouds to CO_2 and a 'slow' response of clouds to the surface temperature increase (i.e., the usual feedback response) (Gregory and Webb, 2008). The radiative effect of clouds mainly depends on their fraction, optical depth and temperature. The contribution of these variables to the cloud feedback has been quantified for the multi-model CMIP3 (Soden and Vecchi, 2011) and CFMIP1 database (Zelinka et al., 2012). These findings are consistent with the radiative changes

obtained with the CMIP5 models (Figure 12.17) and may be summarized as follows (see Section 7.2.5 for more details).

The dominant contributor to the SW cloud feedback is the change in cloud fraction. The reduction of cloud fraction between 50°S and 50°N, except along the equator and the eastern part of the ocean basins (Figure 12.17), contributes to an increase in the absorbed solar radiation (Figure 12.16c). Physical mechanisms and the role of different parameterizations have been proposed to explain this reduction of low level clouds (Zhang and Bretherton, 2008; Caldwell and Bretherton, 2009; Brient and Bony, 2013; Webb et al., 2013). Poleward of 50°S, the cloud fraction and the cloud optical depth increases, thereby increasing cloud reflectance. This leads to a decrease of solar absorption around Antarctica where the ocean is nearly ice free in summer (Figure 12.16c). However, there is *low confidence* in this result since GCMs do not reproduce the nearly 100% cloud cover observed there and the negative feedback could be overestimated (Trenberth and Fasullo, 2010) or, at the opposite, underestimated since the cloud optical depth simulated by models is biased high there (Zelinka et al., 2012).

In the LW domain, the tropical high cloud changes exert the dominant effect. A lifting of the cloud top with warming is simulated consistently across models (Meehl et al., 2007b) which leads to a positive feedback whereby the LW emissions from high clouds decrease as they cool (Figure 12.16b). The dominant driver of this effect is the increase of tropopause height and physical explanations have been proposed (Hartmann and Larson, 2002; Lorenz and DeWeaver, 2007; Zelinka and Hartmann, 2010). Although the decrease in cloudiness generally increases OLR and partly offsets the effect of cloud rising, the net effect is a consistent positive global-mean LW cloud feedback across CMIP and CFMIP models. Global-mean SW cloud feedbacks range from slightly negative to strongly positive (Soden and Vecchi, 2011; Zelinka et al., 2012), with an inter-model spread in net cloud feedback being mainly attributable to low-level cloud changes.

In summary, both the multi-model mean and the inter-model spread of the cloud fraction and radiative flux changes simulated by the CMIP5 models are consistent with those previously obtained by the CMIP3 models. These include decreases in cloud amount in the subtropics, increases at high latitudes and increases in the altitude of high level clouds in convective regions. Many of these changes have been understood primarily as responses to large-scale circulation changes (see Section 7.2.6).

[INSERT FIGURE 12.17 HERE]

Figure 12.17: CMIP5 multi-model changes in annual mean total cloud fraction (in %) relative to 1986–2005 for 2081–2100 under the RCP2.6 (left), RCP4.5 (centre) and RCP8.5 (right) forcing scenarios. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

12.4.4 Changes in Atmospheric Circulation

Projected changes in energy and water cycles couple with changes in atmospheric circulation and mass distribution. Understanding this coupling is necessary to assess physical behaviour underlying projected changes, particularly at regional scales, revealing why changes occur and the realism of the changes. The focus in this section is on atmospheric circulation behaviour that CMIP5 GCMs resolve well. Thus, the section includes discussion of extratropical cyclones but not tropical cyclones: extratropical cyclones are fairly well resolved by most CMIP5 GCMs, whereas tropical cyclones are not, requiring resolutions finer than used by the large majority of CMIP5 GCMs (see Section 9.5.4.3). Detailed discussion of tropical cyclones appears in Section 14.6.1 (see also Section 11.3.2.5.3 for near term changes and Section 3.4.4 in Seneviratne et al. (2012)). Regional detail concerning extratropical storm tracks, including causal processes, appears in Section 14.6.2 (see also Section 11.3.2.4 for near-term changes and Seneviratne et al. (2012) for an assessment of projected changes related to weather and climate extremes).

12.4.4.1 Mean Sea Level Pressure and Upper-Air Winds

Sea level pressure gives an indication of surface changes in atmospheric circulation (Figure 12.18). As in previous assessments, a robust feature of the pattern of change is a decrease in high latitudes and increases in the mid-latitudes, associated with poleward shifts in the Southern Hemisphere mid-latitude storm tracks

(Section 12.4.4.3) and positive trends in the annular modes (Section 14.5) as well as an expansion of the Hadley Cell (Section 12.4.4.2). Similar patterns of sea level pressure change are found in observed trends over recent decades, suggesting an already detectable change (Gillett and Stott, 2009; Section 10.3.3.4), although the observed patterns are influenced by both natural and anthropogenic forcing as well as internal variability and the relative importance of these influences is likely to change in the future. Internal variability has been found to play a large role in uncertainties of future sea level pressure projections, particularly at higher latitudes (Deser et al., 2012a).

In boreal winter, decreases of sea level pressure over NH high latitudes are slightly weaker in the CMIP5 ensemble compared to previous assessments, consistent with Scaife et al. (2012) and Karpechko and Manzini (2012) who suggest that improvements in the representation of the stratosphere can influence this pattern. In austral summer, the SH projections are impacted by the additional influence of stratospheric ozone recovery (see Section 11.3.2.4.2) which opposes changes due to greenhouse gases. Under the weaker GHG emissions of RCP2.6, decreases in sea level pressure over the SH mid-latitudes and increases over SH high latitudes are consistent with expected changes from ozone recovery (Arblaster et al., 2011; McLandress et al., 2011; Polvani et al., 2011). For all other RCPs, the magnitude of SH extratropical changes scales with the radiative forcing, as found in previous model ensembles (Paeth and Pollinger, 2010; Simpkins and Karpechko, 2012).

Large increases in seasonal sea level pressure are also found in regions of sub-tropical drying such as the Mediterranean and northern Africa in DJF and Australia in JJA. Projected changes in the tropics are less consistent across the models, however a decrease in the eastern equatorial Pacific and increase over the maritime continent, associated with a weakening of the Walker Circulation (Vecchi and Soden, 2007; Power and Kociuba, 2011b), is found in all RCPs.

[INSERT FIGURE 12.18 HERE]

Figure 12.18: CMIP5 multi model ensemble average of DJF (top row) and JJA (bottom row) mean sea level pressure change (2081–2100 minus 1986–2005) for, from left to right, RCP2.6, 4.5 and 8.5. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

Future changes in zonal and annual mean zonal winds (Figure 12.19) are seen throughout the atmosphere with stronger changes in higher RCPs. Large increases in winds are evident in the tropical stratosphere and a poleward shift and intensification of the SH tropospheric jet is seen under RCP4.5 and RCP8.5, associated with an increase in the SH upper tropospheric meridional temperature gradient (Figure 12.12) (Wilcox et al., 2012). In the NH, the response of the tropospheric jet is weaker and complicated by the additional thermal forcing of polar amplification (Woollings, 2008). Barnes and Polvani (2013) evaluate changes in the annual mean mid-latitude jets in the CMIP5 ensemble, finding consistent poleward shifts in both hemispheres under RCP8.5 for the end of the 21st century. In the NH, the poleward shift is $\sim 1^\circ$, similar to that found for the CMIP3 ensemble (Woollings and Blackburn, 2012). In the SH, the annual mean mid-latitude jet shifts poleward by $\sim 2^\circ$ under RCP8.5 at the end of the 21st century in the CMIP5 multi model mean (Barnes and Polvani, 2013), with a similar shift of 1.5° in the surface westerlies (Swart and Fyfe, 2012). A strengthening of the SH surface westerlies is also found under all RCPs except RCP2.6 (Swart and Fyfe, 2012), with largest changes in the Pacific basin (Bracegirdle et al., 2013). In austral summer, ozone recovery offsets changes in GHGs to some extent, with a weak reversal of the jet shift found in the multi model mean under the low emissions scenario of RCP2.6 (Swart and Fyfe, 2012) and weak or poleward shifts in other RCPs (Swart and Fyfe, 2012; Wilcox et al., 2012). Eyring et al. (2013) note the sensitivity of the CMIP5 SH summertime circulation changes to both the strength of the ozone recovery (simulated by some models interactively) and the rate of greenhouse gas increases.

While the poleward shift of the tropospheric jets are robust across models and *likely* under increased GHGs, the dynamical mechanisms behind these projections are still not completely understood and have been explored in both simple and complex models (Chen et al., 2008; Lim and Simmonds, 2009; Butler et al., 2010). The shifts are associated with a strengthening in the upper tropospheric meridional temperature gradient (Wilcox et al., 2012) and hypotheses for associated changes in planetary wave activity and/or synoptic eddy characteristics that impact on the position of the jet have been put forward (Gerber et al., 2012). Equatorward biases in the position of the SH jet (Section 9.5.3.2), while somewhat improved over

similar biases in the CMIP3 models (Kidston and Gerber, 2010) still remain, limiting our confidence in the magnitude of future changes.

In summary, significant poleward shifts in the SH extratropical tropospheric circulation are *likely* at the end of the 21st century under RCP8.5 with weaker or non-significant shifts under lower emission scenarios. Ozone recovery will *likely* weaken the GHG-induced changes in the SH extratropical circulation in austral summer.

[INSERT FIGURE 12.19]

Figure 12.19: CMIP5 multi model ensemble average of zonal and annual mean wind change (2081–2100 minus 1986–2005) for, from left to right, RCP2.6, 4.5 and 8.5. Black contours represent the multi model average for the 1986–2005 base period. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

12.4.4.2 Planetary-Scale Overturning Circulations

Large-scale atmospheric overturning circulations and their interaction with other atmospheric mechanisms are significant in determining tropical climate and regional changes in response to enhanced radiative forcing. Observed changes in tropical atmospheric circulation are assessed in Section 2.7.5, while Section 10.3.3 discusses attribution of these observed changes to anthropogenic forcing. Evidence is inconclusive on recent trends in the strength of the Hadley (Stachnik and Schumacher, 2011) and Walker circulations (Vecchi et al., 2006; Sohn and Park, 2010; Merrifield, 2011; Luo et al., 2012; Tokinaga et al., 2012), though there is *medium confidence* of an anthropogenic influence on the observed widening of the Hadley circulation (Hu and Fu, 2007; Johanson and Fu, 2009; Davis and Rosenlof, 2012). In the projections, there are indications of a weakening of tropical overturning of air as the climate warms (Held and Soden, 2006; Vecchi and Soden, 2007; Gastineau et al., 2008; Gastineau et al., 2009; Chou and Chen, 2010; Chadwick et al., 2012; Bony et al., 2013). In the SRES A1B scenario, CMIP3 models show a remarkable agreement in simulating a weakening of the tropical atmospheric overturning circulation (Vecchi and Soden, 2007). CMIP5 models also show a consistent weakening (Chadwick et al., 2012). Along the ascending branches of tropical overturning cells, a reduction in convective mass flux from the boundary layer to the free atmosphere is implied by the differential response to global warming of the boundary-layer moisture content and surface evaporation. This weakening of vertical motion along the ascending regions of both the tropical meridional and near-equatorial zonal cells is associated with an imbalance in the rate of atmospheric moisture increase and that of global mean precipitation (Held and Soden, 2006). A reduction in the compensating climatological subsidence along the downward branches of overturning circulations, where the rate of increase of static stability exceeds radiative cooling, is implied.

Several mechanisms have been suggested for the changes in the intensity of the tropical overturning circulation. The weakening of low-level convective mass flux along ascending regions of tropical overturning cells has been ascribed to changes in the hydrologic cycle (Held and Soden, 2006; Vecchi and Soden, 2007). Advection of dry air from subsidence regions towards the ascending branches of large-scale tropical circulation has been suggested to be a feasible mechanism weakening ascent along the edges of convection regions (Chou et al., 2009). A deepening of the tropical troposphere in response to global warming increases the vertical extent of convection, which has been shown to increase the atmosphere's moist stability and thus also weakening overturning cells (Chou and Chen, 2010). An imbalance between the increase in diabatic heating of the troposphere and in static stability whereby the latter increases more rapidly has also been thought to play a role in weakening tropical ascent (Lu et al., 2008). Mean advection of enhanced vertical stratification under greenhouse gas forcing which involves cooling of convective regions and warming of subsidence regions has been shown to slow down tropical cells (Ma et al., 2012). The latest findings using CMIP5 models reveal that an increase in greenhouse gases (particularly CO₂) contributes significantly to weakening tropical overturning cells by reducing radiative cooling in the upper atmosphere (Bony et al., 2013). SST gradients have also been found to play a role in altering the strength of tropical cells (Tokinaga et al., 2012; Ma and Xie, 2013). Evidence has been provided suggesting that the Southern Hemisphere Hadley cell may strengthen in response to meridional SST gradients featuring reduced warming in the Southern Hemisphere subtropical oceans relative to the Northern Hemisphere, particularly over the Pacific and Indian Oceans (Ma and Xie, 2013). The north-to-south SST warming gradients are a source of intermodel differences in their projections of changes in the Southern Hemisphere Hadley circulation.

Apart from changes in Hadley circulation strength, a robust feature in 21st century climate model simulations is an increase in the cell's depth and width (Mitas and Clement, 2006; Frierson et al., 2007; Lu et al., 2007; Lu et al., 2008), with the latter change translating to a broadening of tropical regions (Seidel and Randel, 2007; Seidel et al., 2008) and a poleward displacement of subtropical dry zones (Lu et al., 2007; Scheff and Frierson, 2012). The increase in the cell's depth is consistent with a tropical tropopause rise. The projected increase in the height of the tropical tropopause and the associated increase in meridional temperature gradients close to the tropopause slope have been proposed to be an important mechanism behind the Hadley cell expansion and the poleward displacement of the subtropical westerly jet (Lu et al., 2008; Johanson and Fu, 2009). An increase in subtropical and mid-latitude static stability has been found to be an important factor widening the Hadley cell by shifting baroclinic eddy activity and the associated eddy-driven jet and subsidence poleward (Mitas and Clement, 2006; Lu et al., 2008). The projected widening of the Hadley cell is consistent with late twentieth century observations, where $\sim 2^\circ$ - 5° latitude expansion was found (Fu et al., 2006; Johanson and Fu, 2009). The consistency of simulated changes in CMIP3 and CMIP5 models and the consistency of Hadley cell changes with the projected tropopause rise and increase in subtropical and midlatitude static stability indicate that a widening and weakening of the NH Hadley cell by the late 21st century is *likely*.

The zonally asymmetric Walker Circulation is projected to weaken under global warming (Power and Kociuba, 2011a; Power and Kociuba, 2011b), more than the Hadley circulation (Lu et al., 2007; Vecchi and Soden, 2007). The consistency of the projected Walker circulation slowdown from CMIP3 to CMIP5 suggests that its change is robust (Ma and Xie, 2013). Almost everywhere around the equatorial belt, changes in the 500 hPa vertical motion oppose the climatological background motion, notably over the maritime continent (Vecchi and Soden, 2007; Shongwe et al., 2011). Around the Indo-Pacific warm pool, in response to a spatially uniform SST warming, the climatological upper tropospheric divergence weakens (Ma and Xie, 2013). Changes in the strength of the Walker circulation also appear to be linked to differential warming between the Indian and Pacific Ocean warming at low latitudes (Luo et al., 2012). Over the equatorial Pacific Ocean, where mid-tropospheric ascent is projected to strengthen, changes in zonal SST and hence sea-level pressure gradients induce low-level westerly wind anomalies which act to weaken the low-level branch of the Pacific Walker circulation. These projected changes in the tropical Pacific circulation are already occurring (Zhang and Song, 2006). However, the projected weakening of the Pacific Walker cell does not imply an increase in the frequency and/or magnitude of El-Niño events (Collins et al., 2010). The consistency of simulated changes in CMIP3 and CMIP5 models and the consistency of Walker cell changes with equatorial SST and pressure-gradient changes that are already observed indicate that a weakening of the Walker cell by the late 21st century is *likely*.

In the upper atmosphere, a robust feature of projected stratospheric circulation change is that the Brewer-Dobson circulation will *likely* strengthen in the 21st century (Butchart et al., 2006; Li et al., 2008; McLandress and Shepherd, 2009; Butchart et al., 2010; Shepherd and McLandress, 2011). In a majority of model experiments, the projected changes in the large-scale overturning circulation in the stratosphere feature an intensification of tropical upward mass flux, which may extend to the upper stratosphere. The proposed driver of the increase in mass flux at the tropical lower stratosphere is the enhanced propagation of wave activity, mainly resolved planetary waves, associated with a positive trend in zonal wind structure (Butchart and Scaife, 2001; Garcia and Randel, 2008). In the 21st century, increases in wave excitation from diabatic heating in the upper tropical troposphere could reinforce the wave forcing on the tropical upwelling branch of the stratospheric mean meridional circulation (Calvo and Garcia, 2009). Parameterized orographic gravity waves which result from strengthening of subtropical westerly jets and cause more waves to propagate into the lower stratosphere also play a role (Sigmond et al., 2004; Butchart et al., 2006). The projected intensification in tropical upwelling is counteracted by enhanced mean extra-tropical/polar lower stratospheric subsidence. In the Northern Hemisphere high latitudes, the enhanced downwelling is associated with an increase in stationary planetary wave activities (McLandress and Shepherd, 2009). The intensification of the stratospheric meridional residual circulation has already been reported in studies focussing on the last decades of the 20th century (Garcia and Randel, 2008; Li et al., 2008; Young et al., 2012). The projected increase in troposphere-to-stratosphere mass exchange rate (Butchart et al., 2006) and stratospheric mixing associated with the strengthening of the Brewer-Dobson circulation will *likely* result in a decrease in the mean age of air in the lower stratosphere. In the mid-latitude lower stratosphere, quasi-horizontal mixing is a significant contributor to reducing the lifetimes of air. There are some suggestions that

the changes in stratospheric overturning circulation could lead to a reduction in tropical ozone concentrations and an increase at high latitudes (Jiang et al., 2007) and an increase in the amplitude of the annual cycle of stratospheric ozone (Randel et al., 2007).

12.4.4.3 Extratropical Storms: Tracks and Influences on Planetary-Scale Circulation and Transports

Since the AR4, there has been continued evaluation of changes in extratropical storm tracks under projected warming using both CMIP3 and, more recently, CMIP5 simulations, as well as supporting studies using single models or idealized simulations. CMIP3 analyses use a variety of methods for diagnosing storm tracks, but diagnosis of changes in the tracks appears to be relatively insensitive to methods used (Ulbrich et al., 2013). Analyses of Southern Hemisphere storm tracks generally agree with earlier studies, showing that extratropical storm tracks will tend to shift poleward (Bengtsson et al., 2009; Gastineau et al., 2009; Gastineau and Soden, 2009; Perrie et al., 2010; Schuenemann and Cassano, 2010; Chang et al., 2012b). The behaviour is consistent with a *likely* trend in observed storm-track behaviour (see Section 2.7.6). Similar behaviour appears in CMIP5 simulations for the Southern Hemisphere (Figure 12.20c,d). In Southern Hemisphere winter there is a clear poleward shift in storm tracks of several degrees and a reduction in storm frequency of only a few percent (not shown). The poleward shift at the end of the century is consistent with a poleward shift in the Southern Hemisphere of the latitudes with strongest tropospheric jets (Figure 12.19). This appears to coincide with shifts in baroclinic dynamics governing extratropical storms (Frederiksen et al., 2011), though the degree of jet shift appears to be sensitive to bias in a model's contemporary-climate storm tracks (Chang et al., 2012a; Chang et al., 2012b). Although there is thus some uncertainty in the degree of shift, the consistency of behaviour with observation-based trends, consistency between CMIP5 and CMIP3 projections under a variety of diagnostics and the physical consistency of the storm response with other climatic changes gives *high confidence* that a poleward shift of several degrees in Southern Hemisphere storm tracks is *likely* by the end of the 21st century under the RCP8.5 scenario.

In the Northern Hemisphere winter (Figure 12.20a,b), the CMIP5 multi-model ensemble shows an overall reduced frequency of storms and less indication of a poleward shift in the tracks. The clearest poleward shift in the Northern Hemisphere winter at the end of the 21st century occurs in the Asia-Pacific storm track, where intensification of the westerly jet promotes more intense cyclones in an ensemble of CMIP5 models (Mizuta, 2012). Otherwise, changes in winter storm-track magnitude, as measured by band-pass sea-level pressure fluctuations, show only small change relative to interannual and interdecadal variability by the end of the 21st century in SRES A1B and RCP4.5 simulations for several land areas over the Northern Hemisphere (Harvey et al., 2012). Consistency in CMIP3 and CMIP5 changes seen in the Southern Hemisphere are absent in the Northern Hemisphere (Chang et al., 2012a). Factors identified that affect changes in the North Atlantic basin's storm track include horizontal resolution (Colle et al., 2013) and how models simulate changes in the Atlantic's meridional overturning circulation (Catto et al., 2011; Woollings et al., 2012), the zonal jet and Hadley circulation (Mizuta, 2012; Zappa et al., 2013) and subtropical upper troposphere temperature (Haarsma et al., 2013). Substantial uncertainty and thus *low confidence* remains in projecting changes in Northern Hemisphere winter storm tracks, especially for the North Atlantic basin.

[INSERT FIGURE 12.20 HERE]

Figure 12:20: Change in winter, extratropical storm track density (2081–2100) – (1986–2005) in CMIP5 multi-model ensembles: (a) RCP4.5 Northern Hemisphere DJF and (b) RCP8.5 Northern Hemisphere DJF (c) RCP4.5 Southern Hemisphere JJA and (d) RCP8.5 Southern Hemisphere JJA. Storm-track computation uses the method of Bengtsson et al. (2006, their Figure 13a) applied to six-hourly 850 hPa vorticity computed from horizontal winds in the CMIP5 archive. The number of models used appears in the upper right of each panel. DJF panels include data for December 1985 and 2080 and exclude December 2005 and December 2100 for in-season continuity. Stippling marks locations where at least 90% of the models agree on the sign of the change; note that this criterion differs from that used for many other figures in this chapter, due to the small number of models providing sufficient data to estimate internal variability of twenty-year means of storm-track statistics. Densities have units (number density/month/unit area), where the unit area is equivalent to a 5° spherical cap (~10⁶ km²). Locations where the scenario or contemporary-climate ensemble average is below 0.5 density units are left white.

Additional analyses of CMIP3 GCMs have determined other changes in properties of extratropical storms. Most analyses find that the frequency of storms decreases in projected climates (Finnis et al., 2007; Favre and Gershunov, 2009; Dowdy et al., 2013), though the occurrence of strong storms may increase in some

regions (Pinto et al., 2007; Bengtsson et al., 2009; Ulbrich et al., 2009; Zappa et al., 2013). Many studies focus on behaviour of specific regions, and results of these studies are detailed in Section 14.6.2.

Changes in extratropical storms in turn may influence other large-scale climatic changes. Kug et al. (2010) in a set of time-slice simulations show that a poleward shift of storm tracks in the Northern Hemisphere could enhance polar warming and moistening. The Arctic Oscillation is sensitive to synoptic eddy vorticity flux, so that projected changes in storm tracks can alter the Arctic Oscillation (Choi et al., 2010). The net result is that changes in extratropical storms alter the climate in which they are embedded, so that links between surface warming, extratropical storms and their influence on climate are more complex than simple responses to changes in baroclinicity (O’Gorman, 2010).

12.4.5 Changes in the Water Cycle

The water cycle consists of water stored on the Earth in all its phases, along with the movement of water through the Earth’s climate system. In the atmosphere, water occurs primarily as gaseous water vapour, but it also occurs as solid ice and liquid water in clouds. The ocean is primarily liquid water, but is partly covered by ice in polar regions. Terrestrial water in liquid form appears as surface water (lakes, rivers), soil moisture and groundwater. Solid terrestrial water occurs in ice sheets, glaciers, frozen lakes, snow and ice on the surface and permafrost. Projections of future changes in the water cycle are inextricably connected to changes in the energy cycle (Section 12.4.3) and atmospheric circulation (Section 12.4.4).

Saturation vapour pressure increases with temperature, but projected future changes in the water cycle are far more complex than projected temperature changes. Some regions of the world will be subject to decreases in hydrologic activity while others will be subject to increases. There are important local seasonal differences among the responses of the water cycle to climate change as well.

At first sight, the water cycles simulated by CMIP3/5 models may appear to be inconsistent, particularly at regional scales. Anthropogenic changes to the water cycle are superimposed on complex naturally varying modes of the climate (such as ENSO, AO, PDO, etc.) aggravating the differences between model projections. However, by careful consideration of the interaction of the water cycle with changes in other aspects of the climate system, the mechanisms of change are revealed, increasing confidence in projections.

12.4.5.1 Atmospheric Humidity

Atmospheric water vapour is the primary greenhouse gas in the atmosphere. Its changes affect all parts of the water cycle. However, the amount of water vapour is dominated by naturally occurring processes and not significantly affected directly by human activities. A common experience from past modelling studies is that relative humidity (RH) remains approximately constant on climatological time scales and planetary space scales, implying a strong constraint by the Clausius-Clapeyron relationship on how specific humidity will change. The AR4 stated that “a broad-scale, quasi-unchanged RH response [to climate change] is uncontroversial” (Randall et al., 2007). However, underlying this fairly straight-forward behaviour are changes in RH that can influence changes in cloud cover and atmospheric convection (Sherwood, 2010). More recent analysis provides further detail and insight on RH changes. Analysis of CMIP3 and CMIP5 models shows near-surface RH decreasing over most land areas as temperatures increase with the notable exception of parts of tropical Africa (O’Gorman and Muller, 2010) (Figure 12.21). The prime contributor to these decreases in RH over land is the larger temperature increases over land than over ocean in the RCP scenarios (Joshi et al., 2008; Fasullo, 2010; O’Gorman and Muller, 2010). The specific humidity of air originating over more slowly warming oceans will be governed by saturation temperatures of oceanic air. As this air moves over land and is warmed, its relative humidity drops as any further moistening of the air over land is insufficient to maintain constant RH, a behaviour (Sherwood et al., 2010) term a last-saturation-temperature constraint. The RH decrease over most land areas by the end of the 21st century is consistent with a last-saturation-temperature constraint and with observed behaviour during the first decade of the current century (Section 2.5.5; Simmons et al., 2010). Land-ocean differences in warming are projected to continue through the 21st century, and although the CMIP5 projected changes are small, they are consistent with a last-saturation constraint, indicating with *medium confidence* that reductions in near-surface RH over many land areas are *likely*.

[INSERT FIGURE 12.21]

Figure 12.21: Projected changes in near-surface relative humidity from the CMIP5 models under RCP8.5 for the DJF (left), JJA (middle) and annual mean (ANN, right) averages relative to 1986–2005 for the periods 2046–2065 (top row), 2081–2100 (bottom row). The changes are differences in relative humidity percentage (as opposed to a fractional or relative change). Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

12.4.5.2 Patterns of Projected Average Precipitation Changes

Global mean precipitation changes have been presented in Section 12.4.1.1. The processes that govern large-scale changes in precipitation are presented in Section 7.6, and are used here to interpret the projected changes in RCP scenarios. Changes in precipitation extremes are presented in Section 12.4.5.5. Further discussion of regional changes, in particular the monsoon systems, is presented in Chapter 14.

Figure 12.22 shows the CMIP5 multi-model average percentage change in seasonal-mean precipitation in the middle of the 21st century, at the end of the 21st century and at the end of the 22nd century for the RCP8.5 scenario relative to the 1986–2005 average. Precipitation changes for all the scenarios are shown in Annex I Supplementary Material and scale approximately with the global mean temperature (Section 12.4.2). In many regions, changes in precipitation exhibit strong seasonal characteristics so that, in regions where the sign of the precipitation changes varies with the season, the annual mean values (Figure 12.10) may hide some of these seasonal changes, resulting in weaker confidence than seasonal mean values (Chou et al., 2013; Huang et al., 2013).

The patterns of multi-model precipitation changes displayed in Figure 12.22 tend to smooth and decrease the spatial contrast of precipitation changes simulated by each model, in particular over regions where model results disagree. Thus the amplitude of the multi-model ensemble mean precipitation response significantly underestimates the median amplitude computed from each individual model (Neelin et al., 2006; Knutti et al., 2010a). The CMIP3/5 multi-model ensemble precipitation projections must be interpreted in the context of uncertainty. Multi-model projections are not probabilistic statements about the likelihood of changes. Maps of multi-model projected changes are smoothly varying but observed changes are and will continue to be much more granular.

To analyze the patterns of projected precipitation changes, a useful framework consists in decomposing them into a part which is related to atmospheric circulation changes and a part which is related mostly to water vapour changes, referred to as dynamical and thermodynamical components, respectively. However, the definition of these two components may differ among studies. At the time of the AR4, the robust changes of the difference between precipitation and evaporation (P-E) were interpreted as a wet-get-wetter and dry-get-drier type of response (Mitchell et al., 1987; Chou and Neelin, 2004; Held and Soden, 2006). The theoretical background, which is more relevant over oceans than over land, is that the lower-tropospheric water vapour increase with temperature enhances the moisture transported by the circulation. This leads to additional moisture convergence within the convergence zones and to additional moisture divergence in the descent zones, increasing the contrast in precipitation minus evaporation values between moisture convergence and divergence regions. A weakening of the tropical overturning circulation (see Section 12.4.4.2) partially opposes this thermodynamic response (Chou and Neelin, 2004; Held and Soden, 2006; Vecchi and Soden, 2007; Chou et al., 2009; Seager et al., 2010; Allan, 2012; Bony et al., 2013). At the regional scale the dynamic response may be larger than the thermodynamic response, and this has been analyzed in more detail since the AR4 (Chou et al., 2009; Seager et al., 2010; Xie et al., 2010; Muller and O’Gorman, 2011; Chadwick et al., 2012; Scheff and Frierson, 2012; Bony et al., 2013; Ma and Xie, 2013). Over continents, this simple wet-get-wetter and dry-get-drier type of response fails for some important regions such as the Amazon. At the global scale, the net water vapour transport from oceans to land increases, and therefore the average P-E over continents also increases (Liepert and Previdi, 2012).

In the mid and high latitudes, a common feature across generations of climate models is a simulated increased precipitation. The thermodynamical component explains most of the projected increase (Emori and Brown, 2005; Seager et al., 2010). This is consistent with theoretical explanations assuming fixed atmospheric flow patterns but increased water vapor in the lower troposphere (Held and Soden, 2006). In addition to this thermodynamical effect, water transport may be modified by the poleward shift of the storm

tracks and by the increase of their intensity (Seager et al., 2010; Wu et al., 2011b), although confidence in such changes in storm tracks may not be high (see Section 12.4.4). On seasonal time scales, the minimum and maximum values of precipitation both increase, with a larger increase of the maximum and therefore an increase of the annual precipitation range (Seager et al., 2010; Chou and Lan, 2012). In particular, the largest changes over northern Eurasia and North America are projected to occur during winter. At high latitudes of the Northern Hemisphere, the precipitation increase may lead to an increase of snowfall in the colder regions and a decrease of snowfall in the warmer regions due to the decreased number of freezing days (see Section 12.4.6.2).

Most models simulate a large increase of the annual mean precipitation over the equatorial ocean and an equatorward shift of the ITCZ, in both summer and winter seasons, that are mainly explained by atmospheric circulation changes (Chou et al., 2009; Seager et al., 2010; Sobel and Camargo, 2011). The changes of the atmospheric circulation have different origins. Along the margins of the convection zones, spatial inhomogeneities, including local convergence feedback or the rate at which air masses from dry regions tend to flow into the convection zone, can yield a considerable sensitivity in precipitation response (Chou et al., 2006; Neelin et al., 2006). Along the equator, atmosphere-ocean interactions yield to a maximum of SST warming and a large precipitation increase there (Xie et al., 2010; Ma and Xie, 2013). Model studies with idealized configurations suggest that tropical precipitation changes should be interpreted as responses to changes of the atmospheric energy budget rather than responses to changes of SST (Kang and Held, 2012). All of these atmospheric circulation changes, and therefore precipitation changes, can differ considerably from model to model. This is the case over both ocean and land. For instance, the spread of model projections in the Sahel region, West Africa, is large in both the CMIP3 and CMIP5 multi-model data base (Roehrig et al., 2013).

In the subtropical dry regions, there is a robust decrease of P-E that is accounted for by the thermodynamic contribution (Chou and Neelin, 2004; Held and Soden, 2006; Chou et al., 2009; Seager et al., 2010; Bony et al., 2013). Over ocean, the spatial heterogeneity of temperature increase impacts the lower-tropospheric water vapor increase, which impacts both the thermodynamic and the dynamic responses (Xie et al., 2010; Ma and Xie, 2013). In addition, the pattern of precipitation changes in dry regions may be different from that of P-E because the contribution of evaporation changes can be as large (but of opposite sign) as the moisture transport changes (Chou and Lan, 2012; Scheff and Frierson, 2012; Bony et al., 2013). This is especially the case over the subsidence regions during the warm season over land where the agreement between models is the smallest (Chou et al., 2009; Allan, 2012). A robust feature is the decline of precipitation on the poleward flanks of the subtropical dry zones as a consequence of the Hadley cell expansion, with possible additional decrease from a poleward shift of the mid latitude storm tracks (Seager et al., 2010; Scheff and Frierson, 2012). On seasonal time scales, the minimum and the maximum values of precipitation both increase, with a larger increase of the maximum and therefore an increase of the annual precipitation range (Sobel and Camargo, 2011; Chou and Lan, 2012).

Long term precipitation changes are mainly driven by the increase of the surface temperature, as presented above, but other factors also contribute to them. Recent studies suggest that CO₂ increase has a significant direct influence on atmospheric circulation, and therefore on global and tropical precipitation changes (Andrews et al., 2010; Bala et al., 2010; Cao et al., 2012; Bony et al., 2013). Over the ocean, the positive radiative forcing from increased atmospheric CO₂ reduces the radiative cooling of the troposphere and the large scale rising motion and hence reduces precipitation in the convective regions. Over large landmasses, the direct effect of CO₂ on precipitation is the opposite owing to the small thermal inertia of land surfaces (Andrews et al., 2010; Bala et al., 2010; Cao et al., 2012; Bony et al., 2013). Regional precipitation changes are also influenced by aerosol and ozone (Ramanathan et al., 2001; Allen et al., 2012; Shindell et al., 2013a) through both local and large scale processes, including changes in the circulation. Stratospheric ozone depletion contributes to the poleward expansion of the Hadley cell and the related change of precipitation in the Southern Hemisphere (Kang et al., 2011) whereas black carbon and tropospheric ozone increases are major contributors in the Northern Hemisphere (Allen et al., 2012). Regional precipitation changes depend on regional forcings and on how models simulate their local and remote effects. Based on CMIP3 results, the inter-model spread of the estimate of precipitation changes over land is larger than the inter-scenario spread except in East Asia (Frieler et al., 2012).

Projected precipitation changes vary greatly between models, much more so than for temperature projections. Part of this variance is due to genuine differences between the models including their ability to replicate observed precipitation patterns (see Section 9.4.1.1). However, a large part of it is also the result of the small ensemble size from each model (Rowell, 2012). This is especially true for regions of small projected changes located between two regions: one experiencing significant increases while the other experiences significant decreases. Individual climate model realizations will differ in their projection of future precipitation changes in these regions simply due to their internal variability (Deser et al., 2012b; Deser et al., 2012a). Multi-model projections containing large numbers of realizations would tend to feature small changes in these regions, and hatching in Figure 12.22 indicates regions where the projected multi-model mean change is less than one standard deviation of internal variability (method (a), Box 12.1). Confidence in projections in regions of limited or no change in precipitation may be more difficult to obtain than confidence in regions of large projected changes. However, Power et al. (2012) and Tebaldi et al. (2011) show that for some of the regions featuring small multi-model average projected changes, effective consensus in projections may be better than the metrics reported in AR4 would imply.

Since the AR4, progress has been made in the understanding of the processes that control large scale precipitation changes. There is *high confidence* that the contrast of seasonal mean precipitation between dry and wet regions will increase in a warmer climate over most of the globe although there may be regional exceptions to this general pattern. This response is particularly robust when considering P-E changes as a function of atmospheric dynamical regimes. However it is important to note that significant exceptions can occur in specific regions especially along the equator and on the poleward edges of the subtropical dry zone. In these regions, atmospheric circulation changes lead to shifts of the precipitation patterns. There is *high confidence* that the contrast between wet and dry seasons will increase over most of the globe as temperatures increase. Over the mid and high latitude regions, projected precipitation increases in winter are larger than in summer. Over most of the subtropical oceans, projected precipitation increases in summer are larger than in winter.

The changes in precipitation shown in Figure 12.22 exhibit patterns that become more pronounced and confidence in them increases as temperatures increase. More generally, the spatial and temporal changes in precipitation between two scenarios or within two periods of a given scenario exhibit the pattern scaling behavior and limitations described in Section 12.4.2. The patterns and the associated multi-model spreads in CMIP5 for the RCP scenarios are very similar to those in CMIP3 for the SRES scenarios discussed in the AR4, with the projections in CMIP5 being slightly more consistent over land than those from CMIP3 (Knutti and Sedláček, 2013). The largest percentage changes are at the high latitudes. By the end of this century, over the large northern land masses, increased precipitation is *likely* under the RCP8.5 scenario in the winter and spring poleward of 50N. The robustness across scenarios, the magnitude of the projected changes versus natural variability and physical explanations described above yield *high confidence* that the projected changes would be larger than natural twenty-year variations (see Box 12.1). In the tropics, precipitation changes exhibit strong regional contrasts, with increased precipitation over the equatorial Pacific and Indian oceans and decreases over much of the subtropical ocean. However, decreases are not projected to be larger than natural twenty-year variations anywhere until the end of this century under the RCP8.5 scenario. Decreased precipitation in the Mediterranean, Caribbean and Central America, southwestern United States and South Africa is *likely* under the RCP8.5 scenario and is projected with *medium confidence* to be larger than natural variations by the end of the next century in some seasons (Box 12.1). The CMIP3 models' historical simulations of zonal mean precipitation trends were shown to underestimate observed trends (Gillett et al., 2004; Lambert et al., 2005; Zhang et al., 2007; Liepert and Previdi, 2009) (see Section 10.3.2.2). Therefore it is *more likely than not* that the magnitude of the projected future changes in Figure 12.22 based on the multi model mean is underestimated. Observational uncertainties including limited global coverage and large natural variability, in addition to challenges in precipitation modeling, limit confidence in assessment of climatic changes in precipitation.

[INSERT FIGURE 12.22 HERE]

Figure 12.22: Multi-model CMIP5 average percentage change in seasonal mean precipitation relative to the reference period 1985–2005 averaged over the periods 2045–2065, 2081–2100 and 2181–2200 under the RCP8.5 forcing scenario. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

12.4.5.3 Soil Moisture

Near-surface soil moisture is the net result of a suite of complex processes (e.g., precipitation evapotranspiration, drainage, overland flow, infiltration), and heterogeneous and difficult-to-characterize aboveground and belowground system properties (e.g., slope, soil texture). As a result, regional to global-scale simulations of soil moisture and drought remain relatively uncertain (Burke and Brown, 2008; Henderson-Sellers et al., 2008). The AR4 (Section 8.2.3.2) discussed the lack of assessments of global-scale models in their ability to simulate soil moisture, and this problem appears to have persisted (Section 9.4.4.2). Furthermore, consistent multi-model projections of total soil moisture are difficult to make due to substantial differences between climate models in the depth of their soil. However, Koster et al. (2009a) argued that once climatological statistics affecting soil moisture were accounted for, different models tend to agree on soil moisture projections.

The AR4 summarized multi-model projections of 21st century annual mean soil moisture changes as decreasing in the subtropics and Mediterranean region, and increasing in east Africa and central Asia. Dai (2013) found similar changes in an ensemble of 11 CMIP5 GCMs under RCP4.5. Figure 12.23 shows projected changes in surface soil moisture (upper 10 cm) in the CMIP5 ensemble at the end of the 21st century under the RCPs 2.6, 4.5, 6.0 and 8.5. We focus on this new CMIP5 specification because it describes soil moisture at a consistent depth across all CMIP5 models. The broad patterns are moderately consistent across the RCPs, with the changes tending to become stronger as the strength of the forcing change increases. The agreement among CMIP5 models and the consistency with other physical features of climate change indicate *high confidence* in certain regions where surface soils are projected to dry. There is little-to-no confidence anywhere in projections of moister surface soils. Under RCP8.5, with the largest projected change, individual ensemble members (not shown) show consistency across the ensemble for drying in the Mediterranean region, northeast and southwest South America, southern Africa, and southwestern USA. However, ensemble members show disagreement on the sign of change in large regions such as central Asia or the high northern latitudes. The Mediterranean, southwestern USA, northeast South America and southern African drying regions are consistent with projected widening of the Hadley circulation that shifts downwelling, thus inhibiting precipitation in these regions. The large scale drying in the Mediterranean, southwest USA, and southern Africa appear across generations of projections and climate models and is deemed *likely* as global temperatures rise and will increase the risk of agricultural drought. Additionally, an analysis of CMIP3 and CMIP5 projections of soil moisture in five drought-prone regions indicates that the differences in future forcing scenarios are the largest source of uncertainty in such regions rather than differences between model responses (Orlowsky and Seneviratne, 2012).

Other recent assessments include multi-model ensemble approaches, dynamical downscaling, and regional climate models applied around the globe and illustrate the variety of issues influencing soil moisture changes. Analyses of the southwestern USA using CMIP3 models (Christensen and Lettenmaier, 2007; Seager et al., 2007) show consistent projections of drying, primarily due to a decrease in winter precipitation. In contrast, Kellomaki et al. (2010) find that SRES A2 projections for Finland yield decreased snow depth, but soil moisture generally increasing, consistent with the general increase in precipitation occurring in high northern latitudes. Kolomyts and Surova (2010), using projections from the CMIP3 models, GISS and HadCM2, under the SRES A2 forcing, show that vegetation type has substantial influence on the development of pronounced drying over the 21st century in Middle Volga Region forests.

Projected changes in soil moisture from the CMIP3/5 models also show substantial seasonal variation. For example, soil moisture changes in the North American midlatitudes, coupled with projected warming, increases the strength of land-atmosphere coupling during spring and summer in 15 GCMs under RCP8.5 (Dirmeyer et al., 2013). For the Cline River watershed in western Canada, Kienzle et al. (2012) find decreases in summer soil moisture content, but annual increases averaging 2.6% by the 2080s using a suite of CMIP3 GCMs simulating B1, A1B and A2 scenarios to drive a regional hydrology model. Hansen et al. (2007), using dynamical downscaling of one GCM running the A2 scenario, find summer soil moisture decreases in Mongolia of up to 6% due to increased potential evaporation in a warming climate and decreased precipitation and decreased precipitation.

Soil moisture projections in high latitude permafrost regions are critically important for assessing future climate feedbacks from trace-gas emissions (Zhuang et al., 2004; Riley et al., 2011) and vegetation changes (Chapin et al., 2005). In addition to changes in precipitation, snow cover and evapotranspiration, future changes in high latitude soil moisture also will depend on permafrost degradation, thermokarst evolution, rapid changes in drainage (Smith et al., 2005), and changes in plant communities and their water demands. Current understanding of these interacting processes at scales relevant to climate is poor, so that full incorporation in current GCMs is lacking.

[INSERT FIGURE 12.23 HERE]

Figure 12.23: Change in annual mean soil moisture (mass of water in all phases in the uppermost 10 cm of the soil) (mm) relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

12.4.5.4 Runoff and Evaporation

In the AR4, 21st century model-projected runoff consistently showed decreases in southern Europe, the Middle East, and southwestern U.S. and increases in Southeast Asia, tropical East Africa, and at high northern latitudes. The same general features appear in the CMIP5 ensemble of GCMs for all four RCPs shown in Figure 12.24, with the areas of most robust change typically increasing with magnitude of forcing change. However, the robustness of runoff decreases in the southwestern USA is less in the CMIP5 models compared to the AR4. The large decreases in runoff in southern Europe and southern Africa are consistent with changes in the Hadley circulation and related precipitation decreases and warming-induced evapotranspiration increases. The high northern latitude runoff increases are *likely* under RCP8.5 and consistent with the projected precipitation increases (Figure 12.22). The consistency of changes across different generations of models and different forcing scenarios, together with the physical consistency of change indicates that decreases are also *likely* in runoff in southern Europe, the Middle East, and southern Africa in this scenario.

A number of reports since the AR4 have updated findings from CMIP3 models and analyzed a large set of mechanisms affecting runoff. Several studies have focused on the Colorado River basin in the United States (Christensen and Lettenmaier, 2007; McCabe and Wolock, 2007; Barnett and Pierce, 2008; Barnett et al., 2008) showing that runoff reductions that do happen under global warming occur through a combination of evapotranspiration increases and precipitation decreases, with the overall reduction in river flow exacerbated by human water demands on the basin's supply.

A number of CMIP3 analyses have examined trends and seasonal shifts in runoff. For example, Kienzle et al. (2012) studied climate change scenarios over the Cline River watershed in western Canada and projected (1) spring runoff and peak streamflow up to four weeks earlier than in 1961–1990; (2) significantly higher streamflow between October and June; and (3) lower streamflow between July and September. For the Mediterranean basin, an ensemble of regional climate models driven by several GCMs using the A1B scenario have a robust decrease in runoff emerging only after 2050 (Sanchez-Gomez et al., 2009).

[INSERT FIGURE 12.24 HERE]

Figure 12.24: Change in annual mean runoff (mm) relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

Annual mean surface evaporation in the models assessed in AR4 showed increases over most of the ocean and increases or decreases over land with largely the same pattern over land as increases and decreases in precipitation. Similar behaviour occurs in an ensemble of CMIP5 models (Figure 12.25). Evaporation increases over most of the ocean and land, with prominent areas of decrease over land occurring in southern Africa and northwestern Africa along the Mediterranean. The areas of decrease correspond to areas with reduced precipitation. There is some uncertainty about storm-track changes over Europe (see Sections 12.4.3

and 14.6.2). However, the consistency of the decreases across different generations of models and different forcing scenarios along with the physical basis for the precipitation decrease indicates that these decreases in annual mean evaporation are *likely* under RCP8.5, but with *medium confidence*. Annual mean evaporation increases over land in the northern high latitudes are consistent with the increase in precipitation and the overall warming that would increase potential evaporation. For the northern high latitudes, the physical consistency and the similar behaviour across multiple generations and forcing scenarios indicates that annual mean evaporation increases there are *likely*, with *high confidence*.

Evapotranspiration changes partly reflect changes in precipitation. However, some changes might come from altered biological processes. For example, increased atmospheric CO₂ promotes stomatal closure and reduced transpiration (Betts et al., 2007; Cruz et al., 2010) which can potentially yield increased runoff. There is potential for substantial feedback between vegetation changes and regional water cycles, though the impact of such feedback remains uncertain at this point due to limitations on modeling crop and other vegetation processes in GCMs (e.g., Newlands et al., 2012) and uncertainties in plant response, ecosystem shifts, and land management changes.

[INSERT FIGURE 12.25 HERE]

Figure 12.25: Change in annual mean evaporation (mm) relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

12.4.5.5 Extreme Events in the Water Cycle

In addition to the changes in the seasonal pattern of mean precipitation described above, the distribution of precipitation events is projected to undergo profound changes (Gutowski et al., 2007; Sun et al., 2007; Boberg et al., 2010). At daily to weekly scales, a shift to more intense individual storms and fewer weak storms is projected (Seneviratne et al., 2012). At seasonal or longer time scales, increased evapotranspiration over land can lead to more frequent and more intense periods of agricultural drought.

A general relationship between changes in total precipitation and extreme precipitation does not exist (Seneviratne et al., 2012). Two possible mechanisms controlling short-term extreme precipitation amounts are discussed at length in the literature and are similar to the thermodynamic and dynamical mechanisms detailed above for changes in average precipitation.

The first considers that extreme precipitation events occur when most of the available atmospheric water vapour rapidly precipitates out in a single storm. The maximum amount of water vapour in air (saturation) is determined by the Clausius-Clapeyron relationship. As air temperature increases, this saturated amount of water also increases (Allen and Ingram, 2002; Pall et al., 2007; Allan and Soden, 2008; Kendon et al., 2010). Kunkel et al. (2013) examined the CMIP5 model RCP4.5 and 8.5 projections for changes in maximum water vapour concentrations, a principal factor controlling the probable bound on maximum precipitation, concluding that maximum water vapour changes are comparable to mean water vapour changes but that the potential for changes in dynamical factors is less compelling. Such increases in atmospheric water vapour are expected to increase the intensity of individual precipitation events, but have less impact on their frequency. As a result projected increases in extreme precipitation may be more reliable than similar projections of changes in mean precipitation in some regions (Kendon et al., 2010).

A second mechanism for extreme precipitation put forth by O’Gorman and Schneider (2009a, 2009b) is that such events are controlled by anomalous horizontal moisture flux convergence and associated convective updrafts which would change in a more complicated fashion in a warmer world (Sugiyama et al., 2010). Emori and Brown (2005) showed that the thermodynamic mechanism dominated over the dynamical mechanism nearly everywhere outside the tropical warm pool. However, Utsumi et al. (2011) used gridded observed daily data to find that daily extreme precipitation monotonically increases with temperature only at high latitudes, with the opposite behaviour in the tropics and a mix in the midlatitudes. Li et al. (2011a) found that both mechanisms contribute to extreme precipitation in a high-resolution aquaplanet model with updrafts as the controlling element in the tropics and air temperature controlling the midlatitudes consistent with the results by Chou et al. (2012). Using a high resolution regional model, Berg et al. (2009) found a

seasonal dependence in Europe with the Clausius-Clapeyron relationship providing an upper limit to daily precipitation intensity in winter but water availability rather than storage capacity is the controlling factor in summer. Additionally, Lenderink and Van Meijgaard (2008) found that very short (sub-daily) extreme precipitation events increase at a rate twice the amount predicted by Clausius-Clapeyron scaling in a very high-resolution model over Europe suggesting that both mechanisms can interact jointly. Gastineau and Soden (2009) found in the CMIP3 models that the updrafts associated with the most extreme tropical precipitation events actually weaken despite an increase in the frequency of the heaviest rain rates further complicating simple mechanistic explanations. See also Sections 7.6.5 and 11.3.2.5.2.

Projections of changes in future extreme precipitation may be larger at the regional scales than for future mean precipitation, but natural variability is also larger causing a tendency for signal-to-noise ratios to decrease when considering increasingly extreme metrics. However, mechanisms of natural variability still are a large factor in assessing the robustness of projections (Kendon et al., 2008). In addition, large-scale circulation changes, which are uncertain, could dominate over the above mechanisms depending on the rarity and type of events considered. However, analysis of CMIP3 models suggests circulation changes are potentially insufficient to offset the influence of increasing atmospheric water vapour on extreme precipitation change over Europe at least on large spatial scales (Kendon et al., 2010). An additional shift of the storm track has been shown in models with a better representation of the stratosphere, and this is found to lead to an enhanced increase in extreme rainfall over Europe in winter (Scaife et al., 2012).

Similar to temperature extremes (Section 12.4.3.3), the definition of a precipitation extreme depends very much on context and is often used in discussion of particular climate-related impacts (Seneviratne et al. (2012), Box 3.1). Consistently, climate models project future episodes of more intense precipitation in the wet seasons for most of the land areas, especially in the Northern Hemisphere and its higher latitudes, and the monsoon regions of the world, and at a global average scale. The actual magnitude of the projected change is dependent on the model used, but there is strong agreement across the models over the direction of change (Tebaldi et al., 2006; Goubanova and Li, 2007; Chen and Knutson, 2008; Haugen and Iversen, 2008; May, 2008b; Kysely and Beranova, 2009; Min et al., 2011; Sillmann et al., 2013). Regional details are less robust in terms of the relative magnitude of changes but remain in good accord across models in terms of the sign of the change and the large-scale geographical patterns (Meehl et al., 2005a; CCSP, 2008a). In semi-arid regions of the midlatitudes and subtropics such as the Mediterranean, the southwest USA, south-western Australia, southern Africa and a large portion of South America, the tendency manifested in the majority of model simulations is for longer dry periods and is consistent with the average decreases shown in Figure 12.22. Figure 12.26 shows projected percent changes in RX5day, the annual maximum of consecutive five-day precipitation over land regions obtained from the CMIP5 models (Box 2.4, table 1). Globally averaged end of 21st century changes over land range from 5% (RCP2.6) to 20% (RCP8.5) more precipitation during very wet five-day periods. Results from the CMIP3 models are shown for comparison (see Section 12.4.9). Locally, the few regions where this index of extreme precipitation decreases in the late 21st century RCP8.5 projection coincide with areas of robust decreases in the mean precipitation of Figure 12.22.

Drought is discussed extensively in the SREX report (Seneviratne et al., 2012) and the conclusions about future drought risk described there based on CMIP3 models are reinforced by the CMIP5 models. As noted in the SREX reports, assessments of changes in drought characteristics with climate change should be made in the context of specific impacts questions. The risk of future agricultural drought episodes is increased in the regions of robust soil moisture decrease described in Section 12.4.5.3 and shown in Figure 12.23. Other measures in the literature of future agricultural drought are largely focused on the Palmer Drought Severity Index (Wehner et al., 2011; Schwalm et al., 2012; Dai, 2013) and project “extreme” drought as the normal climatological state by the end of the 21st century under the high emission scenarios in many mid-latitude locations. However, this measure of agricultural drought has been criticized as overly sensitive to increased temperatures due to a simplified soil moisture model (Hoerling et al., 2012). The consecutive dry-day index (CDD) is the length of the longest period of consecutive days with precipitation less than 1mm (Box 2.4, table 1). CMIP5 projected changes in CDD over the 2081–2100 period under the RCP8.5 scenario (relative to the 1981–2000 reference period in common with CMIP3) from the CMIP5 models are shown in Figure 12.26c and exhibit patterns similar to projected changes in both precipitation and soil moisture (Sillmann et al., 2013). Substantial increases in this measure of meteorological drought are projected in the Mediterranean, Central America, Brazil, South Africa and Australia while decreases are projected in high Northern latitudes.

[INSERT FIGURE 12.26 HERE]

Figure 12.26: a and b) Projected percent changes (relative to the 1981–2000 reference period in common with CMIP3) from the CMIP5 models in RX5day, the annual maximum five-day precipitation accumulation a) Global average percent change over land regions for the RCP2.6, 4.5 and 8.5 scenarios. Shading in the time series represents the interquartile ensemble spread (25th and 75th quantiles). The box-and-whisker plots show the interquartile ensemble spread (box) and outliers (whiskers) for 11 CMIP3 model simulations of the SRES scenarios A2 (orange), A1B (cyan), and B1 (purple) globally averaged over the respective future time periods (2046–2065 and 2081–2100) as anomalies from the 1981–2000 reference period. b) Percent change over the 2081–2100 period in the RCP8.5 scenario. c) Projected change in annual CDD, the maximum number of consecutive dry days when precipitation is less than 1 mm, over the 2081–2100 period in the RCP8.5 scenario (relative to the 1981–2000 reference period) from the CMIP5 models. Stippling indicates gridpoints with changes that are significant at the 5% level using a Wilcoxon signed-ranked test. Updated from Sillmann et al. (2013), excluding the FGOALS-s2 model.

Truly rare precipitation events can cause very significant impacts. The statistics of these events at the tails of the precipitation distribution are well described by Extreme Value (EV) Theory although there are significant biases in the direct comparison of gridded model output and actual station data (Smith et al., 2009). There is also strong evidence that model resolution plays a key role in replicating EV quantities estimated from gridded observational data, suggesting that high-resolution models may provide somewhat more confidence in projection of changes in rare precipitation events (Fowler et al., 2007a; Wehner et al., 2011). Figure 12.27 shows the late 21st century changes per °C in local warming in twenty-year return values of annual maximum daily precipitation relative to the late 20th century (left) and the associated return periods of late 20th century twenty year return values at the end of the 21st century from the CMIP5 models. Across future emission scenarios, the global average of the CMIP5 multi-model median return value sensitivity is an increase of 5.3% per °C (Kharin et al., 2013). The CMIP5 land average is close to the CMIP3 value of 4% per °C reported by Min et al. (2011) for a subset of CMIP3 models. Corresponding with this change, the global average of return periods of late 20th century twenty-year return values is reduced from 20 years to 14 years for a 1°C local warming. Return periods are projected to be reduced by about 10–20% per °C over the most of the mid-latitude land masses with larger reductions over wet tropical regions (Kharin et al., 2013). Hence, extreme precipitation events will very likely be more intense and more frequent in these regions in a warmer climate. Reductions in return values (or equivalently, increases in return period) are confined to convergent oceanic regions where circulation changes have reduced the available water vapour.

[INSERT FIGURE 12.27 HERE]

Figure 12.27: Left: The average 2081–2100 CMIP5 multi-model ensemble median percent change in twenty year return values of annual maximum daily precipitation per 1°C of local warming relative to the 1986–2005 reference period. Right: The average 2081–2100 CMIP5 multi-model ensemble median of the return periods (years) of 1986–2005 twenty year return values of annual maximum daily precipitation corresponding to 1°C of local warming. Regions of no change would have return periods of twenty years.

Severe thunderstorms, associated with large hail, high winds, and tornadoes, are another example of extreme weather associated with the water cycle. The large-scale environments in which they occur are characterized by large Convective Available Potential Energy (CAPE) and deep tropospheric wind shear (Brooks et al., 2003; Brooks, 2009). Del Genio et al. (2007), Trapp et al. (2007; 2009), and Van Klooster and Roebber (2009) found a general increase in the energy and decrease in the shear terms from the late 20th century to the late 21st century over the United States using a variety of regional model simulations embedded in global-model SRES scenario simulations. The relative change between these two competing factors would tend to favour more environments that would support severe thunderstorms, providing storms are initiated. Trapp et al. (2009), for example, found an increase in favourable thunderstorm conditions for all regions of the United States east of the Rocky Mountains. Large variability in both the energy and shear terms means that statistical significance is not reached until late in the 21st century under high forcing scenarios. One way of assessing the possibility of a change in frequency of future thunderstorms is to look at historical records of observed tornado, hail, and wind occurrence with respect to the environmental conditions (Brooks, 2013). This indicates that an increase in the fraction of severe thunderstorms containing non-tornadic winds would be consistent with the model projections of increased energy and decreased shear, but there has not been enough research to make a firm conclusion regarding future changes in frequency or magnitude.

Less work has been done on projected changes outside of the United States. Marsh et al. (2009) found that mean energy decreased in the warm season in Europe while it increased in the cool season. Even though the

energy decreases in the warm season, the number of days with favourable environments for severe thunderstorms increases because of an increasing number of days with relatively large values of available energy. For Europe, with the Mediterranean Sea and Sahara Desert to the south, questions remain about changes in boundary layer moisture, a main driver of the energy term. Niall and Walsh (2005) examined changes in CAPE, which may be associated with hailstorm occurrence in southeastern Australia using a global model, and found little change under warmer conditions. Leslie et al. (2008) reconsidered the southeastern Australia hail question by nesting models with 1 km horizontal grid spacing and using sophisticated microphysical parameterizations and found an increase in the frequency of large hail by 2050 under the SRES A1B scenario, but with extremely large internal variability in the environments and hail size.

Overall, for all parts of the world studied, the results are suggestive of a trend toward environments favouring more severe thunderstorms, but the small number of analyses precludes any likelihood estimate of this change.

12.4.6 Changes in Cryosphere

12.4.6.1 Changes in Sea Ice Cover

Based on the analysis of CMIP3 climate change simulations (e.g., Arzel et al., 2006; Zhang and Walsh, 2006), the AR4 concludes that the Arctic and Antarctic sea ice covers are projected to shrink in the 21st century under all SRES scenarios, with a large range of model responses (Meehl et al., 2007b). It also stresses that, in some projections, the Arctic Ocean becomes almost entirely ice-free in late summer during the second half of the 21st century. These conclusions were confirmed by further analyses of the CMIP3 archives (e.g., Stroeve et al., 2007; Bracegirdle et al., 2008; Lefebvre and Goosse, 2008; Boé et al., 2009b; Sen Gupta et al., 2009; Wang and Overland, 2009; Zhang, 2010b; NRC, 2011; Körper et al., 2013). Figures 12.28 and 12.29 and the studies of Maksym et al. (2012), Massonnet et al. (2012), Stroeve et al. (2012) and Wang and Overland (2012) show that the CMIP5 AOGCMs/ESMs as a group also project decreases in sea ice extent through the end of this century in both hemispheres under all RCPs. However, as in the case of CMIP3, the inter-model spread is considerable.

[INSERT FIGURE 12.28 HERE]

Figure 12.28: Changes in sea ice extent as simulated by CMIP5 models over the second half of the 20th century and the whole 21st century under RCP2.6, RCP4.5, RCP6.0 and RCP8.5 for (a) Northern Hemisphere February, (b) Northern Hemisphere September, (c) Southern Hemisphere February and (d) Southern Hemisphere September. The solid curves show the multi-model means and the shading denotes the 5–95% range of the ensemble. The vertical line marks the end of CMIP5 historical climate change simulations. One ensemble member per model is taken into account in the analysis. Sea ice extent is defined as the total ocean area where sea ice concentration exceeds 15% and is calculated on the original model grids. Changes are relative to the reference period 1986–2005. The number of models available for each RCP is given in the legend. Also plotted (solid green curves) are the satellite data of Comiso and Nishio (2008, updated 2012) over 1979–2012.

[INSERT FIGURE 12.29 HERE]

Figure 12.29: February and September CMIP5 multi-model mean sea ice concentrations (%) in the Northern and Southern Hemispheres for the periods (a) 1986–2005, (b) 2081–2100 under RCP4.5 and (c) 2081–2100 under RCP8.5. The model sea ice concentrations are interpolated onto a $1^\circ \times 1^\circ$ regular grid. One ensemble member per model is taken into account in the analysis, and the multi-model mean sea ice concentration is shown where it is larger than 15%. The number of models available for each RCP is given in parentheses. The pink lines indicate the observed 15% sea ice concentration limits averaged over 1986–2005 (Comiso and Nishio, 2008, updated 2012).

In the Northern Hemisphere, in accordance with CMIP3 results, the absolute rate of decrease of the CMIP5 multi-model mean sea ice areal coverage is greatest in September. The reduction in sea ice extent between the time periods 1986–2005 and 2081–2100 for the CMIP5 multi-model average ranges from 8% for RCP2.6 to 34% for RCP8.5 in February and from 43% for RCP2.6 to 94% for RCP8.5 in September. *Medium confidence* is attached to these values as projections of sea ice extent decline in the real world due to errors in the simulation of present-day sea ice extent (mean and trends—see Section 9.4.3) and because of the large spread of model responses. About 90% of the available CMIP5 models reach nearly ice-free conditions (sea ice extent less than 1×10^6 km² for at least five years) during September in the Arctic before 2100 under RCP8.5 (about 45% under RCP4.5). By the end of the 21st century, the decrease in multi-model

mean sea ice volume ranges from 29% for RCP2.6 to 73% for RCP8.5 in February and from 54% for RCP2.6 to 96% for RCP8.5 in September. *Medium confidence* is attached to these values as projections of the real world sea ice volume. In February, these percentages are much higher than the corresponding ones for sea ice extent, which is indicative of a substantial sea ice thinning.

A frequent criticism of the CMIP3 models is that, as a group, they strongly underestimate the rapid decline in summer Arctic sea ice extent observed during the past few decades (e.g., Stroeve et al., 2007; Winton, 2011), which suggests that the CMIP3 projections of summer Arctic sea ice areal coverage might be too conservative. As shown in Section 9.4.3 and Figure 12.28b, the magnitude of the CMIP5 multi-model mean trend in September Arctic sea ice extent over the satellite era is more consistent with, but still underestimates, the observed one (see also Massonnet et al., 2012; Stroeve et al., 2012; Wang and Overland, 2012; Overland and Wang, 2013). Due to the shortness of the observational record, it is difficult to ascertain the relative influence of natural variability on this trend. This hinders the comparison between modelled and observed trends, and hence the estimate of the sensitivity of the September Arctic sea ice extent to global surface temperature change (i.e., the decrease in sea ice extent per degree global warming) (Kay et al., 2011; Winton, 2011; Mahlstein and Knutti, 2012). This sensitivity may be crucial for determining future sea ice losses. Indeed, a clear relationship exists at longer than decadal time scales in climate change simulations between the annual mean or September mean Arctic sea ice extent and the annual mean global surface temperature change for ice extents larger than $\sim 1 \times 10^6 \text{ km}^2$ (e.g., Ridley et al., 2007; Zhang, 2010b; NRC, 2011; Winton, 2011; Mahlstein and Knutti, 2012). This relationship is illustrated in Figure 12.30 for both CMIP3 and CMIP5 models. From this figure, it can be seen that the sea ice sensitivity varies significantly from model to model and is generally larger and in better agreement among models in CMIP5.

[INSERT FIGURE 12.30 HERE]

Figure 12.30: September Arctic sea ice extent as a function of the annual mean global surface warming relative to the period 1986–2005 for (a) CMIP3 models (all SRES scenarios) and (b) CMIP5 models (all RCPs). The ice extents and global temperatures are computed on a common latitude-longitude grid for CMIP3 and on the original model grids for CMIP5. One ensemble member per model is taken into account in the analysis. A 21-year running mean is applied to the model output. The full black circle and vertical bar on the left-hand side of the y-axis indicate the mean and ± 2 standard deviations about the mean of the observed September Arctic sea ice extent over 1986–2005, respectively (Comiso and Nishio, 2008, updated 2012). The horizontal line corresponds to a nearly ice-free Arctic Ocean in September.

A complete and detailed explanation for what controls the range of Arctic sea ice responses in models over the 21st century remains elusive, but the Arctic sea ice provides an example where process-based constraints can be used to reduce the spread of model projections (Overland et al., 2011; Collins et al., 2012; Hodson et al., 2012). For CMIP3 models, results indicate that the changes in Arctic sea ice mass budget over the 21st century are related to the late 20th century mean sea ice thickness distribution (Holland et al., 2010), average sea ice thickness (Bitz, 2008; Hodson et al., 2012), fraction of thin ice cover (Boé et al., 2009b) and oceanic heat transport to the Arctic (Mahlstein and Knutti, 2011). For CMIP5 models, Massonnet et al. (2012) showed that the time needed for the September Arctic sea ice areal coverage to drop below a certain threshold is highly correlated with the September sea ice extent and annual mean sea ice volume averaged over the past several decades (Figure 12.31a,b). The timing of a seasonally ice-free Arctic Ocean or the fraction of remaining sea ice in September at any time during the 21st century were also found to be correlated with the past trend in September Arctic sea ice extent and the amplitude of the mean seasonal cycle of sea ice extent (Boé et al., 2009b; Collins et al., 2012; Massonnet et al., 2012) (Figure 12.31c,d). All these empirical relationships can be understood on simple physical grounds (see the aforementioned references for details).

[INSERT FIGURE 12.31 HERE]

Figure 12.31: (a–d) First year during which the September Arctic sea ice extent falls below $1 \times 10^6 \text{ km}^2$ in CMIP5 climate projections (37 models, RCP8.5) as a function of (a) the September Arctic sea ice extent averaged over 1986–2005, (b) the annual mean Arctic sea ice volume averaged over 1986–2005, (c) the amplitude of the 1986–2005 mean seasonal cycle of Arctic sea ice extent and (d) the trend in September Arctic sea ice extent over 1979–2012. The sea ice diagnostics displayed are calculated on the original model grids. The correlations and one-tailed p -values are computed from the multi-member means for models with several ensemble members (coloured crosses), but the ensemble members of individual models are also depicted (coloured dots). The vertical solid and dashed lines show the corresponding observations or bias-adjusted PIOMAS (Pan-Arctic Ice-Ocean Modelling and Assimilation System) reanalysis data (a, c and d: Comiso and Nishio, 2008, updated 2012; b: Schweiger et al., 2011) and the $\pm 20\%$ interval

around these data, respectively. (e) Time series of September Arctic sea ice extent (5-year running mean) as simulated by all CMIP5 models and their ensemble members under RCP8.5 (thin curves). The thick, coloured curves correspond to a subset of five CMIP5 models selected on the basis of panels a–d following Massonnet et al. (2012) (see text for details). Note that each of these models only provides one ensemble member for RCP8.5.

These results lend support for weighting/recalibrating the models based on their present-day Arctic sea ice simulations. Today, the optimal approach for constraining sea ice projections from climate models is unclear, although one notes that these methods should have a credible underlying physical basis in order to increase confidence in their results (see Section 12.2). In addition, they should account for the potentially large imprint of natural variability on both observations and model simulations when these two sources of information are to be compared (see Section 9.8.3). This latter point is particularly critical if the past sea ice trend or sensitivity is used in performance metrics given the relatively short observational period (Kay et al., 2011; Overland et al., 2011; Mahlstein and Knutti, 2012; Massonnet et al., 2012; Stroeve et al., 2012). A number of studies have applied such metrics to the CMIP3 and CMIP5 models. Stroeve et al. (2007) and Stroeve et al. (2012) rejected several CMIP3 and CMIP5 models, respectively, on the basis of their simulated late 20th century mean September Arctic sea ice extent. Wang and Overland (2009) selected a subset of CMIP3 models (and Wang and Overland (2012) did the same for the CMIP5 models) based on their fidelity to the observed mean seasonal cycle of Arctic sea ice extent in the late 20th century and then scaled the chosen models to the recently observed September sea ice extent. Zhang (2010b) retained a number of CMIP3 models based on the regression between summer sea ice loss and Arctic surface temperature change. Boé et al. (2009b) and Mahlstein and Knutti (2012) did not perform a model selection but rather recalibrated the CMIP3 Arctic sea ice projections on available observations of September Arctic sea ice trend and sensitivity to global surface temperature change, respectively. Finally, Massonnet et al. (2012) selected a subset of CMIP5 models on the basis of the four relationships illustrated in Figure 12.31a–d.

These various methods all suggest a faster rate of summer Arctic sea ice decline than the multi-model mean. Although they individually provide a reduced range for the year of near disappearance of the September Arctic sea ice compared to the original CMIP3/CMIP5 multi-model ensemble, they lead to different timings (Overland and Wang, 2013). Consequently, the time interval obtained when combining all these studies remains wide: 2020–2100⁺ (2100⁺ = not before 2100) for the SRES A1B scenario and RCP4.5 (Stroeve et al., 2007; Boé et al., 2009b; Wang and Overland, 2009; Zhang, 2010b; Massonnet et al., 2012; Stroeve et al., 2012; Wang and Overland, 2012) and 2020–2060 for RCP8.5 (Massonnet et al., 2012; Wang and Overland, 2012). The method proposed by Massonnet et al. (2012) is applied here to the full set of models that provided the CMIP5 database with sea ice output. The natural variability of each of the four diagnostics shown in Figure 12.31a–d is first estimated by averaging over all available models with more than one ensemble member the diagnostic standard deviations derived from the model ensemble members. Then, for each model, a ± 2 standard deviation interval is constructed around the ensemble mean or single realization of the diagnostic considered. A model is retained if, for each diagnostic, either this interval overlaps a $\pm 20\%$ interval around the observed/reanalysed value of the diagnostic or at least one ensemble member from that model gives a value for the diagnostic that falls within $\pm 20\%$ of the observational/reanalysed data. The outcome is displayed in Figure 12.31e for RCP8.5. Among the five selected models (ACCESS1.0, ACCESS1.3, GFDL-CM3, IPSL-CM5A-MR, MPI-ESM-MR), four project a nearly ice-free Arctic Ocean in September before 2050 (2080) for RCP8.5 (RCP4.5), the earliest and latest years of near disappearance of the sea ice pack being ~ 2040 and ~ 2060 (~ 2040 and 2100⁺), respectively. It should be mentioned that Maslowski et al. (2012) projected that it would take only until ~ 2016 to reach a nearly ice-free Arctic Ocean in summer, based on a linear extrapolation into the future of the recent sea ice volume trend from a hindcast simulation conducted with a regional model of the Arctic sea ice–ocean system. However, such an extrapolation approach is problematic as it ignores the negative feedbacks that can occur when the sea ice cover becomes thin (e.g., Bitz and Roe, 2004; Notz, 2009) and neglects the effect of year-to-year or longer-term variability (Overland and Wang, 2013). Mahlstein and Knutti (2012) encompassed the dependence of sea ice projections on the forcing scenario by determining the annual mean global surface warming threshold for nearly ice-free conditions in September. Their best estimate of $\sim 2^\circ\text{C}$ above present derived from both CMIP3 models and observations is consistent with the 1.6–2.1 $^\circ\text{C}$ range (mean value: 1.9 $^\circ\text{C}$) obtained from the CMIP5 model subset shown in Figure 12.31e (see also Figure 12.30b). The reduction in September Arctic sea ice extent by the end of the 21st century, averaged over this subset of models, ranges from 56% for RCP2.6 to 100% for RCP8.5.

In light of all these results, it is *very likely* that the Arctic sea ice cover will continue to shrink and thin all year round during the 21st century as the annual mean global surface temperature rises. It is also *likely* that the Arctic Ocean will become nearly ice-free in September before the middle of the century for high greenhouse gas emissions such as those corresponding to RCP8.5 (*medium confidence*). The potential irreversibility of the Arctic sea ice loss and the possibility of an abrupt transition toward an ice-free Arctic Ocean are discussed in Section 12.5.5.7.

In the Southern Hemisphere, the decrease in sea ice extent between 1986–2005 and 2081–2100 projected by the CMIP5 models as a group varies from 16% for RCP2.6 to 67% for RCP8.5 in February and from 8% to 30% in September. In contrast with the Northern Hemisphere, the absolute rate of decline is greatest in wintertime. Eisenman et al. (2011) argue that this hemispheric asymmetry in the seasonality of sea ice loss is fundamentally related to the geometry of coastlines. For each forcing scenario, the relative changes in multi-model mean February and September Antarctic sea ice volumes by the end of the century are of the same order as the corresponding ones for sea ice extent. About 75% of the available CMIP5 models reach a nearly ice-free state in February within this century under RCP8.5 (about 60% under RCP4.5). For RCP8.5, only small portions of the Weddell and Ross Seas stay ice-covered in February during 2081–2100 in those models that do not project a seasonally ice-free Southern Ocean (see Figure 12.29c). Nonetheless, there is *low confidence* in these Antarctic sea ice projections because of the wide range of model responses and the inability of almost all of the models to reproduce the mean seasonal cycle, interannual variability and overall increase of the Antarctic sea ice areal coverage observed during the satellite era (see Section 9.4.3; Maksym et al., 2012; Turner et al., 2013; Zunz et al., 2013).

12.4.6.2 Changes in Snow Cover and Frozen Ground

Excluding ice sheets and glaciers, analyses of seasonal snow cover changes generally focus on the Northern Hemisphere, where the configuration of the continents on Earth induces a larger maximum seasonal snow cover extent (SCE) and a larger sensitivity of SCE to climate changes. Seasonal snow cover extent and snow water equivalent (SWE) respond to both temperature and precipitation. At the beginning and the end of the snow season, SCE decreases are closely linked to a shortening of the seasonal snow cover duration, while SWE is more sensitive to snowfall amount (Brown and Mote, 2009). Future widespread reductions of SCE, particularly in spring, are simulated by the CMIP3 models (Roesch, 2006; Brown and Mote, 2009) and confirmed by the CMIP5 ensemble (Brutel-Vuilmet et al., 2013). The Northern Hemisphere spring (March–April average) snow cover area changes are coherent in the CMIP5 models although there is considerable scatter. Relative to the 1986–2005 reference period, the CMIP5 models simulate a weak decrease of about $7 \pm 4\%$ (one sigma inter-model dispersion) for RCP2.6 during the last two decades of the 21st century, while SCE decreases of about $13 \pm 4\%$ are simulated for RCP4.5, $15 \pm 5\%$ for RCP6.0, and $24 \pm 7\%$ for RCP8.5 (Figure 12.32). There is *medium confidence* in these numbers because of the considerable inter-model scatter mentioned above and because snow processes in global climate models are strongly simplified.

Projections for the change in annual maximum SWE are more mixed. Warming decreases SWE both by reducing the fraction of precipitation that falls as snow and by increasing snowmelt, but projected increases in precipitation over much of the northern high latitudes during winter months act to increase snow amounts. Whether snow covering the ground will become thicker or thinner depends on the balance between these competing factors. Both in the CMIP3 (Räisänen, 2008) and in the CMIP5 models (Brutel-Vuilmet et al., 2013), annual maximum SWE tends to increase or only marginally decrease in the coldest regions, while annual maximum SWE decreases are strong closer to the southern limit of the seasonally snow-covered area.

It is thus very likely (*high confidence*) that by the end of the 21st century, Northern Hemisphere spring snow cover extent will be substantially lower than today if anthropogenic climate forcing is similar to the stronger scenarios considered here. Conversely, there is only *medium confidence* in the latitudinal pattern of annual maximum SWE changes (increase or little change in the coldest regions, stronger decrease further to the South) because annual maximum SWE is influenced by competing factors (earlier melt onset, higher solid precipitation rates in some regions).

[INSERT FIGURE 12.32 HERE]

Figure 12.32: Northern Hemisphere spring (March to April average) snow cover extent change (in %) in the CMIP5 ensemble, relative to the simulated extent for the 1986–2005 reference period. Thick lines mark the multi-model

average, shading indicates the inter-model spread (one standard deviation). The observed March to April average snow cover extent for the 1986–2005 reference period is $32.6 \cdot 10^6 \text{ km}^2$ (Brown and Robinson, 2011).

The strong projected warming across the northern high latitudes in climate model simulations has implications for frozen ground. Recent projections of the extent of near-surface permafrost degradation continue to vary widely depending on the underlying climate forcing scenario and model physics, but virtually all of them indicate substantial near-surface permafrost degradation and thaw depth deepening over much of the permafrost area (Saito et al., 2007; Lawrence et al., 2008a; Koven et al., 2011; Lawrence et al., 2012; Eliseev et al., 2013; Koven et al., 2013; Slater and Lawrence, 2013). Permafrost at greater depths is less directly relevant to the surface energy and water balance, and its degradation naturally occurs much more slowly (Delisle, 2007). Climate models are beginning to represent permafrost physical processes and properties more accurately (Alexeev et al., 2007; Nicolsky et al., 2007; Lawrence et al., 2008a; Rinke et al., 2008; Koven et al., 2009; Gouttevin et al., 2012), but there are large disagreements in the calculation of current frozen soil extent and active layer depth due to differences in the land model physics in the CMIP5 ensemble (Koven et al., 2013). The projected changes in permafrost are a response not only to warming, but also to changes in snow conditions because snow properties and their seasonal evolution exert significant control on soil thermal state (Zhang, 2005; Lawrence and Slater, 2010; Shkolnik et al., 2010; Koven et al., 2013). Applying the surface frost index method (Nelson and Outcalt, 1987) to coupled climate model anomalies from the CMIP5 models (Slater and Lawrence, 2013) yields a reduction of the diagnosed 2080–2099 near-surface permafrost area (continuous plus discontinuous near-surface permafrost) by $37 \pm 11\%$ (RCP2.6), $51 \pm 13\%$ (RCP4.5), $58 \pm 13\%$ (RCP6.0), and $81 \pm 12\%$ (RCP8.5), compared to the 1986–2005 diagnosed near-surface permafrost area, with *medium confidence* in the numbers as such because of the strongly simplified soil physical processes in current-generation global climate models (Figure 12.33). The uncertainty range given here is the 1 sigma inter-model dispersion. Applying directly the model output to diagnose permafrost extent and its changes over the 21st century yields similar relative changes (Koven et al., 2013). In summary, based on high agreement across CMIP5 and older model projections, fundamental process understanding, and paleoclimatic evidence (e.g., Vaks et al., 2013), it appears virtually certain (*high confidence*) that near-surface permafrost extent will shrink as global climate warms. However, the amplitude of the projected reductions of near-surface permafrost extent not only depends on the emission scenario and the global climate model response, but also very much on the permafrost-related soil processes taken into account in the models.

[INSERT FIGURE 12.33 HERE]

Figure 12.33: Northern hemisphere near-surface permafrost area, diagnosed for the available CMIP5 models by Slater and Lawrence (2013) following Nelson and Outcalt (1987) and using 20-year average bias-corrected monthly surface air temperatures and snow depths. Blue: RCP2.6; Light blue: RCP4.5; Orange: RCP6.0; Red: RCP8.5. Thick lines: multi-model average. Shading and thin lines indicate the inter-model spread (one standard deviation). The black line for the historical period is diagnosed from the average of the ERA, JRA, MERRA and CFSRR reanalyses (Slater and Lawrence, 2013). Estimated present permafrost extent is between 12 and 17 million km^2 (Zhang et al., 2000).

12.4.7 Changes in the Ocean

12.4.7.1 Sea Surface Temperature, Salinity, and Ocean Heat Content

Projected increase of sea surface temperature (SST) and heat content over the next two decades is relatively insensitive to the emissions trajectory. However, projected outcomes diverge as the 21st century progresses. When SSTs increase as a result of external forcing, the interior water masses respond to the integrated signal at the surface, which is then propagated down to greater depth (Gleckler et al., 2006; Gregory, 2010). Changes in globally-averaged ocean heat content currently account for about 90% of the change in global energy inventory since 1970 (see Box 3.1). Heat is transported within the interior of the ocean by its large-scale general circulation and by smaller-scale mixing processes. Changes in transports lead to redistribution of existing heat content and can cause local cooling even though the global mean heat content is rising (Banks and Gregory, 2006; Lowe and Gregory, 2006; Xie and Vallis, 2012).

Figure 12.12 shows the multi-model mean projections of zonally-averaged ocean temperature change under three emission scenarios. The differences in projected ocean temperature changes for different RCPs manifest themselves more markedly as the century progresses. The largest warming is found in the top few hundred meters of the subtropical gyres, similar to the observed pattern of ocean temperature changes

(Levitus et al., 2012, see also Section 3.2). Surface warming varies considerably between the emission scenarios ranging from about 1°C (RCP2.6) to more than 3°C in RCP8.5. Mixing and advection processes gradually transfer the additional heat to deeper levels of about 2000 meters at the end of the 21st century. Depending on the emission scenario, global ocean warming between 0.5°C (RCP2.6) and 1.5°C (RCP8.5) will reach a depth of about 1 km by the end of the century. The strongest warming signal is found at the surface in subtropical and tropical regions. At depth the warming is most pronounced in the Southern Ocean. From an energy point of view, for RCP4.5 by the end of the 21st century, half of the energy taken up by the ocean is in the uppermost 700 m, and 85% is in the uppermost 2000 m.

In addition to the upper-level warming, the patterns are further characterized by a slight cooling in parts of the northern mid- and high latitudes below 1000m and a pronounced heat uptake in the deep Southern Ocean at the end of the 21st century. The cooling may be linked to the projected decrease of the strength of the Atlantic Meridional Overturning circulation (AMOC) (see Section 12.4.7.2; 13.4.1; Banks and Gregory, 2006).

The response of ocean temperatures to external forcing comprises mainly two time-scales: a relatively fast adjustment of the ocean mixed layer and the slow response of the deep ocean (Hansen et al., 1985; Knutti et al., 2008a; Held et al., 2010). Simulations with coupled ocean-atmosphere general circulation models suggest time-scales of several millennia until the deep ocean is in equilibrium with the external forcing (Stouffer, 2004; Hansen et al., 2011; Li et al., 2013a). Thus, the long time-scale of the ocean response to external forcing implies an additional commitment to warming for many centuries when greenhouse gas emissions are decreased or concentrations kept constant (see Section 12.5.2). Further assessment of ocean heat uptake and its relationship to projections of sea level rise is presented in Section 13.4.1.

Durack and Wijffels (2010) and Durack et al. (2012) examined trends in global sea surface salinity (SSS) changes over the period 1950–2008. Their analysis revealed strong, spatially-coherent, trends in SSS over much of the global ocean, with a pattern that bears striking resemblance to the climatological SSS field and is associated with an intensification of the global water cycle (see Sections 3.3.2.1, 10.4.2 and 12.4.5). The CMIP5 climate model projections available suggest that high SSS subtropical regions that are dominated by net evaporation are typically getting more saline; lower SSS regions at high latitudes are typically getting fresher. They also suggest a continuation of this trend in the Atlantic where subtropical surface waters become more saline as the century progresses (Figure 12.34) (see also Terray et al., 2012). At the same time, the North Pacific is projected to become less saline.

[INSERT FIGURE 12.34 HERE]

Figure 12.34: Projected sea surface salinity differences 2081–2100 for RCP8.5 relative to 1986–2005 from CMIP5 models. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner.

12.4.7.2 Atlantic Meridional Overturning

Almost all climate model projections reveal an increase of high latitude temperature and high latitude precipitation (Meehl et al., 2007b). Both of these effects tend to make the high latitude surface waters lighter and hence increase their stability. As seen in Figure 12.35, all models show a weakening of the Atlantic meridional overturning circulation (AMOC) over the course of the 21st century (see Section 12.5.5.2 for further analysis). Projected changes in the strength of the AMOC at high latitudes appear stronger in GFDL CM2.1 when density is used as a vertical coordinate instead of depth (Zhang, 2010a). Once the radiative forcing is stabilized, the AMOC recovers, but in some models to less than its preindustrial level. The recovery may include a significant overshoot (i.e., a weaker circulation may persist) if the anthropogenic radiative forcing is eliminated (Wu et al., 2011a). Gregory et al. (2005) found that for all eleven models analysed (six from CMIP2/3 and five EMICs), the AMOC reduction was caused more by changes in surface heat flux than changes in surface freshwater flux. They further found that models with a stronger AMOC in their control run exhibited a larger weakening (see also Gregory and Tailleux, 2011).

Based on the assessment of the CMIP5 RCP simulations and on our understanding gleaned from analysis of CMIP3 models, observations and our understanding of physical mechanisms, it is *very likely* that the AMOC

will weaken over the 21st century. The best estimate decrease in 2100 is about 20–30% for the RCP4.5 scenario and 36–44% for the RCP8.5 scenario

[INSERT FIGURE 12.35 HERE]

Figure 12.35: Multi model projections of Atlantic meridional overturning circulation (AMOC) strength at 30°N from 1850 through to the end of the RCP extensions. Results are based on a small number of CMIP5 models available. Curves show results from only the first member of the submitted ensemble of experiments.

12.4.7.3 Southern Ocean

A dominant and robust feature of the CMIP3 climate projections assessed in AR4 is the weaker surface warming at the end of the 21st century in the Southern Ocean area compared to the global mean. Furthermore, the Antarctic Circumpolar Current (ACC) moves southward in most of the climate projections analysed in response to the simulated southward shift and strengthening of the Southern Hemisphere mid-latitude westerlies (Meehl et al., 2007b).

The additional analyses of the CMIP3 model output performed since the release of AR4 confirm and refine the earlier findings. The displacement and intensification of the mid-latitude westerlies contribute to a large warming between 40°S and 60°S from the surface to mid-depths (Fyfe et al., 2007; Sen Gupta et al., 2009). Part of this warming has been attributed to the southward translation of the Southern Ocean current system (Sen Gupta et al., 2009). Moreover, the wind changes influence the surface temperature through modifications of the latent and sensible heat fluxes and force a larger northward Ekman transport of relatively cold polar surface water (Screen et al., 2010). This also leads to a stronger upwelling that brings southward and upward relatively warm and salty deep water, resulting in a subsurface salinity increase at mid-depths south of 50°S (Sen Gupta et al., 2009; Screen et al., 2010).

Overall, CMIP3 climate projections exhibit a decrease in mixed layer depth at southern mid- and high latitudes by the end of the 21st century. This feature is a consequence of the enhanced stratification resulting from surface warming and freshening (Lefebvre and Goosse, 2008; Sen Gupta et al., 2009; Capotondi et al., 2012). Despite large inter-model differences, there is a robust weakening of Antarctic Bottom Water production and its northward outflow, which is consistent with the decrease in surface density and is manifest as a warming signal close to the Antarctic margin that reaches abyssal depths (Sen Gupta et al., 2009).

In the vicinity of the Antarctic ice sheet, CMIP3 models project an average warming of ~0.5°C at depths of 200–500 m in 2091–2100 compared to 1991–2000 for the SRES A1B scenario, which has the potential to impact the mass balance of ice shelves (Yin et al., 2011). More detailed regional modelling using the SRES A1B scenario indicates that a redirection of the coastal current into the cavities underlying the Filchner-Ronne ice shelf during the second half of the 21st century might enhance the average basal melting rate there from 0.2 m yr⁻¹ to almost 4 m yr⁻¹ (Hellmer et al., 2012; see Section 13.4.4.2).

There are very few published analyses of CMIP5 climate projections focusing on the Southern Ocean. Meijers et al. (2012) found a wide variety of ACC responses to climate warming scenarios across CMIP5 models. Models show a high correlation between the changes in ACC strength and position, with a southward (northward) shift of the ACC core as the ACC gets stronger (weaker). No clear relationship between future changes in wind stress and ACC strength was identified, while the weakening of the ACC transport simulated at the end of the 21st century by many models was found to be correlated with the strong decrease in the surface heat and freshwater fluxes in the ACC region (Meijers et al., 2012; Downes and Hogg, 2013). In agreement with the CMIP3 assessment (Sen Gupta et al., 2009), subtropical gyres generally strengthen under RCP4.5 and RCP8.5 and all expand southward, inducing a southward shift of the northern boundary of the ACC at most longitudes in the majority of CMIP5 models (Meijers et al., 2012). As in CMIP3 climate projections, an overall shallowing of the deep mixed layers that develop on the northern edge of the ACC in winter is observed, with larger shallowing simulated by models with deeper mixed layers during 1976–2005 (Sallée et al., 2013a). Sallée et al. (2013b) reported a warming of all mode, intermediate and deep water masses in the Southern Ocean. The largest temperature increase is found in mode and intermediate water layers. Consistently with CMIP3 projections (Downes et al., 2010), these water layers experience a freshening, whereas bottom water becomes slightly saltier. Finally, Sallée et al. (2013b) noted

an enhanced upwelling of circumpolar deep water and an increased subduction of intermediate water that are nearly balanced by interior processes (diapycnal fluxes).

A number of studies suggest that oceanic mesoscale eddies might influence the response of the Southern Ocean circulation, meridional heat transport and deep water formation to changes in wind stress and surface buoyancy flux (Böning et al., 2008; Farneti et al., 2010; Downes et al., 2011; Farneti and Gent, 2011; Saenko et al., 2012; Spence et al., 2012). These eddies are not explicitly resolved in climate models and their role in future circulation changes still needs to be precisely quantified. Some of the CMIP5 models have output the meridional overturning due to the Eulerian mean circulation and that induced by parameterized eddies, thus providing a quantitative estimate of the role of the mesoscale circulation in a warming climate. On this basis, Downes and Hogg (2013) found that, under RCP8.5, the strengthening (weakening) of the upper (lower) Eulerian mean meridional overturning cell in the Southern Ocean is significantly correlated with the increased overlying wind stress and surface warming and is partly compensated at best by changes in eddy-induced overturning.

None of the CMIP3 and CMIP5 models include an interactive ice sheet component. When climate–ice sheet interactions are accounted for in an Earth system model of intermediate complexity under a $4 \times \text{CO}_2$ scenario, the meltwater flux from the Antarctic ice sheet further reduces the surface density close to Antarctica and the rate of Antarctic Bottom Water formation. This ultimately results in a smaller surface warming at high southern latitudes compared to a simulation in which the freshwater flux from the melting ice sheet is not taken into account (Swingedouw et al., 2008). Nevertheless, in this study, this effect becomes significant only after more than one century.

12.4.8 Changes Associated with Carbon Cycle Feedbacks and Vegetation Cover

Climate change may affect the global biogeochemical cycles changing the magnitude of the natural sources and sinks of major greenhouse gases. Numerous studies investigated the interactions between climate change and the carbon cycle (e.g., Friedlingstein et al., 2006), methane cycle (e.g., O'Connor et al., 2010), ozone (Cionni et al., 2011) or aerosols (e.g., Carslaw et al., 2010). Many CMIP5 ESMs now include a representation of the carbon cycle as well as atmospheric chemistry, allowing interactive projections of greenhouse gases (mainly CO_2 and O_3) and aerosols. With such models, projections account for the imposed changes in anthropogenic emissions, but also for changes in natural sources and sinks as they respond to changes in climate and atmospheric composition. If included in ESMs, the impact on projected concentration, radiative forcing and hence on climate can be quantified. Climate induced changes on the carbon cycle are assessed below, while changes in natural emissions of CH_4 are assessed in chapter 6, changes in atmospheric chemistry in Chapter 11, and climate-aerosols interactions are assessed in Chapter 7.

12.4.8.1 Carbon Dioxide

As presented in Section 12.3, the CMIP5 experimental design includes, for the RCP8.5 scenario, experiments driven either by prescribed anthropogenic CO_2 emissions or concentration. The historical and 21st century emission driven simulations allow evaluating the climate response of the Earth system when atmospheric CO_2 and the climate response are interactively being calculated by the ESMs. In such ESMs, the atmospheric CO_2 is calculated as the difference between the imposed anthropogenic emissions and the sum of land and ocean carbon uptakes. As most of these ESMs accounts for land use changes and their CO_2 emissions, the only external forcing is fossil fuel CO_2 emissions (along with all non- CO_2 forcings as in the C-driven RCP8.5 simulations). For a given ESM, the emission driven and concentration driven simulations would show different climate projections if the simulated atmospheric CO_2 in the emission driven run is significantly different from the one prescribed for the concentration driven runs. This would happen if the ESMs carbon cycle is different from the one simulated by MAGICC6, the model used to calculate the CMIP5 GHGs concentrations from the emissions for the four RCPs (Meinshausen et al., 2011c). When driven by CO_2 concentration, the ESMs can calculate the fossil fuel CO_2 emissions that would be compatible with the prescribed atmospheric CO_2 trajectory, allowing comparison with the set of CO_2 emissions initially estimated by the IAMs (Arora et al., 2011; Jones et al., 2013) (see Section 6.4.3, Box 6.4).

Figure 12.36 shows the simulated atmospheric CO_2 and global average surface air temperature warming (relative to the 1986–2005 reference period) for the RCP8.5 emission driven simulations from the CMIP5

ESMs, compared to the concentration driven simulations from the same models. Most (seven out of eleven) of the models estimate a larger CO₂ concentration than the prescribed one. By 2100, the multi models average CO₂ concentration is 985 ± 97 ppm (full range 794–1142 ppm), while the CO₂ concentration prescribed for the RCP8.5 is 936 ppm. Figure 12.36 also shows the range of atmospheric CO₂ projections when the MAGICC6 model, used to provide the RCP concentrations, is tuned to emulate combinations of climate sensitivity uncertainty taken from 19 CMIP3 models and carbon cycle feedbacks uncertainty taken from 10 C⁴MIP models, generating 190 model simulations (Meinshausen et al., 2011c; Meinshausen et al., 2011b). The emulation of the CMIP3/C⁴MIP models shows for the RCP8.5, a range of simulated CO₂ concentrations of 794–1149 ppm (90% confidence level), extremely similar to what is obtained with the CMIP5 ESMs, with atmospheric concentration as high as 1150 ppm by 2100, i.e., more than 200 ppm above the prescribed CO₂ concentration.

Global warming simulated by the E-driven runs show higher upper ends than when atmospheric CO₂ concentration is prescribed. For the models assessed here, the global surface temperature change (2081–2100 average relative to 1986–2005 average) ranges between 2.6°C and 4.7°C, with a multi-model average of 3.7°C ± 0.7°C for the concentration driven simulations, while the emission driven simulations give a range of 2.5°C to 5.6°C, with a multi-model average of 3.9°C ± 0.9°C, i.e., 5% larger than for the concentration driven runs. The models that simulate the largest CO₂ concentration by 2100, have the largest warming amplification in the emission driven simulations, with an additional warming of more than 0.5°C.

[INSERT FIGURE 12.36 HERE]

Figure 12.36: Simulated changes in a) atmospheric CO₂ concentration and b) global averaged surface temperature (°C) as calculated by the CMIP5 ESMs for the RCP8.5 scenario when CO₂ emissions are prescribed to the ESMs as external forcing (blue). Also shown (panel b, in red) is the simulated warming from the same ESMs when directly forced by atmospheric CO₂ concentration (panel a, red white line). Panel c and d show the range of CO₂ concentrations and global average surface temperature change simulated by the MAGICC6 simple climate model when emulating the CMIP3 models climate sensitivity range and the C⁴MIP models carbon cycle feedbacks. The default line in panel c is identical to the one in panel a.

The uncertainty on the carbon-cycle has been shown to be of comparable magnitude to the uncertainty arising from physical climate processes (Gregory et al., 2009). Huntingford et al. (2009) used a simple model to characterize the relative role of carbon cycle and climate sensitivity uncertainties in contributing to the range of future temperature changes, concluding that the range of carbon cycle processes represent about 40% of the physical feedbacks. Perturbed parameter ensembles systematically explore land carbon cycle parameter uncertainty and illustrate that a wide range of carbon cycle responses are consistent with the same underlying model structures and plausible parameter ranges (Booth et al., 2012; Lambert et al., 2012). Figure 12.37 shows how the comparable range of future climate change (SRES A1B) arises from parametric uncertainty in land carbon cycle and atmospheric feedbacks. The same ensemble shows that the range of atmospheric CO₂ in the land carbon cycle ensemble is wider than the full SRES concentration range (B1 to A1FI scenario).

[INSERT FIGURE 12.37 HERE]

Figure 12.37: Uncertainty in global mean temperature from HadCM3 results exploring atmospheric physics and terrestrial carbon cycle parameter perturbations under the SRES A1B scenario (Murphy et al., 2004; Booth et al., 2012). Relative uncertainties in the Perturbed Carbon Cycle (PCC, green plume) and Perturbed Atmospheric Processes (PAP, blue plume) on global mean anomalies of temperature (relative to the 1986–2005 period). The standard simulations from the two ensembles, HadCM3 (blue solid) and HadCM3C (green solid) are also shown. Three bars are shown on the right illustrating the 2100 temperature anomalies associated with the CMIP3/AR4 ensemble (black) the PAP ensemble (blue), and PCC ensemble (green). The ranges indicate the full range, 10th–90th, 25th–75th and 50th percentiles.

The CMIP5 ESMs described above do not include the positive feedback arising from the carbon release from high latitudes permafrost thawing under a warming scenario, which could further increase the atmospheric CO₂ concentration and the warming. Two recent studies investigated the climate-permafrost feedback from simulations with models of intermediate complexity (EMICs) that accounts for a permafrost carbon module (MacDougall et al., 2012; Schneider von Deimling et al., 2012). Burke et al. (2012) also estimated carbon loss from permafrost, from a diagnostic of the present-day permafrost carbon store and future soil warming as simulated by CMIP5 models. However, this last study did not quantify the effect on global temperature.

Each of these studies found that the range of additional warming due to the permafrost carbon loss is quite large, because of uncertainties in future high latitude soil warming, amount of carbon stored in permafrost soils, vulnerability of freshly thawed organic material, the proportion of soil carbon that might be emitted as carbon dioxide via aerobic decomposition or as methane via anaerobic decomposition (Schneider von Deimling et al., 2012). For the RCP8.5, the additional warming from permafrost ranges between 0.04°C and 0.69°C by 2100 although there is medium confidence in these numbers as are the ones on the amount of carbon released (see Section 12.5.5.4) (MacDougall et al., 2012; Schneider von Deimling et al., 2012).

12.4.8.2 Changes in Vegetation Cover

Vegetation cover can also be affected by climate change, with forest cover potentially being decreasing (e.g., in the tropics) or increasing (e.g., in high latitudes). In particular, the Amazon forest has been the subject of several studies, generally agreeing that future climate change would increase the risk tropical Amazon forest being replaced by seasonal forest or even savannah (Huntingford et al., 2008; Jones et al., 2009; Malhi et al., 2009). Increase in atmospheric CO₂ would partly reduce such risk, through increase in water efficiency under elevated CO₂ (Lapola et al., 2009; Malhi et al., 2009). Recent multi model estimates based on different CMIP3 climate scenarios and different dynamic global vegetation models predict a moderate risk of tropical forest reduction in South America and even lower risk for African and Asian tropical forests (see also Section 12.5.5.6) (Gumpenberger et al., 2010; Huntingford et al., 2013).

ESMs simulations with interactive vegetation confirmed known biophysical feedback associated with large-scale changes in vegetation. In the northern high latitudes, warming-induced vegetation expansion reduces surface albedo, enhancing the warming over these regions (Falloon et al., 2012; Port et al., 2012), with potentially larger amplification due to ocean and sea-ice response (Swann et al., 2010). Over tropical forest, reduction of forest coverage would reduce evapotranspiration, also leading to a regional warming (Falloon et al., 2012; Port et al., 2012).

CMIP5 ESMs also include human induced land cover changes (deforestation, reforestation) affecting the climate system through changes in land surface physical properties (Hurt et al., 2011). Future changes in land cover will have an impact on the climate system through biophysical and biogeochemical processes (e.g., Pongratz et al., 2010). Biophysical processes include changes in surface albedo and changes in partitioning between latent and sensible heat, while biogeochemical feedbacks essentially include change in CO₂ sources and sinks but could potentially also include changes in N₂O or CH₄ emissions. The biophysical response to future land cover changes has been investigated within the SRES scenarios. Using the SRES A2 2100 land cover, Davin et al. (2007) simulated a global cooling of 0.14 K relatively to a simulation with present-day land cover, the cooling being largely driven by change in albedo. Regional analyses have been performed in order to quantify the biophysical impact of biofuels plantation generally finding a local to regional cooling when annual crops are replaced by bioenergy crops, such as sugar cane (Georgescu et al., 2011; Loarie et al., 2011). However, some energy crops require nitrogen inputs for their production, leading inevitably to nitrous oxide (N₂O) emissions, potentially reducing the direct cooling effect and the benefit of biofuels as an alternative to fossil fuel emissions. Such emission estimates are still uncertain, varying strongly for different crops, management methods, soil types and reference systems (St. Clair et al., 2008; Smeets et al., 2009).

In the context of the Land-Use and Climate, Identification of robust impacts (LUCID) project (Pitman et al., 2009) ESMs performed additional CMIP5 simulations in order to separate the biophysical from the biogeochemical effects of land-use changes in the RCP scenarios. The LUCID-CMIP5 experiments were designed to complement RCP8.5 and RCP2.6 simulations of CMIP5, both of which showing an intensification of land use change over the 21st century. The LUCID-CMIP5 analysis was focused on a difference in climate and land-atmosphere fluxes between the average of ensemble of simulations with- and without land-use changes by the end of 21st century (Brovkin et al., 2013). Due to different interpretation of land-use classes, areas of crops and pastures were specific for each ESM (Figure 12.38, left). On the global scale, simulated biophysical effects of land-use changes projected in the CMIP5 experiments with prescribed CO₂ concentrations were not significant. However, these effects were significant for regions with land-use changes >10%. Only three out of six participated models, CanESM2, HadGEM2-ES and MIROC-ESM, reveal statistically significant changes in regional mean annual mean surface air temperature for the RCP8.5 scenario (Figure 12.38, right). However, there is low confidence on the overall effect as there is no

agreement amongst the models on the sign of the global average temperature change due to the biophysical effects of land-use changes (Brovkin et al., 2013). Changes in land surface albedo, available energy, latent and sensible heat fluxes were relatively small but significant in most of ESMs for regions with substantial land-use changes. The scale of climatic effects reflects a small magnitude of land-use changes in both the RCP2.6 and 8.5 scenarios and their limitation mainly to the tropical and subtropical regions where differences between biophysical effects of forests and grasslands are less pronounced than in mid- and high latitudes. LUCID-CMIP5 did not perform similar simulations for the RCP4.5 or RCP6.0 scenarios. As these two scenarios show a global decrease of land-use area, one might expect their climatic impact to be different from the one seen in the RCP2.6 and RCP8.5.

[INSERT FIGURE 12.38 HERE]

Figure 12.38 Impact of land-use change on surface temperature. LUCID-CMIP5 experiments where 6 ESMs were forced either with or without land-use change beyond 2005 under the RCP8.5 scenario. Left maps of changes in total crop and pasture fraction (%) in the RCP8.5 simulations between 2006 and 2100 as implemented in each ESM. Right maps show the differences in surface air temperature (averaged over the 2071–2100 period) between the simulations with- and without land use change beyond 2005. Only statistically significant changes ($p < 0.05$) are shown.

12.4.9 Consistency and Main Differences Between CMIP3/CMIP5 and SRES/RCPs

In the experiments collected under CMIP5, both models and scenario have changed with respect to CMIP3 making a comparison with earlier results and the scientific literature they generated (on which some of this chapter's content is still based) complex. The set of models used in AR4 (the CMIP3 models) have been superseded by the new CMIP5 models (Table 12.1; Chapter 9) and the SRES scenarios have been replaced by four RCPs (Section 12.3.1). In addition, the baseline period used to compute anomalies has advanced 6 years, from 1980–1999 to 1986–2005.

It would be extremely costly computationally to rerun the full CMIP3 ensemble under the new RCPs and/or the full CMIP5 ensemble under the old SRES scenarios in order to separate model and scenario effects. In the absence of a direct comparison, we rely on simplified modelling frameworks to emulate CMIP3/SRES/RCP model behaviour and compare them. Figure 12.39 shows an emulation of the global mean temperature response at the end of the 21st century that one would expect from the CMIP5 models if they were run under SRES A1B. In this case, anomalies are computed with respect to 1980–1999 for direct comparison with the values reported in AR4 (Meehl et al., 2007b) which used that baseline. The method used to emulate the SRES A1B response of the CMIP5 is documented by Good et al. (2011a; 2013). Ensemble-mean A1B radiative forcing was computed from CMIP3 projections using the Forster and Taylor (2006) method, scaled to ensure consistency with the forcing required by the method. The simple model is only used to predict the temperature difference between A1B and RCP8.5, and between A1B and RCP4.5 separately for each model. These differences are then added to CMIP5 GCM simulations of RCP8.5 and RCP4.5 respectively, and averaged to give a single A1B estimate. The emulated CMIP5 SRES A1B results show a slightly larger mean response than the actual CMIP3 models, with a similar spread (± 1 standard deviation is used in this case). The main reasons for this is the slightly larger mean Transient Climate Response (TCR) in the subset of CMIP5 models available in comparison with the AR4 CMIP3 models. An alternative emulation is presented by Knutti and Sedláček (2013) who use the simplified MAGICC models with parameters chosen to emulate the response of the CMIP3 models to RCP6.0 forcing, with anomalies expressed with respect to the 1986–2005 baseline period (Figure 12.39). They too find a larger mean response in the CMIP5 case but also a larger spread (± 1 standard deviation) in CMIP5. Uncertainties in the different approaches to emulating climate model simulations, for example estimating the non-greenhouse gas radiative forcing, and the small sample sizes of CMIP3 and CMIP5 make it difficult to draw conclusions on the statistical significance of the differences displayed in Figure 12.39, but the same uncertainties leads us to conclude that on the basis of these analyses there appears to be no fundamental difference between the behaviour of the CMIP5 ensemble, in comparison with CMIP3.

[INSERT FIGURE 12.39 HERE]

Figure 12.39: Global mean temperature anomalies at the end of the 21st century from GCM experiments and emulators comparing CMIP3/CMIP5 responses under SRES A1B and RCP6.0. The boxes and whiskers indicate the 5th percentile, mean value – 1 standard deviation, mean, mean value + 1 standard deviation and 95th percentile of the distributions. The first box-and-whiskers on the left is computed directly from the CMIP3 ensemble and corresponds to the numbers quoted in AR4. The emulated SRES A1B projections (second from left) of CMIP5 are obtained by the

method of Good et al. (2011a) and are calculated for the period 2080–2099 expressed with respect to the AR4 baseline period of 1980–1999. Because of the method, the subset of CMIP5 that are emulated are restricted to those with preindustrial control, abrupt $4 \times \text{CO}_2$, historical, RCP4.5 and RCP8.5 simulations. The emulated RCP6.0 projections of CMIP3 (third from left, see also Figure 12.8) are from Knutti and Sedláček (2013) obtained using the method of Meinshausen et al. (2011c; 2011b) and are calculated for the slightly different future period 2081–2100 to be consistent with the rest of this chapter, and are expressed with respect to the AR5 baseline period of 1986–2005. The box-and-whiskers fourth from the left are a graphical representation of the numbers shown in Table 12.2. The final box-and-whiskers on the right is a combination of CMIP5 model output and emulation of CMIP5 RCP6.0 numbers for those models that did not run RCP6.0.

Meinshausen et al. (2011a; 2011b) tuned MAGICC6 to emulate 19 GCMs from CMIP3. The results are temperature projections and their uncertainties (based on the empirical distribution of the ensemble) under each of the RCPs, extended to year 2500 (under constant emissions for the lowest RCP and constant concentrations for the remaining three). In the same paper, an ensemble produced by combining carbon cycle parameter calibration to nine C⁴MIP models with the 19 CMIP3 model parameter calibrations is also used to estimate the emissions implied by the various concentration pathways, had the CMIP3 models included a carbon cycle component. Rogelj et al. (2012) used the same tool but performed a fully probabilistic analysis of the SRES and RCP scenarios using a parameter space that is consistent with CMIP3/C⁴MIP but a more general uncertainty characterization for key quantities like equilibrium climate sensitivity, similarly to the approach utilized by Meinshausen et al. (2009). Observational or other historical constraints are also used in this study and the analysis is consistent with the overall assessment of sources and ranges of uncertainties for relevant quantities (equilibrium climate sensitivity above all) from AR4 (Meehl et al., 2007b, Box 10.2). Figure 12.40 summarizes results of this probabilistic comparison for global temperature. The RCPs span a large range of stabilization, mitigation and non-mitigation pathways and the resulting range of temperature changes are larger than those produced under SRES scenarios, which do not consider mitigation options. The SRES results span an interval between just above 1.0°C and 6.5°C when considering the respective likely ranges of all scenarios, including B1 as the lowest and A1FI as the highest. Emissions under RCP8.5 are highest and the resulting temperature changes likely range from 4.0°C to 6.1°C by 2100. The lowest RCP2.6 assumes significant mitigation and the global temperature change likely remains below 2°C.

[INSERT FIGURE 12.40 HERE]

Figure 12.40: Temperature projections for SRES scenarios and the RCPs. (a) Time-evolving temperature distributions (66% range) for the four RCP scenarios computed with the ECS distribution from Rogelj et al. (2012) and a model setup representing closely the carbon-cycle and climate system uncertainty estimates of the AR4 (grey areas). Median paths are drawn in yellow. Red shaded areas indicate time periods referred to in panel b. (b) Ranges of estimated average temperature increase between 2090 and 2099 for SRES scenarios and the RCPs respectively. Note that results are given both relative to 1980–1999 (left scale) and relative to pre-industrial (right scale). Yellow ranges indicate results obtained by Rogelj et al. (2012). Colour-coding of AR4 ranges is chosen to be consistent with AR4 (Meehl et al., 2007b). RCP2.6 is labelled as RCP3-PD here.

Similar temperature change projections by the end of the 21st century are obtained under RCP8.5 and SRES A1FI, RCP6 and SRES B2 and RCP4.5 and SRES B1. There remain large differences though in the transient trajectories, with rates of change slower or faster for the different pairs. These differences can be traced back to the interplay of the (negative) short-term effect of sulphate aerosols and the (positive) effect of long-lived GHGs. Impact studies may be sensitive to the differences in these temporal profiles so care should be taken in approximating SRES with RCPs and vice versa.

While simple models can separate the effect of the scenarios and the model response, no studies are currently available that allow an attribution of the CMIP3–CMIP5 differences to changes in the transient climate response, the carbon cycle, and the inclusion of new processes (chemistry, land surface, vegetation). The fact that these sets of CMIP3 and CMIP5 experiments does not include emission-driven runs would suggest that differences in the representation of the carbon cycle are very unlikely to explain differences in the simulations, since the only effect of changes in the carbon cycle representation would affect the land surface, and thus would have only a minor effect on the climate response at the global scale.

Figure 12.41 shows a comparison of the patterns of warming and precipitation change from CMIP3 (using 23 models and three SRES scenarios) and CMIP5 (using 46 models and four RCPs), utilizing the pattern scaling methodology (Section 12.4.2). The geographic patterns of mean change are very similar across the two ensembles of models, with pattern correlations of 0.98 for temperature and 0.90 for precipitation

changes. However there exist significant differences in the absolute values of the patterns, if not in their geographic shapes. A simple bootstrapping exercise that pooled together all models and scenarios and resampled 500 times the same numbers of models/scenarios divided into two groups, but without distinguishing CMIP3 from CMIP5 (and thus SRES from RCPs) allows to compute a measure of significance of the actual differences in the patterns. Stippling in Figure 12.41 marks the large regions where the difference is significant for temperature and precipitation patterns. The temperature pattern from CMIP5 shows significantly larger warming per °C of global mean temperature change in the Northern Hemisphere and less warming per °C in the Southern Hemisphere compared to the corresponding pattern from CMIP3. For precipitation patterns, CMIP5 shows significantly larger increases per °C in the Northern Hemisphere and significantly larger decreases per °C in the Southern Hemisphere compared to CMIP3. Even in this case we do not have studies that allow tracing the source of these differences to specific changes in models' configurations, processes represented or scenarios run.

Knutti and Sedláček (2013) attempt to identify or rule out at least some of these sources. Differences in model projections spread or its counterpart, robustness, between CMIP3 and CMIP5 are discussed, and it is shown that by comparing the behaviour of only a subset of 11 models, contributed to the two CMIPs by the same group of institutions, the robustness of CMIP5 versus that of CMIP3 actually decreases slightly. This would suggest that the enhanced robustness of CMIP5 is not clearly attributable to advances in modelling, and may be a result of the fact that the CMIP5 ensemble contains different versions of the same model that are counted as independent in this measure of robustness.

A comparison of CMIP3 and CMIP5 results for extreme indices is provided in Sections 12.4.3.3 and Figure 12.13 for temperature extremes, and Section 12.4.5.5 and Figure 12.26 for extremes in the water cycle.

[INSERT FIGURE 12.41 HERE]

Figure 12.41: Patterns of temperature (left column) and percent precipitation change (right column) for the CMIP3 models average (first row) and CMIP5 models average (second row), scaled by the corresponding global average temperature changes. The patterns are computed in both cases by taking the difference between the averages over the last twenty years of the 21st century experiments (2080–2099 for CMIP3 and 2081–2100 for CMIP5) and the last twenty years of the historic experiments (1980–1999 for CMIP3, 1986–2005 for CMIP5) and rescaling each difference by the corresponding change in global average temperature. This is done first for each individual model, then the results are averaged across models. For the CMIP5 patterns, the RCP2.6 simulation of the FIO-ESM model was excluded because it did not show any warming by the end of the 21st century, thus not complying with the method requirement that the pattern be estimated at a time when the temperature change signal from CO₂ increase has emerged. Stippling indicates a measure of significance of the difference between the two corresponding patterns obtained by a bootstrap exercise. Two subsets of the pooled set of CMIP3 and CMIP5 ensemble members of the same size as the original ensembles, but without distinguishing CMIP3 from CMIP5 members, were randomly sampled 500 times. For each random sample we compute the corresponding patterns and their difference, then the true difference is compared, grid-point by grid-point, to the distribution of the bootstrapped differences, and only grid-points at which the value of the difference falls in the tails of the bootstrapped distribution (less than the 2.5 percentiles or the 97.5 percentiles) are stippled.

12.5 Climate Change Beyond 2100, Commitment, Stabilization and Irreversibility

This section discusses the long term (century to millennia) climate change based on the RCP scenario extensions and idealized scenarios, the commitment from current atmospheric composition and from past emissions, the concept of cumulative carbon and the resulting constraints on emissions for various temperature targets. The term irreversibility is used in various ways in the literature. This report defines a perturbed state as irreversible on a given timescale if the recovery timescale from this state due to natural processes is significantly longer than the time it takes for the system to reach this perturbed state (see Glossary), e.g., the climate change resulting from the long residence time of a CO₂ perturbation in the atmosphere. These results are discussed in Sections 12.5.2–12.5.4. Aspects of irreversibility in the context of abrupt change, multiple steady states and hysteresis are discussed in Section 12.5.5 and in Chapter 13 for ice sheets and sea level rise.

12.5.1 RCP Extensions

The CMIP5 intercomparison project includes simulations extending the four RCP scenarios to the year 2300 (see Section 12.3.1). This allows exploring the longer-term climate response to idealized GHG and aerosols

forcings (Meinshausen et al., 2011c). Continuing greenhouse gas emissions beyond 2100 as in the RCP8.5 extension induces a total radiative forcing above 12 W m^{-2} by 2300, while sustaining negative emissions beyond 2100, as in the RCP2.6 extension, induces a total radiative forcing below 2 W m^{-2} by 2300. The projected warming for 2281–2300, relative to 1986–2005, is 0.6°C (range 0.0°C – -1.2°C) for RCP2.6, 2.5°C (range 1.5°C – 3.5°C) for RCP4.5, and 7.8°C (range 3.0°C – -12.6°C) for RCP8.5 (*medium confidence*, based on a limited number of CMIP5 simulations) (Figures 12.3 and 12.5, Table 12.2).

EMICs simulations have been performed following the same CMIP5 protocol for the historical simulation and RCP scenarios extended to 2300 (Zickfeld et al., 2013). These scenarios have been prolonged beyond 2300 to investigate longer-term commitment and irreversibility (see below). Up to 2300, projected warming and the reduction of the AMOC as simulated by the EMICs are similar to those simulated by the CMIP5 ESMs (Figure 12.5, Figure 12.42).

[INSERT FIGURE 12.42 HERE]

Figure 12.42: a) Atmospheric CO_2 , b) projected global mean surface temperature change and c) projected change in the Atlantic meridional overturning circulation, as simulated by EMICs for the four RCPs up to 2300 (Zickfeld et al., 2013). A ten-year smoothing was applied. Shadings and bars denote the minimum to maximum range. The dashed line on panel (a) indicates the pre-industrial CO_2 concentration.

12.5.2 Climate Change Commitment

Climate change commitment, the fact that the climate will change further after the forcing or emissions have been eliminated or held constant, has attracted increased attention by scientists and policy makers shortly before the completion of IPCC AR4 (Hansen et al., 2005a; Meehl et al., 2005b; Wigley, 2005; Meehl et al., 2006) (see also AR4 Section 10.7.1). However, the argument that the surface response would lag the radiative forcing due to the large thermal reservoir of the ocean in fact goes back much longer (Bryan et al., 1982; Hansen et al., 1984; Siegenthaler and Oeschger, 1984; Hansen et al., 1985; Schlesinger, 1986; Mitchell et al., 2000; Wetherald et al., 2001). The discussion in this section is framed largely in terms of temperature change, but other changes in the climate system (e.g., precipitation) are closely related to changes in temperature (see Sections 12.4.1.1 and 12.4.2). A summary of how past emissions relate to future warming is also given in FAQ 12.3.

The Earth system has multiple response timescales related to different thermal reservoirs (see also Section 12.5.3). For a step change in forcing (instantaneous increase in the magnitude of the forcing and constant forcing after that), a large fraction of the total of the surface temperature response will be realized within years to a few decades (Brasseur and Roeckner, 2005; Knutti et al., 2008a; Murphy et al., 2009; Hansen et al., 2011). The remaining response, realized over centuries, is controlled by the slow mixing of the energy perturbation into the ocean (Stouffer, 2004). The response timescale depends on the amount of ocean mixing and the strength of climate feedbacks, and is longer for higher climate sensitivity (Hansen et al., 1985; Knutti et al., 2005). The transient climate response is therefore smaller than the equilibrium response, in particular for high climate sensitivities. This can also be interpreted as the ocean heat uptake being a negative feedback (Dufresne and Bony, 2008; Gregory and Forster, 2008). Delayed responses can also occur due to processes other than ocean warming, e.g., vegetation change (Jones et al., 2009) or ice sheet melt that continues long after the forcing has been stabilized (see Section 12.5.3).

Several forms of commitment are often discussed in the literature. The most common is the “constant composition commitment”, the warming that would occur after stabilizing all radiative constituents at a given year (for example year 2000) levels. For year 2000 commitment, AOGCMs estimated a most likely value of about 0.6°C for 2100 (relative to 1980–1999, AR4 Section 10.7.1). A present-day composition commitment simulation is not part of CMIP5, so direct comparison with CMIP3 is not possible. However, the available CMIP5 results based on the RCP4.5 extension with constant radiative forcing (see Section 12.5.1) are consistent with those numbers, with an additional warming of about 0.5°C 200 years after stabilization of the forcing (Figures 12.5 and 12.42).

A measure of constant composition commitment is the fraction of realized warming which can be estimated as the ratio of the warming at a given time to the long-term equilibrium warming (e.g., Stouffer, 2004; Meehl et al., 2007b, Section 10.7.2; Eby et al., 2009; Solomon et al., 2009). EMIC simulations have been performed

with RCPs forcing up to 2300 prolonged until the end of the millennium with a constant forcing set at the value reached by 2300 (Figure 12.43). When the forcing stabilizes, the fraction of realized warming is significantly below unity. However, the fraction of realized warming depends on the history of the forcing. For the RCP4.5 and RCP6.0 extension scenarios with early stabilization, it is about 75% at the time of forcing stabilisation; while for the RCP2.6 and RCP8.5, with stabilization occurring later, it is about 85% (see Figure 12.43); but for a $1\% \text{ yr}^{-1} \text{ CO}_2$ increase to $2 \times \text{CO}_2$ or $4 \times \text{CO}_2$ and constant forcing thereafter, the fraction of realized warming is much smaller, about 40–70% at the time when the forcing is kept constant. The fraction of realized warming rises typically by 10% over the century following the stabilization of forcing. Due to the long timescales in the deep ocean, full equilibrium is reached only after hundreds to thousands of years (Hansen et al., 1985; Gregory et al., 2004; Stouffer, 2004; Meehl et al., 2007b, Section 10.7.2; Knutti et al., 2008a; Danabasoglu and Gent, 2009; Held et al., 2010; Hansen et al., 2011; Li et al., 2013a).

[INSERT FIGURE 12.43 HERE]

Figure 12.43: a) Atmospheric CO_2 , b) projected global mean surface temperature change and c) fraction of realized warming calculated as the ratio of global temperature change at a given time to the change averaged over the 2980–2999 time period, as simulated by EMICs for the 4 RCPs up to 2300 followed by a constant (year 2300 level) radiative forcing up to the year 3000 (Zickfeld et al., 2013). A ten-year smoothing was applied. Shadings and bars denote the minimum to maximum range. The dashed line on panel (a) indicates the pre-industrial CO_2 concentration.

“Constant emission commitment” is the warming that would result from maintaining annual anthropogenic emissions at the current level. Few studies exist but it is estimated to be about 1°C – 2.5°C by 2100 assuming constant (year 2010) emissions in the future, based on the MAGICC model calibrated to CMIP3 and C⁴MIP models (Meinshausen et al., 2011a; Meinshausen et al., 2011b) (see FAQ 12.3). Such a scenario is different from non-intervention economic scenarios, and it does not stabilize global temperature, as any plausible emission path after 2100 would cause further warming. It is also different from a constant cumulative emission scenario which implies zero emissions in the future.

Another form of commitment involves climate change when anthropogenic emissions are set to zero (“zero emission commitment”). Results from a variety of models ranging from EMICs (Meehl et al., 2007b; Weaver et al., 2007; Matthews and Caldeira, 2008; Plattner et al., 2008; Eby et al., 2009; Solomon et al., 2009; Friedlingstein et al., 2011) to ESMs (Frölicher and Joos, 2010; Gillett et al., 2011; Gillett et al., 2013) show that abruptly setting CO_2 emissions to zero (keeping other forcings constant if accounted for) results in approximately constant global temperature for several centuries onward. Those results indicate that past emissions commit us to persistent warming for hundreds of years, continuing at about the level of warming that has been realized. On near equilibrium timescales of a few centuries to about a millennium, the temperature response to CO_2 emissions is controlled by climate sensitivity (see Box 12.2) and the cumulative airborne fraction of CO_2 over these time-scales. After about a thousand years (i.e., near thermal equilibrium) and cumulative CO_2 emissions less than about 2000 PgC, approximately 20–30% of the cumulative anthropogenic carbon emissions still remain in the atmosphere (Montenegro et al., 2007; Plattner et al., 2008; Archer et al., 2009; Frölicher and Joos, 2010; Joos et al., 2013) (see Box 6.1) and maintain a substantial temperature response long after emissions have ceased (Friedlingstein and Solomon, 2005; Hare and Meinshausen, 2006; Weaver et al., 2007; Matthews and Caldeira, 2008; Plattner et al., 2008; Eby et al., 2009; Lowe et al., 2009; Solomon et al., 2009; Frölicher and Joos, 2010; Solomon et al., 2010; Zickfeld et al., 2012). In the transient phase, on a hundred to thousand year time scale, the approximately constant temperature results from a compensation between delayed commitment warming (Meehl et al., 2005b; Wigley, 2005) and the reduction in atmospheric CO_2 resulting from ocean and land carbon uptake as well as from the nonlinear dependence of radiative forcing on atmospheric CO_2 (Meehl et al., 2007b; Plattner et al., 2008; Solomon et al., 2009; Solomon et al., 2010). The commitment associated with past emissions depends, as mentioned above, on the value of climate sensitivity and cumulative CO_2 airborne fraction, but it also depends on the choices made for other radiative forcing constituents. In a CO_2 only case and for equilibrium climate sensitivities near 3°C , the warming commitment (i.e., the warming relative to the time when emissions are stopped) is near zero or slightly negative. For high climate sensitivities, and in particular if aerosol emissions are eliminated at the same time, the commitment from past emission can be significantly positive, and is a superposition of a fast response to reduced aerosols emissions and a slow response associated with high climate sensitivities (Brasseur and Roeckner, 2005; Hare and Meinshausen, 2006; Armour and Roe, 2011; Knutti and Plattner, 2012; Matthews and Zickfeld, 2012) (see FAQ 12.3). In the real world, the emissions of CO_2 and non- CO_2 forcing agents are of course coupled. All of the above studies

support the conclusion that temperatures would decrease only very slowly (if at all), even for strong reductions or complete elimination of CO₂ emissions, and might even increase temporarily for an abrupt reduction of the short-lived aerosols (FAQ 12.3). The implications of this fact for climate stabilization are discussed in Section 12.5.4.

New EMIC simulations with pre-industrial CO₂ emissions and zero non-CO₂ forcings after 2300 (Zickfeld et al., 2013) confirm this behaviour (Figure 12.44) seen in many earlier studies (see above). Switching off anthropogenic CO₂ emissions in 2300 leads to a continuous slow decline of atmospheric CO₂, to a significantly slower decline of global temperature and to a continuous increase in ocean thermal expansion over the course of the millennium. Larger forcings induce longer delays before the Earth system would reach equilibrium. For RCP8.5, by year 3000 (700 years after emissions have ceased) global temperature has only decreased by 1°C–2°C (relative to its peak value by 2300) and ocean thermal expansion has almost doubled (relative to 2300) and is still increasing (Zickfeld et al., 2013).

[INSERT FIGURE 12.44 HERE]

Figure 12.44: a) Compatible anthropogenic CO₂ emissions up to 2300, followed by zero emissions after 2300, b) prescribed atmospheric CO₂ concentration up to 2300 followed by projected CO₂ concentration after 2300, c) global mean surface temperature change and d) ocean thermal expansion as simulated by EMICs for the four concentration driven RCPs with all forcings included (Zickfeld et al., 2013). A 10-year smoothing was applied. The drop in temperature in 2300 is a result of eliminating all non-CO₂ forcings along with CO₂ emissions. Shadings and bars denote the minimum to maximum range. The dashed line on panel (b) indicates the pre-industrial CO₂ concentration.

The previous paragraph discussed climate change commitment from greenhouse gases that have already been emitted. Another form of commitment refers to climate change associated with heat and carbon that has gone into the land surface and oceans. This would be relevant to the consequences of a one-time removal of all of the excess CO₂ in the atmosphere and is computed by taking a transient simulation and instantaneously setting atmospheric CO₂ concentrations to initial (pre-industrial) values (Cao and Caldeira, 2010). In such an extreme case, there would be a net flux of CO₂ from the ocean and land surface to the atmosphere, releasing an amount of CO₂ representing about 30% of what was removed from the atmosphere, i.e., the airborne fraction applies equally to positive and negative emissions, and it depends on the emissions history. A related form of experiment investigates the consequences of an initial complete removal followed by sustained removal of any CO₂ returned to the atmosphere from the land surface and oceans, and is computed by setting atmospheric CO₂ concentrations to pre-industrial values and maintaining this concentration (Cao and Caldeira, 2010). In this case, only about one-tenth of the pre-existing temperature perturbation persists for more than half of a century. A similar study performed with a GFDL AOGCM where forcing was instantaneously returned to its preindustrial value, found larger residual warming, up to 30% of the pre-existing warming (Held et al., 2010).

Several studies on commitment to past emissions have demonstrated that the persistence of warming is substantially longer than the lifetime of anthropogenic greenhouse gases themselves, as a result of non-linear absorption effects as well as the slow heat transfer into and out of the ocean. In much the same way as the warming to a step increase of forcing is delayed, the cooling after setting radiative forcing to zero is also delayed. Loss of excess heat from the ocean will lead to a positive surface air temperature anomaly for decades to centuries (Held et al., 2010; Solomon et al., 2010; Bouttes et al., 2013).

A more general form of commitment is the question of how much warming we are committed to as a result of inertia and hence commitments related to the time-scales for energy system transitions and other societal, economic and technological aspects (Grubb, 1997; Washington et al., 2009; Davis et al., 2010). For example, Davis et al. (2010) estimated climate commitment of 1.3°C (range 1.1°C–1.4°C, relative to preindustrial) from existing CO₂-emitting devices under specific assumptions regarding their lifetimes. These forms of commitment however are strongly based on political, economic and social assumptions that are outside the domain of IPCC WGI and are not further considered here.

12.5.3 Forcing and Response, Timescales of Feedbacks

Equilibrium climate sensitivity (ECS), transient climate response (TCR) and climate feedbacks are useful concepts to characterize the response of a model to an external forcing perturbation. However, there are limitations to the concept of radiative forcing (Joshi et al., 2003; Shine et al., 2003; Hansen et al., 2005b;

Stuber et al., 2005), and the separation of forcings and fast (or rapid) responses (e.g., clouds changing almost instantaneously as a result of CO₂ induced heating rates rather than as a response to the slower surface warming) is sometimes difficult (Andrews and Forster, 2008; Gregory and Webb, 2008). Equilibrium warming also depends on the type of forcing (Stott et al., 2003; Hansen et al., 2005b; Davin et al., 2007). ECS is time or state dependent in some models (Senior and Mitchell, 2000; Gregory et al., 2004; Boer et al., 2005; Williams et al., 2008; Colman and McAvaney, 2009; Colman and Power, 2010), and in some but not all models climate sensitivity from a slab ocean version differs from that of coupled models or the effective climate sensitivity (see Glossary) diagnosed from a transient coupled integration (Gregory et al., 2004; Danabasoglu and Gent, 2009; Li et al., 2013a). The computational cost of coupled AOGCMs is often prohibitively large to run simulations to full equilibrium, and only a few models have performed those (Manabe and Stouffer, 1994; Voss and Mikolajewicz, 2001; Gregory et al., 2004; Danabasoglu and Gent, 2009; Li et al., 2013a). Because of the time dependence of effective climate sensitivity, fitting simple models to AOGCMs over the first few centuries may lead to errors when inferring the response on multi-century timescales. In the HadCM3 case the long term warming would be underestimated by 30% if extrapolated from the first century (Gregory et al., 2004), in other models the warming of the slab and coupled model is almost identical (Danabasoglu and Gent, 2009). The assumption that the response to different forcings is approximately additive appears to be justified for large scale temperature changes but limited for other climate variables (Boer and Yu, 2003; Sexton et al., 2003; Gillett et al., 2004; Meehl et al., 2004; Jones et al., 2007). A more complete discussion of the concept of ECS and the limitations is given in Knutti and Hegerl (2008). The CMIP5 model estimates of ECS and TCR are also discussed in Section 9.7. Despite all limitations, the ECS and TCR remain key concepts to characterize the transient and near equilibrium warming as a response to radiative forcing on timescales of centuries. Their overall assessment is given in Box 12.2.

A number of recent studies suggest that equilibrium climate sensitivities determined from AOGCMs and recent warming trends may significantly underestimate the true Earth System Sensitivity (see Glossary) which is realized when equilibration is reached on millennial timescales (Hansen et al., 2008; Rohling et al., 2009; Lunt et al., 2010; Pagani et al., 2010; Rohling and Members, 2012). The argument is that slow feedbacks associated with vegetation changes and ice sheets have their own intrinsic long timescales and are not represented in most models (Jones et al., 2009). Additional feedbacks are mostly thought to be positive but negative feedbacks of smaller magnitude are also simulated (Swingedouw et al., 2008; Goelzer et al., 2011). The climate sensitivity of a model may therefore not reflect the sensitivity of the full Earth system because those feedback processes are not considered (see also Sections 10.8, 5.3.1, 5.3.3.2, Box 5.1). Feedbacks determined in very different base state (e.g., the Last Glacial Maximum) differ from those in the current warm period (Rohling and Members, 2012), and relationships between observables and climate sensitivity are model dependent (Crucifix, 2006; Schneider von Deimling et al., 2006; Edwards et al., 2007; Hargreaves et al., 2007; Hargreaves et al., 2012). Estimates of climate sensitivity based on paleoclimate archives (Hansen et al., 2008; Rohling et al., 2009; Lunt et al., 2010; Pagani et al., 2010; Schmittner et al., 2011; Rohling and Members, 2012), most but not all based on climate states colder than present, are therefore not necessarily representative for an estimate of climate sensitivity today (see also Sections 5.3.1, 5.3.3.2, Box 5.1). Also it is uncertain on which timescale some of those Earth system feedbacks would become significant.

Equilibrium climate sensitivity undoubtedly remains a key quantity, useful to relate a change in greenhouse gases or other forcings to a global temperature change. But the above caveats imply that estimates based on past climate states very different from today, estimates based on timescales different than those relevant for climate stabilization (e.g., estimates based on climate response to volcanic eruptions), or based on forcings other than greenhouse gases (e.g., spatially non-uniform land cover changes, volcanic eruptions or solar forcing) may differ from the climate sensitivity measuring the climate feedbacks of the Earth system today, and this measure, in turn, may be slightly different from the sensitivity of the Earth in a much warmer state on timescales of millennia. The transient climate response (TCR) and the transient climate response to cumulative carbon emissions (TCRE) are often more directly relevant to evaluate short term changes and emission reductions needed for stabilization (see Section 12.5.4)

12.5.4 Climate Stabilization and Long-Term Climate Targets

This section discusses the relation between emissions and climate targets, in the context of the uncertainties characterizing both the transient and the equilibrium climate responses to emissions. ‘Climate targets’ considered here are both stabilizing temperature at a specified value and avoiding a warming beyond a predefined threshold. The latter idea of limiting peak warming is a more general concept than stabilization of temperature or atmospheric CO₂, and one that is more realistic than an exact climate stabilization which would require perpetual non-zero positive emissions to counteract the otherwise unavoidable long-term slow decrease in global temperature (Matsuno et al., 2012a) (Figure 12.44).

12.5.4.1 Background

The concept of stabilization is strongly linked to the ultimate objective of the UNFCCC, which is “to achieve [...] stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.” Recent policy discussions focused on a global temperature increase, rather than on greenhouse gas concentrations. The most prominent target currently discussed is the 2°C temperature target, i.e., to limit global temperature increase relative to preindustrial times to below 2°C. The 2°C target has been used first by the European Union as a policy target in 1996 but can be traced further back (Jaeger and Jaeger, 2010; Randalls, 2010). Climate impacts however are geographically diverse (Joshi et al., 2011) and sector specific, and no objective threshold defines when dangerous interference is reached. Some changes may be delayed or irreversible, and some impacts are likely to be beneficial. It is thus not possible to define a single critical threshold without value judgments and without assumptions on how to aggregate current and future costs and benefits. Targets other than 2°C have been proposed (e.g., 1.5°C global warming relative to preindustrial), or targets based on CO₂ concentration levels, e.g., 350 ppm in (Hansen et al., 2008). The rate of change may also be important (e.g., for adaptation). This section does not advocate or defend any threshold, nor does it judge the economic or political feasibility of such goals, but simply assesses the implications of different illustrative climate targets on allowed carbon emissions, based on our current understanding of climate and carbon cycle feedbacks.

12.5.4.2 Constraints on Cumulative Carbon Emissions

The current radiative forcing from greenhouse gases maintained indefinitely (i.e., the commitment from constant greenhouse gas concentrations) would correspond to approximately 2°C warming. That however does not imply that the commitment from past emissions has already exceeded 2°C. Part of the positive radiative forcing from greenhouse gases is currently compensated by negative aerosol forcing, and stopping greenhouse gas emissions would lead to a decrease in the greenhouse gas forcing. Actively removing CO₂ from the atmosphere, for example by the combined use of biomass energy and carbon capture and storage, would further accelerate the decrease in greenhouse gas forcing.

The total amount of anthropogenic CO₂ released in the atmosphere (often termed cumulative carbon emission) is a good indicator of the atmospheric CO₂ concentration and hence of the global warming response to CO₂. The ratio of global temperature change to total cumulative anthropogenic CO₂ emissions (transient climate response to carbon emissions, TCRE) is relatively constant over time and independent of the scenario, but is model dependent as it depends on the model cumulative airborne fraction of CO₂ and ECS/TCR (Matthews and Caldeira, 2008; Allen et al., 2009; Gregory et al., 2009; Matthews et al., 2009; Meinshausen et al., 2009; Zickfeld et al., 2009; Bowerman et al., 2011; Knutti and Plattner, 2012; Zickfeld et al., 2012; Zickfeld et al., 2013). This is consistent with an earlier study indicating that the global warming potential of CO₂ is approximately independent of the scenario (Caldeira and Kasting, 1993). The concept of a constant ratio of cumulative emissions of CO₂ to temperature holds only well until temperatures peak (see Figure 12.45e) and only for smoothly varying cumulative CO₂ emissions (Gillett et al., 2013). It does not hold for stabilization on millennial timescales or for non CO₂ forcings, and there is limited evidence for its applicability for cumulative emissions exceeding 2000 PgC due to limited simulations available (Plattner et al., 2008; Hajima et al., 2012; Matsuno et al., 2012b; Gillett et al., 2013; Zickfeld et al., 2013). For non-CO₂ forcings with shorter atmospheric life times than CO₂ the rate of emissions at the time of peak warming is more important than the cumulative emissions over time (Smith et al., 2012).

Assuming constant climate sensitivity and fixed carbon cycle feedbacks, long-term (several centuries to millennium) stabilization of global temperatures requires eventually the stabilization of atmospheric concentrations (or decreasing concentrations if the temperature should be stabilized more quickly). This

requires decreasing emissions to near-zero (Jones et al., 2006; Meehl et al., 2007b; Weaver et al., 2007; Matthews and Caldeira, 2008; Plattner et al., 2008; Allen et al., 2009; Matthews et al., 2009; Meinshausen et al., 2009; Zickfeld et al., 2009; Friedlingstein et al., 2011; Gillett et al., 2011; Roeckner et al., 2011; Knutti and Plattner, 2012; Matsuno et al., 2012a).

The relationships between cumulative emissions and temperature for various studies is shown in Figure 12.45. Note that some lines mark the evolution of temperature as a function of emissions over time while other panels show peak temperatures for different simulations. Also some models prescribe only CO₂ emissions while others use multi gas scenarios, and the time horizons differ. The warming is usually larger if non-CO₂ forcings are considered, since the net effect of the non-CO₂ forcings is positive in most scenarios (Hajima et al., 2012). Not all numbers are therefore directly comparable. Matthews et al. (2009) estimated the transient climate response to emission (TCRE) as 1°C–2.1°C per 1000 PgC (TtC, or 10¹² metric tons of carbon) (5–95%) based on the C⁴MIP model range (Figure 12.45a). The ENSEMBLES E1 show a range of 1°C–4°C per 1000 PgC (scaled from 0.5°C–2°C for 500 PgC, Figure 12.45d) (Johns et al., 2011). Rogelj et al. (2012) estimate a 5–95% range of about 1°C–2°C per 1000 PgC (Figure 12.45e) based on the MAGICC model calibrated to the C⁴MIP model range and the likely range of 2°C–4.5°C for climate sensitivity given in AR4. Allen et al. (2009) used a simple model and found 1.3°C–3.9°C per 1000 PgC (5–95%) for peak warming (Figure 12.45g) and 1.4°C–2.5°C for TCRE. The EMICs TCRE simulations suggest a range of about 1.4°C–2.5°C per 1000 PgC and a mean of 1.9°C per 1000 PgC (Zickfeld et al., 2013) (Figure 12.45h). The results by Meinshausen et al. (2009) confirm the approximate linearity between temperature and CO₂ emissions (Figure 12.45b). Their results are difficult to compare due to the shorter time period considered, but the model was found to be consistent with that of Allen et al. (2009). Zickfeld et al. (2009), using an EMIC, find a best estimate of about 1.5°C PgC⁻¹. Gillett et al. (2013) find a range of 0.8°C–2.4°C per 1000 PgC in 15 CMIP5 models and derive an observationally constrained range of 0.7°C–2.0°C per 1000 PgC. Results from much earlier model studies support the near linear relationship of cumulative emissions and global temperature, even though these studies did not discuss the linear relationship. An example is given in Figure 12.45c based on data shown in IPCC TAR Figure 13.3 (IPCC, 2001) and IPCC AR4 Figure 10.35 (Meehl et al., 2007b). The relationships between cumulative CO₂ emissions and temperature in CMIP5 are shown in Figure 12.45f for the 1% yr⁻¹ CO₂ increase scenarios and in Figure 12.45i for the RCP8.5 emission driven ESM simulations. Compatible emissions from concentration driven CMIP5 ESMs are discussed in Section 6.4.3.3.

Expert judgement based on the available evidence therefore suggests that the transient climate response to cumulative carbon emission (TCRE) is *likely* between 0.8°C–2.5°C per 1000 PgC, for cumulative CO₂ emissions less than about 2000 PgC until the time at which temperature peaks. Under these conditions, and for low to medium estimates of climate sensitivity, the TCRE is nearly identical to the peak climate response to cumulative carbon emissions. For high climate sensitivity, strong carbon cycle climate feedbacks or large cumulative emissions, the peak warming can be delayed and the peak response may be different from TCRE, but is often poorly constrained by models and observations. The range of TCRE assessed here is consistent with other recent attempts to synthesize the available evidence (NRC, 2011; Matthews et al., 2012). The results by Schwartz et al. (2010, 2012) imply a much larger warming for the carbon emitted over the historical period and have been questioned by Knutti and Plattner (2012) for neglecting the relevant response timescales and combining a transient airborne fraction with an equilibrium climate sensitivity.

The TCRE can be compared to the temperature response to emissions on a timescale of about 1000 years after emissions cease. This can be estimated from the *likely* range of equilibrium climate sensitivity (1.5°C–4.5°C) and a cumulative CO₂ airborne fraction after about 1000 years of about 25 ± 5% (Archer et al., 2009; Joos et al., 2013). Again combining the extreme values would suggest a range of 0.6°C–2.7°C per 1000 PgC, and 1.5°C per 1000 PgC for an ECS of 3°C and a cumulative airborne fraction of 25%. However, this equilibrium estimate is based on feedbacks estimated for the present day climate. Climate and carbon cycle feedbacks may increase substantially on long timescales and for high cumulative CO₂ emissions (see Section 12.5.3), introducing large uncertainties in particular on the upper bound. Based on paleoclimate data and an analytical model, Goodwin et al. (2009) estimate a long term radiative forcing of 1.5 W m⁻² for an emission of 1000 PgC. For an equilibrium climate sensitivity of 3°C this corresponds to a warming of 1.2°C on millennial timescales, consistent with the climate carbon cycle models results discussed above.

The uncertainty in TCRE is caused by the uncertainty in the physical feedbacks and ocean heat uptake (reflected in TCR) and uncertainties in carbon cycle feedbacks (affecting the cumulative airborne fraction of CO₂). TCRE only characterizes the warming due to CO₂ emissions, and contributions from non-CO₂ gases need to be considered separately when estimating likelihoods to stay below a temperature limit. Warming as a function cumulative CO₂ emissions is similar in the four RCP scenarios, and larger than that due to CO₂ alone, since non-CO₂ forcings contribute warming in these scenarios (compare Figure 12.45 panel f and i) (Hajima et al., 2012).

Box 12.2: Equilibrium Climate Sensitivity and Transient Climate Response

Equilibrium climate sensitivity (ECS) and Transient Climate Response (TCR) are useful metrics summarising the global climate system's temperature response to an externally-imposed radiative forcing. ECS is defined as the equilibrium change in annual mean global surface temperature following a doubling of the atmospheric CO₂ concentration (see Glossary), while TCR is defined as the annual mean global surface temperature change at the time of CO₂ doubling following a linear increase in CO₂ forcing over a period of 70 years (see Glossary). Both metrics have a broader application than these definitions imply: ECS determines the eventual warming in response to stabilisation of atmospheric composition on multi-century timescales, while TCR determines the warming expected at a given time following any steady increase in forcing over a 50- to 100-year timescale.

ECS and TCR can be estimated from various lines of evidence. The estimates can be based on the values of ECS and TCR diagnosed from climate models (Section 9.7.1, Table 9.5), or they can be constrained by analysis of feedbacks in climate models (see Section 9.7.2), patterns of mean climate and variability in models compared to observations (Section 9.7.3.3), temperature fluctuations as reconstructed from paleoclimate archives (Section 5.3.1, 5.3.3.2, Box 5.1), observed and modelled short term perturbations of the energy balance like those caused by volcanic eruptions (Section 10.8), and the observed surface and ocean temperature trends since preindustrial (see Section 10.8.1, 10.8.2; Figure 10.20). For many applications, the limitations of the forcing-feedback analysis framework and the dependence of feedbacks on timescales and the climate state (see Section 12.5.3) must be kept in mind. Some studies estimate the TCR as the ratio of global mean temperature change to radiative forcing (Section 10.8.2.2) (Gregory and Forster, 2008; Padilla et al., 2011; Schwartz, 2012). Those estimates are scaled by the radiative forcing of $2 \times \text{CO}_2$ (3.7 W m^{-2}) (Myhre et al., 1998) to be comparable to TCR in the following discussion.

Newer studies of constraints based on the observed warming since preindustrial, analysed using simple and intermediate complexity models, improved statistical methods, and several different and newer datasets, are assessed in detail in Section 10.8.2. Together with results from feedback analysis and paleoclimate constraints (Section 5.3.1, 5.3.3.2, Box 5.1) these studies show ECS is *likely* between 1.5°C–4.5°C (*medium confidence*) and *extremely unlikely* less than 1.0°C (see Section 10.8.2). A few studies argued for very low values of climate sensitivity, but many of them have received criticism in the literature (see Section 10.8.2). Estimates based on AOGCMs and feedback analysis indicate a range of 2°C–4.5°C, with the CMIP5 model

mean at 3.2°C, similar to CMIP3. A summary of published ranges and PDFs of equilibrium climate sensitivity is given in Box 12.2, Figure 1. Distributions and ranges for the transient climate response are shown in Box 12.2, Figure 2.

[INSERT BOX 12.2, FIGURE 1 HERE]

Box 12.2, Figure 1: Probability density functions, distributions and ranges for equilibrium climate sensitivity, based on Figure 10.20b plus climatological constraints shown in IPCC AR4 (Meehl et al., 2007b, Box 10.2, Figure 1), and results from CMIP5 (Table 9.5). The grey shaded range marks the *likely* 1.5°C–4.5°C range, grey solid line the *extremely unlikely* less than 1°C, the grey dashed line the *very unlikely* greater than 6°C. See Figure 10.20b and Chapter 10 Supplementary Material for full caption and details. Labels refer to studies since AR4.

[INSERT BOX 12.2, FIGURE 2 HERE]

Box 12.2, Figure 2: Probability density functions, distributions and ranges (5–95%) for the transient climate response from different studies, based on Figure 10.20a, and results from CMIP5 (black histogram, Table 9.5). The grey shaded range marks the *likely* 1°C–2.5°C range, the grey solid line marks the *extremely unlikely* greater than 3°C. See Figure 10.20a and Chapter 10 Supplementary Material for full caption and details.

Simultaneously imposing different constraints from the observed warming trends, volcanic eruptions, model climatology, and paleoclimate, e.g., by using a distribution obtained from the Last Glacial Maximum as a prior for the 20th century analysis, yields a more narrow range for climate sensitivity (see Figure 10.20; Section 10.8.2.5) (e.g., Annan and Hargreaves, 2006; Hegerl et al., 2006; Annan and Hargreaves, 2011b; Aldrin et al., 2012). However, such methods are sensitive to assumptions of independence of the various lines of evidence, which might have shared biases (Lemoine, 2010), and the assumption that each individual line of evidence is unbiased and its uncertainties are captured completely. Expert elicitations for PDFs of climate sensitivity exist (Morgan and Keith, 1995; Zickfeld et al., 2010), but have also received some criticism (Millner et al., 2013). They are not used formally here because the experts base their opinion on the same studies as we assess. The peer-reviewed literature provides no consensus on a formal statistical method to combine different lines of evidence. All methods in general are sensitive to the assumed prior distributions. These limitations are discussed in detail in Section 10.8.2.

Based on the combined evidence from observed climate change including the observed 20th century warming, climate models, feedback analysis and paleoclimate, equilibrium climate sensitivity (ECS) is *likely* in the range 1.5°C–4.5°C with *high confidence*. ECS is positive, *extremely unlikely* less than 1°C (*high confidence*), and *very unlikely* greater than 6°C (*medium confidence*). The upper limit of the likely range is unchanged compared to AR4. The lower limit of the likely range of 1.5°C is less than the lower limit of 2°C in AR4. This change reflects the evidence from new studies of observed temperature change, using the extended records in atmosphere and ocean. These studies suggest a best fit to the observed surface and ocean warming for ECS values in the lower part of the likely range. Note that these studies are not purely observational, because they require an estimate of the response to radiative forcing from models. In addition, the uncertainty in ocean heat uptake remains substantial (see Section 3.2, Box 13.1). Accounting for short term variability in simple models remains challenging, and it is important not to give undue weight to any short time period which might be strongly affected by internal variability (see Box 9.2). On the other hand, AOGCMs show very good agreement with observed climatology with ECS values in the upper part of the 1.5°C–4.5°C range (Section 9.7.3.3), but the simulation of key feedbacks like clouds remains challenging in those models. The estimates from the observed warming, paleoclimate, and from climate models are consistent within their uncertainties, each is supported by many studies and multiple datasets, and in combination they provide *high confidence* for the assessed likely range. Even though this assessed range is similar to previous reports (Charney, 1979; IPCC, 2001), confidence today is much higher as a result of high quality and longer observational records with a clearer anthropogenic signal, better process understanding, more and better understood evidence from paleoclimate reconstructions, and better climate models with higher resolution that capture many more processes more realistically. Box 12.2 Figure 1 illustrates that all these lines of evidence individually support the assessed likely range of 1.5°C–4.5°C.

The tails of the ECS distribution are now better understood. Multiple lines of evidence provide *high confidence* that an ECS value less than 1°C is *extremely unlikely*. The assessment that ECS is *very unlikely* greater than 6°C is an expert judgment informed by several lines of evidence. First, the comprehensive climate models used in the CMIP5 exercise produce an ECS range of 2.1°C–4.7°C (Table 9.5), very similar to CMIP3. Second, comparisons of perturbed-physics ensembles against the observed climate find that

models with ECS values in the range 3°C–4°C show the smallest errors for many fields (Section 9.7.3.3). Third, there is increasing evidence that the aerosol radiative forcing of the twentieth century is not strongly negative, which makes it unlikely that the observed warming was caused by a very large ECS in response to a very small net forcing. Fourth, multiple and at least partly independent observational constraints from the satellite period, instrumental period and palaeoclimate studies continue to yield very low probabilities for ECS larger than 6°C, particularly when including most recent ocean and atmospheric data (see Box 12.2, Figure 1).

Analyses of observations and simulations of the instrumental period are estimating the effective climate sensitivity (a measure of the strengths of the climate feedbacks today, see glossary), rather than ECS directly. In some climate models ECS tends to be higher than the effective climate sensitivity (see Section 12.5.3), because the feedbacks that are represented in the models (water vapour, lapse rate, albedo and clouds) vary with the climate state. On timescales of many centuries, additional feedbacks with their own intrinsic timescales (e.g., vegetation, ice sheets; see Section 5.3.3, 12.5.3) (Jones et al., 2009; Goelzer et al., 2011) may become important but are not usually modelled. The resulting Earth System Sensitivity (ESS) is less well constrained but likely to be larger than ECS (Hansen et al., 2008; Rohling et al., 2009; Lunt et al., 2010; Pagani et al., 2010; Rohling and Members, 2012), implying that lower atmospheric CO₂ concentrations are needed to meet a given temperature target on multi-century timescales. A number of caveats, however, apply to those studies (see Section 12.5.3.1). Those long-term feedbacks have their own intrinsic timescales, and are less likely to be proportional to global mean temperature change.

For scenarios of increasing radiative forcing, TCR is a more informative indicator of future climate than ECS (Frame et al., 2005; Held et al., 2010). This assessment concludes with *high confidence* that the transient climate response (TCR) is *likely* in the range 1°C–2.5°C, close to the estimated 5–95% range of CMIP5 (1.2°C–2.4°C, see Table 9.5), is positive and *extremely unlikely* greater than 3°C. As with the ECS, this is an expert-assessed range, supported by several different and partly independent lines of evidence, each based on multiple studies, models and datasets. TCR is estimated from the observed global changes in surface temperature, ocean heat uptake and radiative forcing, the detection/attribution studies identifying the response patterns to increasing greenhouse gas concentrations (Section 10.8.1), and the results of CMIP3 and CMIP5 (Section 9.7.1). Estimating TCR suffers from fewer difficulties in terms of state- or time-dependent feedbacks (see Section 12.5.3), and is less affected by uncertainty as to how much energy is taken up by the ocean. Unlike ECS, the ranges of TCR estimated from the observed warming and from AOGCMs agree well, increasing our confidence in the assessment of uncertainties in projections over the 21st century.

Another useful metric relating directly CO₂ emissions to temperature is the transient climate response to cumulative carbon emission (TCRE) (see Sections 12.5.4 and 10.8.4). This metric is useful to determine the allowed cumulative carbon emissions for stabilization at a specific global temperature. TCRE is defined as the annual mean global surface temperature change per unit of cumulated CO₂ emissions, usually 1000 PgC, in a scenario with continuing emissions (see Glossary). It considers physical and carbon cycle feedbacks and uncertainties, but not additional feedbacks associated for example with the release of methane hydrates or large amounts of carbon from permafrost. The assessment based on climate models as well as the observed warming suggests that the TCRE is *likely* between 0.8°C–2.5°C per 1000 PgC (10¹² metric tons of carbon), for cumulative CO₂ emissions less than about 2000 PgC until the time at which temperatures peak. Under these conditions, and for low to medium estimates of climate sensitivity, the TCRE gives an accurate estimate of the peak global mean temperature response to cumulated carbon emissions. TCRE has the advantage of directly relating global mean surface temperature change to CO₂ emissions, but as a result of combining the uncertainty in both TCR and the carbon cycle response, it is more uncertain. It also ignores non-CO₂ forcings and the fact that other components of the climate system (e.g., sea level rise, ice sheets) have their own intrinsic timescales, resulting in climate change not avoided by limiting global temperature change.

[END BOX 12.2 HERE]

12.5.4.3 Conclusions and Limitations

One difficulty of the concept with climate stabilization and targets is that stabilization of global temperature does not imply stabilization for all aspects of the climate system. For example, some models show significant

hysteresis behaviour in the global water cycle, because global precipitation depends on both atmospheric CO₂ and temperature (Wu et al., 2010). Processes related to vegetation changes (Jones et al., 2009) or changes in the ice sheets (Charbit et al., 2008; Ridley et al., 2010) as well as ocean acidification, deep ocean warming and associated sea level rise (Meehl et al., 2005b; Wigley, 2005; Zickfeld et al., 2013) (see Figure 12.44d), and potential feedbacks linking, for example, ocean and the ice sheets (Gillett et al., 2011; Goelzer et al., 2011), have their own intrinsic long timescales. Those will result in significant changes hundreds to thousands of years after global temperature is stabilized. Thermal expansion, in contrast to global mean temperature, also depends on the pathway of surface temperature (Stouffer and Manabe, 1999; Bouttes et al., 2013; Zickfeld et al., 2013).

The simplicity of the concept of a cumulative carbon emission budget makes it attractive for policy (WBGU, 2009). The principal driver of long term warming is the total cumulative emission of CO₂ over time. To limit warming caused by CO₂ emissions to a given temperature target, cumulative CO₂ emissions from all anthropogenic sources therefore need to be limited to a certain budget. Higher emissions in earlier decades simply imply lower emissions by the same amount later on. This is illustrated in the RCP2.6 scenario in Figure 12.46a/b. Two idealized emission pathways with initially higher emissions (even sustained at high level for a decade in one case) eventually lead to the same warming if emissions are then reduced much more rapidly. Even a step-wise emission pathway with levels constant at 2010 and zero near mid-century would eventually lead to a similar warming as they all have identical cumulative emissions.

However, several aspects related to the concept of a cumulative carbon emission budget should be kept in mind. The ratio of global temperature and cumulative carbon is only approximately constant. It is the result of an interplay of several compensating carbon cycle and climate feedback processes operating on different timescales (a cancellation of variations in the increase in radiative forcing per ppm of CO₂, the ocean heat uptake efficiency and the airborne fraction) (Gregory et al., 2009; Matthews et al., 2009; Solomon et al., 2009). It depends on the modelled climate sensitivity and carbon cycle feedbacks. Thus, the allowed emissions for a given temperature target are uncertain (see Figure 12.45) (Matthews et al., 2009; Zickfeld et al., 2009; Knutti and Plattner, 2012). Nevertheless, the relationship is nearly linear in all models. Most models do not consider the possibility that long term feedbacks (Hansen et al., 2007; Knutti and Hegerl, 2008) may be different (see Section 12.5.3). Despite the fact that stabilization refers to equilibrium, the results assessed here are primarily relevant for the next few centuries and may differ for millennial scales. Notably, many of these limitations apply similarly to other policy targets, e.g., stabilizing the atmospheric CO₂ concentration.

Non-CO₂ forcing constituents are important, which requires either assumptions on how CO₂ emission reductions are linked to changes in other forcings (Meinshausen et al., 2006; Meinshausen et al., 2009; McCollum et al., 2013), or separate emission budgets and climate modeling for short lived and long lived gases. So far, many studies ignored non-CO₂ forcings altogether. Those that consider them find significant effects, in particular warming of several tenths of a degree for abrupt reductions in emissions of short-lived species, like aerosols (Brasseur and Roeckner, 2005; Hare and Meinshausen, 2006; Zickfeld et al., 2009; Armour and Roe, 2011; Tanaka and Raddatz, 2011) (see also FAQ 12.3). Other studies, which model reductions that explicitly target warming from short-lived non-CO₂ species only, find important short-term cooling benefits shortly after the reduction of these species (Shindell et al., 2012), but do not extend beyond 2030.

The concept of cumulative carbon also implies that higher initial emissions can be compensated by a faster decline in emissions later or by negative emissions. However, in the real world short-term and long term goals are not independent and mitigation rates are limited by economic constraints and existing infrastructure (Rive et al., 2007; Mignone et al., 2008; Meinshausen et al., 2009; Davis et al., 2010; Friedlingstein et al., 2011; Rogelj et al., 2013). An analysis of 193 published emission pathways with an energy balance model (UNEP, 2010; Rogelj et al., 2011) is shown in Figure 12.46c/d. Those emission pathways that likely limit warming below 2°C (above pre-industrial) by 2100 show emissions of about 31–46 PgCO₂-eq yr⁻¹ and 17–23 PgCO₂-eq yr⁻¹ by 2020 and 2050, respectively. Median 2010 emissions of all models are 48 PgCO₂-eq yr⁻¹. Note that, as opposed to 12.46a/b, many scenarios still have positive emissions in 2100. As these will not be zero immediately after 2100, they imply that the warming may exceed the target after 2100.

The aspects discussed above do not limit the robustness of the overall scientific assessment, but highlight factors that need to be considered when determining cumulative CO₂ emissions consistent with a given temperature target. In conclusion, taking into account the available information from multiple lines of evidence (observations, models and process understanding), the near linear relationship between cumulative CO₂ emissions and peak global mean temperature is well established in the literature and robust for cumulative total CO₂ emissions up to about 2000 PgC. It is consistent with the relationship inferred from past cumulative CO₂ emissions and observed warming, is supported by process understanding of the carbon cycle and global energy balance, and emerges as a robust result from the entire hierarchy of models.

Using a best estimate for the transient climate response to cumulative carbon emissions (TCRE) would provide a most likely value for the cumulative CO₂ emissions compatible with stabilization at a given temperature. However, such a budget would imply an about 50% probability for staying below the temperature target. Higher probabilities for staying below a temperature or concentration target require significantly lower budgets (Knutti et al., 2005; Meinshausen et al., 2009; Rogelj et al., 2012). Based on the evidence presented above, to limit warming caused by CO₂ emissions alone to be *likely* less than 2°C, total CO₂ emissions from all anthropogenic sources would need to be limited to a cumulative budget of about 1000 PgC over the entire industrial era, about half of which [460 to 630 PgC] (Section 6.3.1) have been emitted by 2011. Accounting for non-CO₂ forcings contributing to peak warming, or requiring a higher likelihood of temperatures remaining below 2°C, both imply lower cumulated CO₂ emissions. A possible release of greenhouse gases from permafrost or methane hydrates, not accounted for in current models, would also further reduce the anthropogenic CO₂ emissions compatible with a given temperature target. The concept of a fixed cumulative CO₂ budget holds not just for 2°C, but for any temperature level explored with models so far (up to about 5°C, see Figures 12.44–12.46), with higher temperature levels implying larger budgets.

[INSERT FIGURE 12.46 HERE]

Figure 12.46: a) CO₂ emissions for the RCP2.6 scenario (black) and three illustrative modified emission pathways leading to the same warming, b) global temperature change relative to preindustrial for the pathways shown in panel (a). c) Grey shaded bands show IAM emission pathways over the 21st century. The pathways were grouped based on ranges of *likely* avoided temperature increase in the 21st century. Pathways in the darkest three bands *likely* stay below 2°C, 3°C, 4°C by 2100, respectively (see legend), while those in the lightest grey band are higher than that. Emission corridors were defined by, at each year, identifying the 15th to 85th percentile range of emissions and drawing the corresponding bands across the range. Individual scenarios that follow the upper edge of the bands early on tend to follow the lower edge of the band later on. Black-white lines show median paths per range, d) global temperature relative to preindustrial for the pathways in panel c. Data in panels c, d based on Rogelj et al. (2011). Coloured lines in c, d denote the four RCP scenarios.

12.5.5 Potentially Abrupt or Irreversible Changes

12.5.5.1 Introduction

This report adopts the definition of abrupt climate change used in Synthesis and Assessment Product 3.4 of the U.S. Climate Change Science Program CCSP (CCSP, 2008b). We define *abrupt climate change* as a large-scale change in the climate system that takes place over a few decades or less, persists (or is anticipated to persist) for at least a few decades, and causes substantial disruptions in human and natural systems (see Glossary). Other definitions of abrupt climate change exist. For example, in the AR4 climate change was defined as abrupt if it occurred faster than the typical time scale of the responsible forcing.

A number of components or phenomena within the Earth system have been proposed as potentially possessing critical thresholds (sometimes referred to as tipping points, (Lenton et al., 2008)), beyond which abrupt or non-linear transitions to a different state ensues. The term irreversibility is used in various ways in the literature. The AR5 report defines a perturbed state as *irreversible* on a given timescale if the recovery timescale from this state due to natural processes is significantly longer than the time it takes for the system to reach this perturbed state (see Glossary). In that context, most aspects of the climate change resulting from CO₂ emissions are irreversible, due to the long residence time of the CO₂ perturbation in the atmosphere and the resulting warming (Solomon et al., 2009). These results are discussed in Sections 12.5.2–12.5.4. Here, we also assess aspects of irreversibility in the context of abrupt change, multiple steady states and hysteresis, i.e., the question whether a change (abrupt or not) would be reversible if the forcing was reversed or

removed (e.g., Boucher et al., 2012). Irreversibility of ice sheets and sea level rise are also assessed in Chapter 13.

In this section we examine the main components or phenomena within the Earth system that have been proposed in the literature as potentially being susceptible to abrupt or irreversible change (see Table 12.4). Abrupt changes that arise from nonlinearities within the climate system are inherently difficult to assess and their timing, if any, of future occurrences is difficult to predict. Nevertheless, progress is being made exploring the potential existence of early warning signs for abrupt climate change (see e.g., Dakos et al., 2008; Scheffer et al., 2009).

Table 12.4: Components in the Earth system that have been proposed in the literature as potentially being susceptible to abrupt or irreversible change. Column 2 defines whether or not a potential change can be considered to be abrupt under the AR5 definition. Column 3 states whether or not the process is irreversible in the context of abrupt change, and also gives the typical recovery time scales. Column 4 provides an assessment, if possible, of the likelihood of occurrence of abrupt change in the 21st century for the respective components or phenomena within the Earth system, for the scenarios considered in this chapter.

Change in climate system component	Potentially abrupt (AR5 definition)	Irreversibility if forcing reversed	Projected likelihood of 21st century change in scenarios considered
Atlantic MOC collapse	Yes	Unknown	<i>Very unlikely</i> that the AMOC will undergo a rapid transition (<i>high confidence</i>)
Ice sheet collapse	No	Irreversible for millennia	<i>Exceptionally unlikely</i> that either Greenland or West Antarctic Ice sheets will suffer near-complete disintegration (<i>high confidence</i>)
Permafrost carbon release	No	Irreversible for millennia	Possible that permafrost will become a net source of atmospheric greenhouse gases (<i>low confidence</i>)
Clathrate methane release	Yes	Irreversible for millennia	<i>Very unlikely</i> that methane from clathrates will undergo catastrophic release (<i>high confidence</i>)
Tropical forests dieback	Yes	Reversible within centuries	<i>Low confidence</i> in projections of the collapse of large areas of tropical forest
Boreal forests dieback	Yes	Reversible within centuries	<i>Low confidence</i> in projections of the collapse of large areas of boreal forest
Disappearance of summer Arctic sea ice	Yes	Reversible within years to decades	<i>Likely</i> that the Arctic Ocean becomes nearly ice-free in September before mid-century under high forcing scenarios such as RCP8.5 (<i>medium confidence</i>)
Long-term droughts	Yes	Reversible within years to decades	<i>Low confidence</i> in projections of changes in the frequency and duration of megadroughts
Monsoonal circulation	Yes	Reversible within years to decades	<i>Low confidence</i> in projections of a collapse in monsoon circulations

12.5.5.2 The Atlantic Meridional Overturning

EMICs for which the stability has been systematically assessed by suitably designed hysteresis experiments robustly show a threshold beyond which the Atlantic thermohaline circulation cannot be sustained (Rahmstorf et al., 2005). This is also the case for one low-resolution ESM (Hawkins et al., 2011). However, proximity to this threshold is highly model-dependent and influenced by factors that are currently poorly understood. There is some indication that the CMIP3 climate models may generally overestimate the stability of the Atlantic Ocean circulation (Hofmann and Rahmstorf, 2009; Drijfhout et al., 2010). In particular, De Vries and Weber (2005), Dijkstra (2007), Weber et al. (2007), Huisman et al. (2010), Drijfhout et al. (2010) and Hawkins et al. (2011) suggest that the sign of net freshwater flux into the Atlantic transported through its southern boundary via the overturning circulation determines whether or not the AMOC is in a mono-stable or bi-stable state. For the preindustrial control climate of most of the CMIP3 models, Drijfhout et al. (2010) found that the salt flux was negative (implying a positive freshwater flux), indicating that they were in a mono-stable regime. However, this is not the case in the CMIP5 models where

Weaver et al. (2012) found that the majority of the models were in a bi-stable regime during RCP integrations. Observations suggest that the present day ocean is in a bi-stable regime, thereby allowing for multiple equilibria and a stable ‘off’ state of the AMOC (Bryden et al., 2011; Hawkins et al., 2011).

In addition to the main threshold for a complete breakdown of the circulation, others may exist that involve more limited changes, such as a cessation of Labrador Sea deep water formation (Wood et al., 1999). Rapid melting of the Greenland ice sheet causes increases in freshwater runoff, potentially weakening the AMOC. None of the CMIP5 simulations include an interactive ice sheet component. However, Jungclaus et al. (2006), Mikolajewicz et al. (2007), Driesschaert et al. (2007) and Hu et al. (2009) found only a slight temporary effect of increased melt water fluxes on the AMOC, that was either small compared to the effect of enhanced poleward atmospheric moisture transport or only noticeable in the most extreme scenarios.

While many more model simulations have been conducted since the AR4 under a wide range of forcing scenarios, projections of the AMOC behaviour have not changed. Based on the available CMIP5 models, EMICs and the literature, it remains *very likely* that the AMOC will weaken over the 21st century relative to preindustrial values with a best estimate decrease in 2100 of about 20–30% for the RCP4.5 scenario and 36–44% for the RCP8.5 scenario (Weaver et al., 2012) (see Section 12.4.7.2, Figure 12.35). But there is *low confidence* in the magnitude of the weakening. Drijfhout et al. (2012) show that the AMOC decrease per degree global mean temperature rise varies from 1.5 to 1.9 Sv ($10^6 \text{ m}^3 \text{ s}^{-1}$) for the CMIP5 multi model ensemble members they considered depending on the scenario, but that the standard deviation in this regression is almost half the signal.

The FIO-ESM model shows cooling over much of the Northern hemisphere that may be related to a strong reduction of the AMOC in all RCP scenarios (even RCP2.6), but the limited output available from the model precludes an assessment of the response and realism of this response. Hence it is not included the overall assessment of the likelihood of abrupt changes.

It remains *very unlikely* that the AMOC will undergo an abrupt transition or collapse in the 21st century. No model exhibits an abrupt shutdown of the AMOC after 2100 under any RCP simulation. Only one of the CMIP5 models revealed an eventual slowdown of the AMOC to an off state. But this did not occur abruptly.

As assessed by Delworth et al. (2008), for an abrupt transition of the AMOC to occur, the sensitivity of the AMOC to forcing would have to be far greater than seen in current models. Alternatively, significant ablation of the Greenland ice sheet greatly exceeding even the most aggressive of current projections would be required (Swingedouw et al., 2007; Hu et al., 2009). While neither possibility can be excluded entirely, it is *unlikely* that the AMOC will collapse beyond the end of the 21st century because of global warming based on the models and range of scenarios considered.

12.5.5.3 Ice Sheets

As detailed in Section 13.4.3, all available modelling studies agree that the Greenland ice sheet will significantly decrease in area and volume in a warmer climate as a consequence of increased melt rates not compensated for by increased snowfall rates and amplified by positive feedbacks. Conversely, the surface mass balance of the Antarctic Ice Sheet is projected to increase in most projections because increased snowfall rates outweigh melt increase (see Section 13.4.4).

Irreversibility of ice sheet volume and extent changes can arise because of the surface-elevation feedback that operates when a decrease of the elevation of the ice sheet induces a decreased surface mass balance (generally through increased melting), and therefore essentially applies to Greenland. As detailed in Section 13.4.3.3, several stable states of the Greenland Ice Sheet might exist (Charbit et al., 2008; Ridley et al., 2010; Langen et al., 2012; Robinson et al., 2012; Solgaard and Langen, 2012), and the ice sheet might irreversibly shrink to a stable smaller state once a warming threshold is crossed for a certain amount of time, with the critical duration depending on how far the temperature threshold has been exceeded. Based on the available evidence (see Section 13.4.3.3), an irreversible decrease of the Greenland Ice Sheet due to surface mass balance changes appears *very unlikely* in the 21st century but *likely* on multi-centennial to millennial time scales in the strongest forcing scenarios.

In theory (Weertman, 1974; Schoof, 2007) ice-sheet volume and extent changes can be abrupt because of the grounding line instability that can occur in coastal regions where bedrock is retrograde (that is, sloping towards the interior of the ice sheet) and below sea level (see Section 4.4.4 and Box 13.2). This essentially applies to West Antarctica, but also to parts of Greenland and East Antarctica. Furthermore, ice-shelf decay induced by oceanic or atmospheric warming might lead to abruptly accelerated ice flow further inland (De Angelis and Skvarca, 2003). Because ice sheet growth is usually a slow process, such changes could also be irreversible in the definition adopted here. The available evidence (see Section 13.4) suggests that it is *exceptionally unlikely* that the ice sheets of either Greenland or West Antarctica will suffer a near-complete disintegration during the 21st century. More generally, the potential for abrupt and/or irreversible ice sheet changes (or the initiation thereof) during the 21st century and beyond is discussed in detail in Sections 13.4.3 and 13.4.4.

12.5.5.4 Permafrost Carbon Storage

Since the IPCC AR4, estimates of the amount of carbon stored in permafrost have been significantly revised upwards (Tarnocai et al., 2009), putting the permafrost carbon stock to an equivalent of twice the atmospheric carbon pool (Dolman et al., 2010). Because of low carbon input at high latitudes, permafrost carbon is to a large part of Pleistocene (Zimov et al., 2006) or Holocene (Smith et al., 2004) origin, and its potential vulnerability is dominated by decomposition (Eglin et al., 2010). The conjunction of a long carbon accumulation time scale on one hand and potentially rapid permafrost thawing and carbon decomposition under warmer climatic conditions (Zimov et al., 2006; Schuur et al., 2009; Kuhry et al., 2010) on the other hand suggests potential irreversibility of permafrost carbon decomposition (leading to an increase of atmospheric CO₂ and/or CH₄ concentrations) on timescales of hundreds to thousands of years in a warming climate. Indeed, recent observations (Dorrepaal et al., 2009; Kuhry et al., 2010) suggest that this process, induced by widespread permafrost warming and thawing (Romanovsky et al., 2010), might be already occurring. However, the existing modelling studies of permafrost carbon balance under future warming that take into account at least some of the essential permafrost-related processes (Khvorostyanov et al., 2008; Wania et al., 2009; Koven et al., 2011; Schaefer et al., 2011; MacDougall et al., 2012; Schneider von Deimling et al., 2012) do not yield coherent results beyond the fact that present-day permafrost might become a net emitter of carbon during the 21st century under plausible future warming scenarios (*low confidence*). This also reflects an insufficient understanding of the relevant soil processes during and after permafrost thaw, including processes leading to stabilization of unfrozen soil carbon (Schmidt et al., 2011), and precludes a firm assessment of the amplitude of irreversible changes in the climate system potentially related to permafrost degassing and associated global feedbacks at this stage (see also Sections 6.4.3.4, 6.4.7.2 and FAQ 6.2).

12.5.5.5 Atmospheric Methane from Terrestrial and Oceanic Clathrates

Model simulations (Fyke and Weaver, 2006; Reagan and Moridis, 2007; Lamarque, 2008; Reagan and Moridis, 2009) suggest that clathrate deposits in shallow regions (in particular at high latitude regions and in the Gulf of Mexico) are susceptible to destabilization via ocean warming. However, concomitant sea level rise due to changes in ocean mass enhances clathrate stability in the ocean (Fyke and Weaver, 2006). A recent assessment of the potential for a future abrupt release of methane was undertaken by the U.S. Climate Change Science Program (Synthesis and Assessment Product 3.4 see Brooke et al., 2008). They concluded that it was *very unlikely* that such a catastrophic release would occur this century. However, they argued that anthropogenic warming will *very likely* lead to enhanced methane emissions from both terrestrial and oceanic clathrates (Brooke et al., 2008). While difficult to formally assess, initial estimates of the 21st century positive feedback from methane clathrate destabilization are small but not insignificant (Fyke and Weaver, 2006; Archer, 2007; Lamarque, 2008). Nevertheless, on multi-millennial timescales, the positive feedback to anthropogenic warming of such methane emissions is potentially larger (Archer and Buffett, 2005; Archer, 2007; Brooke et al., 2008). Once more, due to the difference between release and accumulation timescales, such emissions are irreversible. See also FAQ 6.2.

12.5.5.6 Tropical and Boreal Forests

12.5.5.6.1 *Tropical forests*

In today's climate, the strongest growth in the Amazon rainforest occurs during the dry season when strong insolation is combined with water drawn from underground aquifers that store the previous wet season's rainfall (Huete et al., 2006). AOGCMs do not agree about how the dry season length in the Amazon may change in the future under the SRES A1 scenario (Bombardi and Carvalho, 2009), but simulations with coupled regional climate/potential vegetation models are consistent in simulating an increase in dry season length, a 70% reduction in the areal extent of the rainforest by the end of the 21st century using the SRES A2 scenario, and an eastward expansion of the Caatinga vegetation (Cook and Vizzy, 2008; Sorensson et al., 2010). In addition, some models have demonstrated the existence of multiple equilibria of the tropical South American climate-vegetation system (e.g., Oyama and Nobre, 2003). The transition could be abrupt when the dry season becomes too long for the vegetation to survive, although the resilience of the vegetation to a longer dry period may be increased by the CO₂ fertilization effect (Zelazowski et al., 2011). Deforestation may also increase dry season length (Costa and Pires, 2010) and drier conditions increase the likelihood of wildfires that, combined with fire ignition associated with human activity, can undermine the forest's resiliency to climate change (see also Section 6.4.8.1). If climate change brings drier conditions closer to those supportive of seasonal forests rather than rainforest, fire can act as a trigger to abruptly and irreversibly change the ecosystem (Malhi et al., 2009). However the existence of refugia is an important determinant of the potential for the re-emergence of the vegetation (Walker et al., 2009).

Analysis of projected change in the climate-biome space of current vegetation distributions suggest that the risk of Amazonian forest die-back is small (Malhi et al., 2009), a finding supported by modelling when strong carbon dioxide fertilization effects on Amazonian vegetation are assumed (Rammig et al., 2010). However, the strength of carbon dioxide fertilization on tropical vegetation is poorly known (see Box 6.3). Uncertainty concerning the existence of critical thresholds in the Amazonian and other tropical rainforests purely driven by climate change therefore remains high, and so the possibility of a critical threshold being crossed in precipitation volume cannot be ruled out (Nobre and Borma, 2009; Good et al., 2011c; Good et al., 2011b). Nevertheless, there is still some question as to whether a transition of the Amazonian or other tropical rainforests into a lower biomass state could result from the combined effects of limits to carbon fertilization, climate warming, potential precipitation decline in interaction with the effects of human land-use.

12.5.5.6.2 *Boreal forest*

Evidence from field observations and biogeochemical modelling make it scientifically conceivable that regions of the boreal forest could tip into a different vegetation state under climate warming, but uncertainties on the likelihood of this occurring are very high (Lenton et al., 2008; Allen et al., 2010). This is mainly due to large gaps in knowledge concerning relevant ecosystemic and plant physiological responses to warming (Niinemets, 2010). The main response is a potential advancement of the boreal forest northward and the potential transition from a forest to a woodland or grassland state on its dry southern edges in the continental interiors, leading to an overall increase in herbaceous vegetation cover in the affected parts of the boreal zone (Lucht et al., 2006). The proposed potential mechanisms for decreased forest growth and/or increased forest mortality are: increased drought stress under warmer summer conditions in regions with low soil moisture (Barber et al., 2000; Dulamsuren et al., 2009; Dulamsuren et al., 2010); desiccation of saplings with shallow roots due to summer drought periods in the top soil layers, causing suppression of forest reproduction (Hogg and Schwarz, 1997); leaf tissue damage due to high leaf temperatures during peak summer temperatures under strong climate warming; increased insect, herbivory and subsequent fire damage in damaged or struggling stands (Dulamsuren et al., 2008). The balance of effects controlling standing biomass, fire type and frequency, permafrost thaw depth, snow volume and soil moisture remains uncertain. While the existence of, and the thresholds controlling, a potential critical threshold in the Boreal forest are extremely uncertain, its existence cannot at present be ruled out.

12.5.5.7 *Sea Ice*

Several studies based on observational data or model hindcasts suggest that the rapidly declining summer Arctic sea ice cover might reach or might already have passed a tipping point (Lindsay and Zhang, 2005; Wadhams, 2012; Livina and Lenton, 2013). Identifying Arctic sea ice tipping points from the short observational record is difficult due to high interannual and decadal variability. In some climate projections, the decrease in summer Arctic sea ice areal coverage is not gradual but is instead punctuated by 5–10 year

periods of strong ice loss (Holland et al., 2006; Vavrus et al., 2012; Döscher and Koenigk, 2013). Still, these abrupt reductions do not necessarily require the existence of a tipping point in the system or further imply an irreversible behaviour (Amstrup et al., 2010; Lenton, 2012). The 5–10 year events discussed by Holland et al. (2006) arise when large natural climate variability in the Arctic reinforces the anthropogenically-forced change (Holland et al., 2008). Positive trends on the same time scale also occur when internal variability counteracts the forced change until the middle of the 21st century (Holland et al., 2008; Kay et al., 2011; Vavrus et al., 2012).

Further work using single-column energy-balance models (Merryfield et al., 2008; Eisenman and Wettlaufer, 2009; Abbot et al., 2011) yielded mixed results about the possibility of tipping points and bifurcations in the transition from perennial to seasonal sea ice cover. Thin ice and snow covers promote strong longwave radiative loss to space and high ice growth rates (e.g., Bitz and Roe, 2004; Notz, 2009; Eisenman, 2012). These stabilizing negative feedbacks can be large enough to overcome the positive surface-albedo feedback and/or cloud feedback, which act to amplify the forced sea ice response. In such low-order models, the emergence of multiple stable states with increased climate forcing is a parameter-dependent feature (Abbot et al., 2011; Eisenman, 2012). For example, Eisenman (2012) showed with a single-column energy-balance model that certain parameter choices which cause thicker ice or warmer ocean under a given climate forcing make the model more prone to bifurcations and hence irreversible behaviour.

The reversibility of sea ice loss with respect to global or hemispheric mean surface temperature change has been directly assessed in AOGCMs/ESMs by first raising the CO₂ concentration until virtually all sea ice disappears year-round and then lowering the CO₂ level at the same rate as during the ramp-up phase until it reaches again the initial value (Armour et al., 2011; Boucher et al., 2012; Ridley et al., 2012; Li et al., 2013b). None of these studies show evidence of a bifurcation leading to irreversible changes in Arctic sea ice. AOGCMs have also been used to test summer Arctic sea ice recovery after either sudden or very rapid artificial removal, and all had sea ice return within a few years (Schröder and Connolley, 2007; Sedláček et al., 2011; Tietsche et al., 2011). In the Antarctic, as a result of the strong coupling between the Southern Ocean's surface and the deep ocean, the sea ice areal coverage in some of the models integrated with ramp-up and ramp-down atmospheric CO₂ concentration exhibits a significant lag relative to the global or hemispheric mean surface temperature (Ridley et al., 2012; Li et al., 2013b), so that its changes may be considered irreversible on centennial time scales.

Diagnostic analyses of a few global climate models have shown abrupt sea ice losses in the transition from seasonal to year-round Arctic ice-free conditions after raising CO₂ to very high levels (Winton, 2006b; Ridley et al., 2008; Li et al., 2013b), but without evidence for irreversible changes. Winton (2006b; 2008) hypothesized that the small ice cap instability (North, 1984) could cause such an abrupt transition. With a low-order Arctic sea ice model, Eisenman and Wettlaufer (2009) also found an abrupt change behaviour in the transition from seasonal ice to year-round ice-free conditions, accompanied by an irreversible bifurcation to a new stable, annually ice-free state. They concluded that the cause is a loss of the stabilizing effect of sea ice growth when the ice season shrinks in time. The Arctic sea ice may thus experience a sharp transition to annually ice-free conditions, but the irreversible nature of this transition seems to depend on the model complexity and structure.

In conclusion, rapid summer Arctic sea ice losses are *likely* to occur in the transition to seasonally ice-free conditions. These abrupt changes might have consequences throughout the climate system as noted by Vavrus et al. (2011) for cloud cover and Lawrence et al. (2008b) for the high-latitude ground state. Furthermore, the interannual-to-decadal variability in the summer Arctic sea ice extent is projected to increase in response to global warming (Holland et al., 2008; Goosse et al., 2009). These studies suggest that large anomalies in Arctic sea ice areal coverage, like the ones that occurred in 2007 and 2012, might become increasingly frequent. However, there is little evidence in global climate models of a tipping point (or critical threshold) in the transition from a perennially ice-covered to a seasonally ice-free Arctic Ocean beyond which further sea ice loss is unstoppable and irreversible.

12.5.5.8 Hydrologic Variability: Long-Term Droughts and Monsoonal Circulation

12.5.5.8.1 Long Term Droughts

As noted in Sections 5.5.2.4 and 5.6.2, long-term droughts (often called megadroughts, see Glossary) are a recurring feature of Holocene paleoclimate records in North America, east and south Asia, Europe, Africa and India. The transitions into and out of the long-term droughts take many years. Since the long-term droughts all ended they are not irreversible. Nonetheless transitions over years to a decade into a state of long-term drought would have impacts on human and natural systems.

AR4 climate model projections (Milly et al., 2008) and CMIP5 ensembles (Figure 12.23) both suggest widespread drying and drought across most of southwestern North America and many other subtropical regions by the mid to late 21st century (see Section 12.4.5), although without abrupt change. Some studies suggest that this subtropical drying may have already begun in southwestern North America (Seager et al., 2007; Seidel and Randel, 2007; Barnett et al., 2008; Pierce et al., 2008). More recent studies (Hoerling et al., 2010; Seager and Vecchi, 2010; Dai, 2011; Seager and Naik, 2012) suggest that regional reductions in precipitation are primarily due to internal variability and that the anthropogenic forced trends are currently weak in comparison.

While previous long-term droughts in southwest North America arose from natural causes, climate models project that this region will undergo progressive aridification as part of a general drying and poleward expansion of the subtropical dry zones driven by rising greenhouse gases (Held and Soden, 2006; Seager et al., 2007; Seager and Vecchi, 2010). The models project the aridification to intensify steadily as radiative forcing and global warming progress without abrupt changes. Because of the very long lifetime of the anthropogenic atmospheric CO₂ perturbation, such drying induced by global warming would be largely irreversible on millennium time scale (Solomon et al., 2009; Frölicher and Joos, 2010; Gillett et al., 2011) (see Sections 12.5.2 and 12.5.4). For example, Solomon et al. (2009) found in a simulation where atmospheric CO₂ increases to 600 ppm followed by zero emissions, that the 15% reduction in precipitation in areas such as southwest North America, southern Europe and western Australia would persist long after emissions ceased. This however is largely a consequence of the warming persisting for centuries after emissions cease rather than an irreversible behaviour of the water cycle itself.

12.5.5.8.2 Monsoonal circulation

Climate model simulations and paleo-reconstructions provide evidence of past abrupt changes in Saharan vegetation, with the “green Sahara” conditions (Hoelzmann et al., 1998) of the African Humid Period (AHP) during the mid-Holocene serving as the most recent example. However, Mitchell (1990) and Claussen et al. (2003) note that the mid-Holocene is not a direct analogue for future greenhouse gas-induced climate change since the forcings are different: a increased shortwave forcing in the Northern Hemisphere summer versus a globally and seasonally uniform atmospheric CO₂ increase, respectively. Paleoclimate examples suggest that a strong radiative or SST forcing is needed to achieve a rapid climate change, and that the rapid changes are reversible when the forcing is withdrawn. Both the abrupt onset and termination of the AHP were triggered when northern African summer insolation was 4.2% higher than present day, representing a local increase of about 19 W m⁻² (deMenocal et al., 2000). Note that the globally-averaged radiative anthropogenic forcing from 1750 to 2011 (Table 8.7) is small compared to this local increase in insolation. A rapid Saharan greening has been simulated in a climate model of intermediate complexity forced by a rapid increase in atmospheric CO₂, with the overall extent of greening depending on the equilibrium atmospheric CO₂ level reached (Claussen et al., 2003). Abrupt Saharan vegetation changes of the Younger Dryas are linked with a rapid AMOC weakening which is considered very unlikely during the 21st century and unlikely beyond that as a consequence of global warming.

Studies with conceptual models (Zickfeld et al., 2005; Levermann et al., 2009) have shown that the Indian summer monsoon can operate in two stable regimes: besides the “wet” summer monsoon, a stable state exists which is characterized by low precipitation over India. These studies suggest that any perturbation of the radiative budget that tends to weaken the driving pressure gradient has the potential to induce abrupt transitions between these two regimes.

Numerous studies with coupled ocean-atmosphere models have explored the potential impact of anthropogenic forcing on the Indian monsoon (see also Section 14.2). When forced with anticipated increases in greenhouse gas concentrations, the majority of these studies show an intensification of the rainfall associated with the Indian summer monsoon (Meehl and Washington, 1993; Kitoh et al., 1997;

Douville et al., 2000; Hu et al., 2000; May, 2002; Ueda et al., 2006; Kripalani et al., 2007; Stowasser et al., 2009; Cherchi et al., 2010). Despite the intensification of precipitation, several of these modelling studies show a weakening of the summer monsoon circulation (Kitoh et al., 1997; May, 2002; Ueda et al., 2006; Kripalani et al., 2007; Stowasser et al., 2009; Cherchi et al., 2010). The net effect is nevertheless an increase of precipitation due to enhanced moisture transport into the Asian monsoon region (Ueda et al., 2006). In recent years, studies with general circulation models have also explored the direct effect of aerosol forcing on the Indian monsoon (Lau et al., 2006; Meehl et al., 2008; Randles and Ramaswamy, 2008; Collier and Zhang, 2009). Considering absorbing aerosols (black carbon) only, Meehl et al. (2008) found an increase in pre-monsoonal precipitation, but a decrease in summer monsoon precipitation over parts of South Asia. In contrast, Lau et al. (2006) found an increase in May-June-July precipitation in that region. If an increase in scattering aerosols only is considered, the monsoon circulation weakens and precipitation is inhibited (Randles and Ramaswamy, 2008). More recently, Bollasina et al. (2011) showed that anthropogenic aerosols played a fundamental role in driving the recent observed weakening of the summer monsoon. Given that the effect of increased atmospheric regional loading of aerosols is opposed by the concomitant increases in greenhouse gas concentrations, it is *unlikely* that an abrupt transition to the dry summer monsoon regime will be triggered in the 21st century.

[START FAQ 12.1 HERE]

FAQ 12.1: Why are so Many Models and Scenarios Used to Project Climate Change?

Future climate is partly determined by the magnitude of future emissions of greenhouse gases, aerosols and other natural and man-made forcings. These forcings are external to the climate system, but modify how it behaves. Future climate is shaped by the Earth's response to those forcings, along with internal variability inherent in the climate system. A range of assumptions about the magnitude and pace of future emissions helps scientists develop different emission scenarios, upon which climate model projections are based.

Different climate models, meanwhile, provide alternative representations of the Earth's response to those forcings, and of natural climate variability. Together, ensembles of models, simulating the response to a range of different scenarios, map out a range of possible futures, and help us understand their uncertainties.

Predicting socio-economic development is arguably even more difficult than predicting the evolution of a physical system. It entails predicting human behaviour, policy choices, technological advances, international competition and cooperation. The common approach is to use scenarios of plausible future socio-economic development, from which future emissions of greenhouse gases and other forcing agents are derived. It has not, in general, been possible to assign likelihoods to individual forcing scenarios. Rather, a set of alternatives is used to span a range of possibilities. The outcomes from different forcing scenarios provide policy-makers with alternatives and a range of possible futures to consider.

Internal fluctuations in climate are spontaneously generated by interactions between components such as the atmosphere and the ocean. In the case of near-term climate change, they may eclipse the effect of external perturbations, like greenhouse gas increases (see Chapter 11). Over the longer term, however, the effect of external forcings is expected to dominate instead. Climate model simulations project that, after a few decades, different scenarios of future anthropogenic greenhouse gases and other forcing agents—and the climate system's response to them—will differently affect the change in mean global temperature (FAQ 12.1, Figure 1, left panel). Therefore, evaluating the consequences of those various scenarios and responses is of paramount importance, especially when policy decisions are considered.

Climate models are built on the basis of the physical principles governing our climate system, and empirical understanding, and represent the complex, interacting processes needed to simulate climate and climate change, both past and future. Analogues from past observations, or extrapolations from recent trends, are inadequate strategies for producing projections, because the future will not necessarily be a simple continuation of what we have seen thus far.

While it is possible to write down the equations of fluid motion that determine the behaviour of the atmosphere and ocean, it is impossible to solve them without using numerical algorithms through computer model simulation, similarly to how aircraft engineering relies on numerical simulations of similar types of equations. Also, many small-scale physical, biological and chemical processes, such as cloud processes,

cannot be described by those equations, either because we lack the computational ability to describe the system at a fine enough resolution to directly simulate these processes or because we still have a partial scientific understanding of the mechanisms driving these processes. Those need instead to be approximated by so-called parameterizations within the climate models, through which a mathematical relation between directly simulated and approximated quantities is established, often on the basis of observed behaviour.

There are various alternative and equally plausible numerical representations, solutions and approximations for modelling the climate system, given the limitations in computing and observations. This diversity is considered a healthy aspect of the climate modelling community, and results in a range of plausible climate change projections at global and regional scales. This range provides a basis for quantifying uncertainty in the projections, but because the number of models is relatively small, and the contribution of model output to public archives is voluntary, the sampling of possible futures is neither systematic nor comprehensive. Also, some inadequacies persist that are common to all models; different models have different strength and weaknesses; it is not yet clear which aspects of the quality of the simulations that can be evaluated through observations should guide our evaluation of future model simulations.

Models of varying complexity are commonly used for different projection problems. A faster model with lower resolution, or a simplified description of some climate processes, may be used in cases where long multi-century simulations are required, or where multiple realisations are needed. Simplified models can adequately represent large scale average quantities, like global average temperature, but finer details, like regional precipitation, can only be simulated by complex models.

The coordination of model experiments and output by groups such as the Coupled Model Intercomparison Project (CMIP), the World Climate Research Program and its Working Group on Climate Models has seen the science community step up efforts to evaluate the ability of models to simulate past and current climate and to compare future climate change projections. The 'multi-model' approach is now a standard technique used by the climate science community to assess projections of a specific climate variable.

FAQ 12.1, Figure 1, right panels, shows the temperature response by the end of the 21st century for three illustrative models and the highest and lowest RCP scenarios. Models agree on large-scale patterns of warming at the surface, for example, that the land is going to warm faster than ocean, and the Arctic will warm faster than the tropics. But they differ both in the magnitude of their global response for the same scenario, and in small scale, regional aspects of their response. The magnitude of Arctic amplification, for instance, varies among different models, and a subset of models show a weaker warming or slight cooling in the North Atlantic as a result of the reduction in deepwater formation and shifts in ocean currents.

There are inevitable uncertainties in future external forcings, and the climate system's response to them, which are further complicated by internally-generated variability. The use of multiple scenarios and models have become a standard choice in order to assess and characterise them, thus allowing us to describe a wide range of possible future evolutions of the Earth's climate.

[INSERT FAQ 12.1, FIGURE 1 HERE]

FAQ 12.1, Figure 1: Global mean temperature change averaged across all CMIP5 models (relative to 1986–2005) for the four RCP scenarios: RCP2.6 (dark blue), RCP4.5 (light blue), RCP6.0 (orange) and RCP8.5 (red); 32, 42, 25 and 39 models were used respectively for these 4 scenarios. *Likely* ranges for global temperature change by the end of the 21st century are indicated by vertical bars. Note that these ranges apply to the difference between two 20-year means, 2081–2100 relative to 1985–2005, which accounts for the bars being centred at a smaller value than the end point of the annual trajectories. For the highest (RCP8.5) and lowest (RCP2.6) scenario, illustrative maps of surface temperature change at the end of the 21st century (2081–2100 relative to 1986–2005) are shown for three CMIP5 models. These models are chosen to show a rather broad range of response, but this particular set is not representative of any measure of model response uncertainty.

[START FAQ 12.2 HERE]

FAQ 12.2: How will the Earth's Water Cycle Change?

The flow and storage of water in the Earth's climate system are highly variable, but changes beyond those due to natural variability are expected by the end of the current century. In a warmer world, there will be net increases in rainfall, surface evaporation and plant transpiration. However, there will be substantial differences in the changes between locations. Some places will experience more precipitation and an accumulation of water on land. In others, the amount of water will decrease, due to regional drying and loss of snow and ice cover.

The water cycle consists of water stored on the Earth in all its phases, along with the movement of water through the Earth's climate system. In the atmosphere, water occurs primarily as a gas—water vapour—but it also occurs as ice and liquid water in clouds. The ocean, of course, is primarily liquid water, but the ocean is also partly covered by ice in polar regions. Terrestrial water in liquid form appears as surface water—such as lakes and rivers—soil moisture and groundwater. Solid terrestrial water occurs in ice sheets, glaciers, snow and ice on the surface and in permafrost and seasonally frozen soil.

Statements about future climate sometimes say that the water cycle will accelerate, but this can be misleading, for strictly speaking, it implies that the cycling of water will occur more and more quickly with time and at all locations. Parts of the world will indeed experience intensification of the water cycle, with larger transports of water and more rapid movement of water into and out of storage reservoirs. However, other parts of the climate system will experience substantial depletion of water, and thus less movement of water. Some stores of water may even vanish.

As the Earth warms, some general features of change will occur simply in response to a warmer climate. Those changes are governed by the amount of energy that global warming adds to the climate system. Ice in all forms will melt more rapidly, and be less pervasive. For example, for some simulations assessed in this report, summer Arctic sea ice disappears before the middle of this century. The atmosphere will have more water vapour, and observations and model results indicate that it already does. By the end of this century, the average amount of water vapour in the atmosphere could increase by 5–25%, depending on the amount of human emissions of greenhouse gases and radiatively active particles, such as smoke. Water will evaporate more quickly from the surface. Sea level will rise, due to expansion of warming ocean waters and melting land ice flowing into the ocean (see FAQ 13.2).

These general changes are modified by the complexity of the climate system, so that they should not be expected to occur equally in all locations or at the same pace. For example, circulation of water in the atmosphere, on land and in the ocean can change as climate changes, concentrating water in some locations and depleting it in others. The changes also may vary throughout the year: some seasons tend to be wetter than others. Thus, model simulations assessed in this report show that winter precipitation in northern Asia may increase by over 50%, whereas summer precipitation there is projected to hardly change. Humans also intervene directly in the water cycle, through water management and changes in land-use. Changing population distributions and water practices would produce further changes in the water cycle.

Water cycle processes can occur over minutes, hours, days and longer, and over distances from meters to kilometres and greater. Variability on these scales is typically greater than for temperature, so climate changes in precipitation are harder to discern. Despite this complexity, projections of future climate show changes that are common across many models and climate forcing scenarios. Similar changes were reported in the Fourth Assessment Report. These results collectively suggest well understood mechanisms of change, even if magnitudes vary with model and forcing. We focus here on changes over land, where changes in the water cycle have their largest impact on human and natural systems.

Projected climate changes from simulations assessed in this report (shown schematically in FAQ 12.2, Figure 1) generally show an increase in precipitation in the tropics and polar latitudes that could exceed 50% by the end of this century under the most extreme emissions scenario. In contrast, large areas of the subtropics could have decreases of 30% or more. In the tropics, these changes appear to be governed by increases in atmospheric water vapour and changes in atmospheric circulation that further concentrate water vapour in the tropics and thus promote more tropical rainfall. In the subtropics, these circulation changes simultaneously promote less rainfall despite warming in these regions. Because the subtropics are home to most of the world's deserts, these changes imply increasing aridity in already dry areas, and possible expansion of deserts.

Increases at higher latitudes are governed by warmer temperatures, which allow more water in the atmosphere and thus, more water that can precipitate. The warmer climate also allows storm systems in the extratropics to transport more water vapour into the higher latitudes, without requiring substantial changes in typical wind strength. As indicated above, high latitude changes are more pronounced during the colder seasons.

Whether land becomes drier or wetter depends partly on precipitation changes, but also on changes in surface evaporation and transpiration from plants (together called evapotranspiration). Because a warmer atmosphere can have more water vapour, it can induce greater evapotranspiration, given sufficient terrestrial water. However, increased carbon dioxide in the atmosphere reduces a plant's tendency to transpire into the atmosphere, partly counteracting the effect of warming.

In the tropics, increased evapotranspiration tends to counteract the effects of increased precipitation on soil moisture, whereas in the subtropics, already low amounts of soil moisture allow for little change in evapotranspiration. At higher latitudes, the increased precipitation generally outweighs increased evapotranspiration in projected climates, yielding increased annual mean runoff, but mixed changes in soil moisture. As implied by circulation changes in FAQ 12.2, Figure 1, boundaries of high or low moisture regions may also shift.

A further complicating factor is the character of rainfall. Model projections show rainfall becoming more intense, in part because more moisture will be present in the atmosphere. Thus, for simulations assessed in this report, over much of the land, 1-day precipitation events that currently occur on average every 20 years could occur every 10 years or even more frequently by the end of this century. At the same time, projections also show that precipitation events overall will tend to occur less frequently. These changes produce two seemingly contradictory effects: more intense downpours, leading to more floods, yet longer dry periods between rain events, leading to more drought.

At high latitudes and at high elevation, further changes occur due to the loss of frozen water. Some of these are resolved by the present generation of global climate models (GCMs), and some changes can only be inferred because they involve features such as glaciers, which typically are not resolved or included in the models. The warmer climate means that snow tends to start accumulating later in the fall, and melt earlier in the spring. Simulations assessed in this report show March–April snow cover in the Northern Hemisphere is projected to decrease by approximately 10–30% on average by the end of this century, depending on the greenhouse gas scenario. The earlier spring melt alters the timing of peak springtime flow in rivers receiving snowmelt. As a result, later flow rates will decrease, potentially affecting water resource management. These features appear in GCM simulations.

Loss of permafrost will allow moisture to seep more deeply into the ground, but it will also allow the ground to warm, which could enhance evapotranspiration. However, most current GCMs do not include all the processes needed to simulate well permafrost changes. Studies analysing soils freezing or using GCM output to drive more detailed land models suggest substantial permafrost loss by the end of this century. In addition, even though current GCMs do not explicitly include glacier evolution, we can expect that glaciers will continue to recede, and the volume of water they provide to rivers in the summer may dwindle in some locations as they disappear. Loss of glaciers will also contribute to a reduction in springtime river flow. However, if annual mean precipitation increases—either as snow or rain—then these results do not necessarily mean that annual mean river flow will decrease.

[INSERT FAQ 12.2, FIGURE 1 HERE]

FAQ 12.2, Figure 1: Schematic diagram of projected changes in major components of the water cycle. The blue arrows indicate major types of water movement changes through the Earth's climate system: poleward water transport by extratropical winds, evaporation from the surface and runoff from the land to the oceans. The shaded regions denote areas more likely to become drier or wetter. Yellow arrows indicate an important atmospheric circulation change by the Hadley circulation, whose upward motion promotes tropical rainfall, while suppressing subtropical rainfall. Model projections indicate that the Hadley circulation will shift its downward branch poleward in both the Northern and Southern Hemispheres, with associated drying. Wetter conditions are projected at high latitudes, because a warmer atmosphere will allow greater precipitation, with greater movement of water into these regions.

[END FAQ 12.2 HERE]

[START FAQ 12.3 HERE]

FAQ 12.3: What would Happen to Future Climate if We Stopped Emissions Today?

Stopping emissions today is a scenario that is not plausible, but it is one of several idealized cases that provide insight into the response of the climate system and carbon cycle. As a result of the multiple timescales in the climate system, the relation between change in emissions and climate response is quite complex, with some changes still occurring long after emissions ceased. Models and process understanding show that as a result of the large ocean inertia and the long lifetime of many greenhouse gases, primarily carbon dioxide, much of the warming would persist for centuries after greenhouse gas emissions have stopped.

When emitted in the atmosphere, greenhouse gases get removed through chemical reactions with other reactive components or, in the case of carbon dioxide (CO₂), get exchanged with the ocean and the land. These processes characterize the lifetime of the gas in the atmosphere, defined as the time it takes for a concentration pulse to decrease by a factor of e (2.71). How long greenhouse gases and aerosols persist in the atmosphere varies over a wide range, from days to thousands of years. For example, aerosols have a lifetime of weeks, methane (CH₄) of about 10 years, nitrous oxide (N₂O) of about 100 years and hexafluoroethane (C₂F₆) of about 10,000 years. CO₂ is more complicated as it is removed from the atmosphere through multiple physical and biogeochemical processes in the ocean and the land; all operating at different time scales. For an emission pulse of about 1000 PgC, about half is removed within a few decades, but the remaining fraction stays in the atmosphere for much longer. About 20% of the CO₂ pulse is still in the atmosphere after 1000 years.

As a result of the significant lifetimes of major anthropogenic greenhouse gases, the increased atmospheric concentration due to past emissions will persist long after emissions are ceased. Concentration of greenhouse gases would not return immediately to their pre-industrial levels if emissions were halted. Methane concentration would return to values close to pre-industrial level in about 50 years, N₂O concentrations would need several centuries, while CO₂ would essentially never come back to its preindustrial level on timescales relevant for our society. Changes in emissions of short-lived species like aerosols on the other hand would result in nearly instantaneous changes in their concentrations.

The climate system response to the greenhouse gases and aerosols forcing is characterized by an inertia, mainly driven by the ocean. The ocean has a very large capacity of absorbing heat and a slow mixing between the surface and the deep ocean. This means that it will take several centuries for the whole ocean to warm up and to reach equilibrium with the altered radiative forcing. The surface ocean (and hence the continents) will continue to warm until it reaches a surface temperature in equilibrium with this new radiative forcing. The AR4 showed that if concentration of greenhouse gases were held constant at present day level, the Earth surface would still continue to warm by about 0.3°C over the 21st century relative to the year 2000. This is the climate commitment to current concentrations (or constant composition commitment), shown in grey in FAQ 12.3, Figure 1. Constant emissions at current levels would further increase the atmospheric concentration and result in much more warming than observed so far (FAQ 12.3, Figure 1, red lines).

Even if anthropogenic greenhouse gas emissions were halted now, the radiative forcing due to these long-lived greenhouse gases concentrations would only slowly decrease in the future, at a rate determined by the lifetime of the gas (see above). Moreover, the climate response of the Earth system to that radiative forcing would be even slower. Global temperature would not respond quickly to the greenhouse gas concentration changes. Eliminating CO₂ emissions only would lead to near constant temperature for many centuries. Eliminating short-lived negative forcings from sulphate aerosols at the same time (e.g., by air pollution reduction measures) would cause a temporary warming of a few tenths of a degree, as shown in blue in FAQ 12.3, Figure 1. Setting all emissions to zero would therefore, after a short warming, lead to a near stabilization of the climate for multiple centuries. This is called the commitment from past emissions (or zero future emission commitment). The concentration of GHG would decrease and hence the radiative forcing as well, but the inertia of the climate system would delay the temperature response.

As a consequence of the large inertia in the climate and carbon cycle, the long-term global temperature is largely controlled by total CO₂ emissions that have accumulated over time, irrespective of the time when they were emitted. Limiting global warming below a given level (e.g., 2°C above pre-industrial) therefore implies a given budget of CO₂, i.e., higher emissions earlier implies stronger reductions later. A higher climate target allows for a higher CO₂ concentration peak, and hence larger cumulative CO₂ emissions (e.g., permitting a delay in the necessary emission reduction).

Global temperature is a useful aggregate number to describe the magnitude of climate change, but not all changes will scale linearly global temperature. Changes in the water cycle for example also depend on the type of forcing (e.g., greenhouse gases, aerosols, land use change), slower components of the Earth System such as sea level rise and ice sheet would take much longer to respond, and there may be critical thresholds or abrupt or irreversible changes in the climate system.

3

4 **Table 12.1:** Radiative forcing agents in the CMIP5 multi-model global climate projections. See Table 9.A.1 for descriptions of the models and main model references. ESMs are
5 highlighted in bold. Numeric superscripts indicate model-specific references that document forcing implementations. Forcing agents are mostly implemented in close conformance
6 with standard prescriptions (Taylor et al., 2012) and recommended datasets (Lamarque et al., 2010; Cionni et al., 2011; Lamarque et al., 2011; Meinshausen et al., 2011c) provided
7 for CMIP5. Variations in forcing implementations are highlighted with superscripts and expanded in the table footnotes. Entries mean: n.a.: Forcing agent is not included in either the
8 historical or future scenario simulations; Y: Forcing agent included (via prescribed concentrations, distributions or time series data); E: Concentrations of forcing agent calculated
9 interactively driven by prescribed emissions or precursor emissions; Es: Concentrations of forcing agent calculated interactively constrained by prescribed surface concentrations.
10 For a more detailed classification of ozone chemistry and ozone forcing implementations in CMIP5 models see Eyring et al. (2013).

¹¹ Li et al. (2013c)

¹² Bao et al. (2013)

¹³ Levy II et al. (2013)

¹⁴ Shindell et al. (2013a). GISS-E2-R and GISS-E2-H model variants are forced similarly and both represented here as GISS-E2. Both -R and -H model versions have three variants: in physics version 1 (p1) aerosols and ozone are specified from pre-computed transient aerosol and ozone fields, in physics version 2 (p2) aerosols and atmospheric chemistry are calculated online as a function of atmospheric state and transient emissions inventories, while in physics version 3 (p3) atmospheric composition is calculated as for p2 but the aerosol impacts on clouds (and hence the aerosol indirect effect) is calculated interactively. In p1 and p2 variants the aerosol indirect effect is parameterized following Hansen et al. (2005b).

¹⁵ HadGEM2-AO is forced in a similar way to HadGEM2-ES and HadGEM2-CC following Jones et al. (2011), but tropospheric ozone, stratospheric ozone and land cover are prescribed.

Additional notes:

^{cc} Separate entries for CO₂ denote “concentration-driven” and “emissions-driven” experiments as indicated.

^{ac} “Cloud albedo effect” and “Cloud lifetime effect” are classical terms (as used in AR4) to describe indirect effects of radiative forcing associated with aerosols. They relate to the revised terminologies defined in Chapter 7 and used in AR5: “Radiative forcing from aerosol-cloud interactions (RFaci)” and “Effective radiative forcing from aerosol-cloud interactions (ERFaci)”. RFaci equates to cloud albedo effect, while ERFaci is the effective forcing resulting from cloud albedo effect plus cloud lifetime effect, including all rapid adjustments to cloud lifetime and thermodynamics (Section 7.1.3, Figure 7.3).

^p Physiological forcing effect of CO₂ via plant stomatal response and evapotranspiration (Betts et al., 2007) included.

- 1 ^{rc} Separate entries denote different treatments used for radiation and chemistry respectively.
- 2 ^{hf} Separate entries denote treatment for historical and future (RCPs) respectively.
- 3 ^a Three-dimensional tropospheric ozone, stratospheric ozone, methane, and/or aerosol distributions specified as monthly 10-year mean concentrations, computed off-line using
- 4 CAM-Chem – a modified version of CAM3.5 with interactive chemistry – driven with specified emissions for the historical period (Lamarque et al., 2010) and RCPs (Lamarque et
- 5 al., 2011) with sea surface temperature and sea ice boundary conditions based on CCSM3's projections for the closest corresponding AR4 scenarios.
- 6 ^b Ozone prescribed using the original or slightly modified IGAC/SPARC ozone dataset (Cionni et al., 2011); in some models this dataset is modified to add a future solar cycle and in
- 7 some models tropospheric ozone is zonally averaged.
- 8 ^c Linearized 2D ozone chemistry scheme (Cariolle and Teyssedre, 2007) including transport and photochemistry, reactive to stratospheric chlorine concentrations but not
- 9 tropospheric chemical emissions.
- 10 ^d Ozone prescribed using the dataset described in (Hansen et al., 2007), with historical tropospheric ozone being calculated by a CCM and stratospheric ozone taken from Randel and
- 11 Wu (2007) in the past. Tropospheric ozone is held constant from 1990 onwards, while stratospheric ozone is constant from 1997 to 2003 and then returned linearly to its 1979 value
- 12 over the period 2004 to 2050.
- 13 ^e For IPSL-CM5 model versions, ozone and aerosol concentrations are calculated semi-offline with the atmospheric general circulation model including interactive chemistry and
- 14 aerosol, following the four RCPs in the future (Dufresne et al., 2013; Szopa et al., 2013). The same aerosol concentration fields (but not ozone) are also prescribed for the CNRM-
- 15 CM5 model.
- 16 ^f Ozone concentrations computed off-line by Kawase et al. (2011) using a CCM forced with CMIP5 emissions.
- 17 ^g Ozone concentrations computed off-line by Sudo et al. (2003) for the historical period and Kawase et al. (2011) for the future.
- 18 ^h Time dependent climatology based on simulations and observations; aerosols are distinguished only with respect to coarse and fine mode, and anthropogenic and natural origins,
- 19 not with respect to composition.
- 20 ^{op} Separate entries denote different ozone chemistry precursors.
- 21 ^{so} RFac1 from sulphate aerosol only.
- 22 st Separate entries denote stratosphere and troposphere respectively.
- 23 ^{ic} Radiative effects of aerosols on ice clouds are represented.
- 24 ^{pd} Prognostic or diagnostic scheme for dust/sea salt aerosol with emissions/concentrations determined by the model state rather than externally prescribed.
- 25 ^{fx} Fixed prescribed climatology of dust/sea salt aerosol concentrations with no year-to-year variability.
- 26 ^{v0} Explosive volcanic aerosol returns rapidly in future to zero (or near-zero) background, like that in the pre-industrial control experiment.
- 27 ^{v1} Explosive volcanic aerosol returns rapidly in future to constant (average volcano) background, the same as in the pre-industrial control experiment.
- 28 ^{v2} Explosive volcanic aerosol returns slowly in future (over several decades) to constant (average volcano) background like that in the pre-industrial control experiment.
- 29 ^{v3} Explosive volcanic aerosol returns rapidly in future to near-zero background, below that in the pre-industrial control experiment.
- 30 ^{v4} Explosive volcanic aerosol set to zero in future, but constant (average volcano) background in the pre-industrial control experiment.
- 31 ^{v5} Explosive volcanic aerosol returns slowly in future (over several decades) to constant (average volcano) background, but zero background in the pre-industrial control experiment.
- 32 ^{cr} Land use change represented via crop change only.
- 33 ^{or} Realistic time-varying orbital parameters for solar forcing (in historical period only for GISS-E2).
- 34
- 35

Chapter 12: Long-term Climate Change: Projections, Commitments and Irreversibility

Coordinating Lead Authors: Matthew Collins (UK), Reto Knutti (Switzerland)

Date of Draft: 7 June 2013

Figures

Figure 12.1: A summary of the output used to make the CMIP5 figures in this chapter (and some figures in Chapter 11). The climate variable names run along the horizontal axis and use the standard abbreviations in the CMIP5 protocol (Taylor et al., 2012, and online references therein). The climate model names run along the vertical axis. In each box the shading indicates the number of ensemble members available for historical, RCP2.6, RCP4.5, RCP6.0, RCP8.5 and pre-industrial control experiments, although only one ensemble member per model is used in the relevant figures.

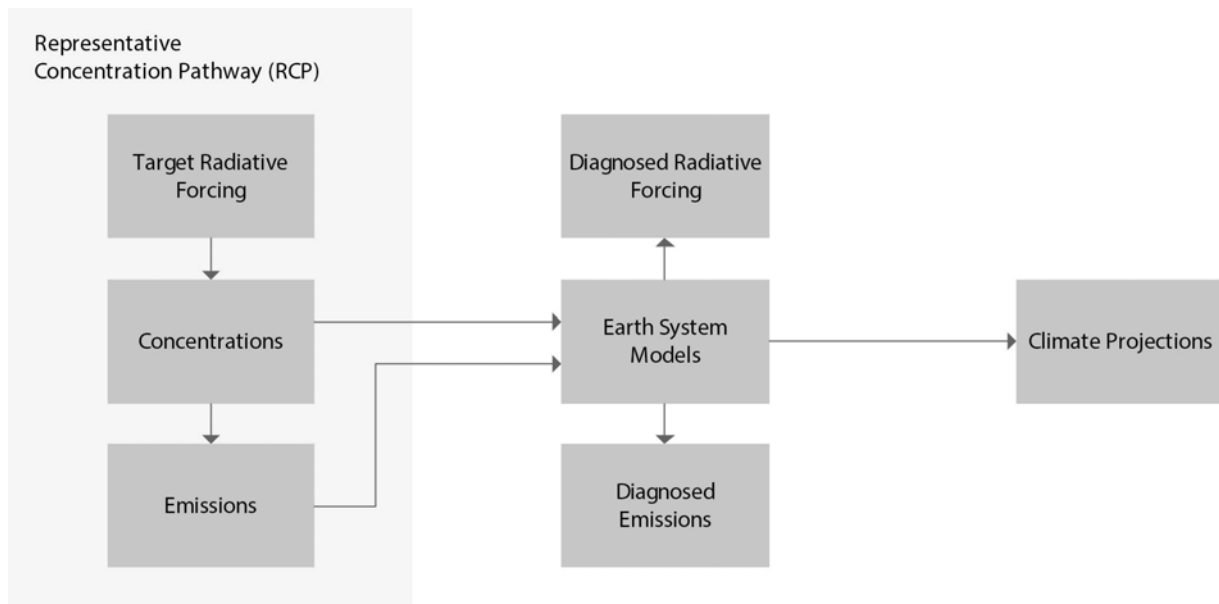

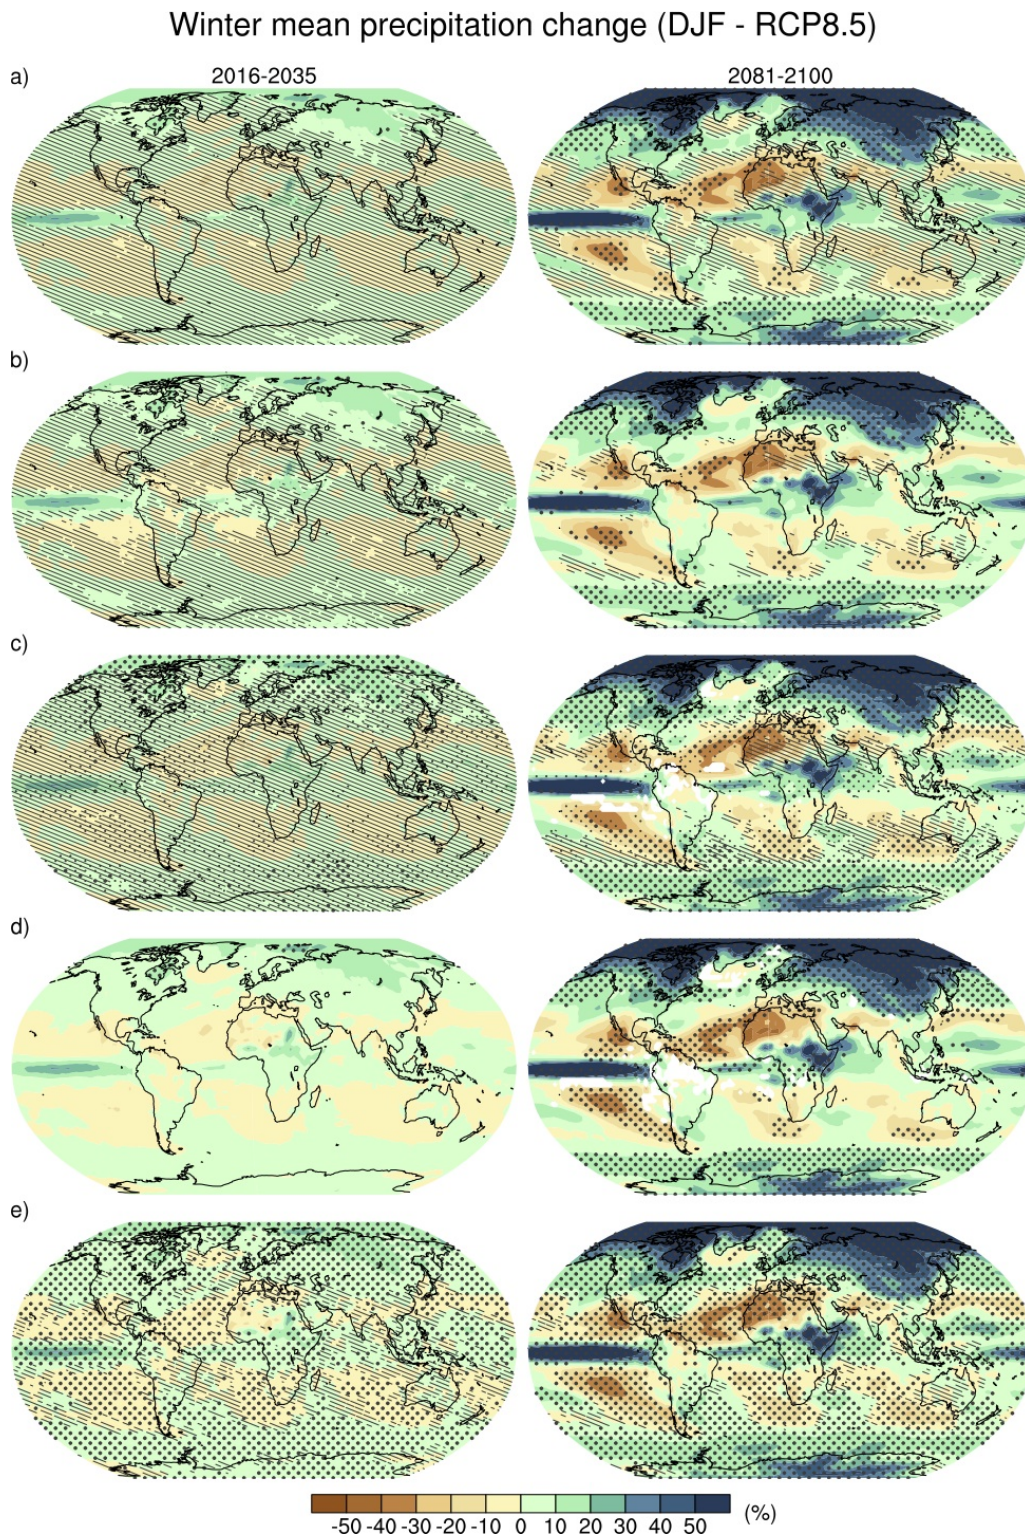

Figure 12.2: Links in the chain from scenarios, through models to climate projections. The Representative Concentration Pathways (RCPs) are designed to sample a range of radiative forcing of the climate system at 2100. The RCPs are translated into both concentrations and emissions of greenhouse gases using Integrated Assessment Models (IAMs). These are then used as inputs to dynamical Earth System Models (ESMs) in simulations that are either concentration-driven (the majority of projection experiments) or emissions-driven (only run for RCP8.5). Aerosols and other forcing factors are implemented in different ways in each ESM. The ESM projections each have a potentially different radiative forcing, which may be viewed as an output of the model and which may not correspond to precisely the level of radiative forcing indicated by the RCP nomenclature. Similarly, for concentration-driven experiments, the emissions consistent with those concentrations diagnosed from the ESM may be different from those specified in the RCP (diagnosed from the IAM). Different models produce different responses even under the same radiative forcing. Uncertainty propagates through the chain and results in a spread of ESM projections. This spread is only one way of assessing uncertainty in projections. Alternative methods, which combine information from simple and complex models and observations through statistical models or expert judgment, are also used to quantify that uncertainty.

Box 12.1, Figure 1: Projected change in December to February precipitation for 2016–2035 and 2081–2100, relative to 1986–2005 from CMIP5 models. The choice of the variable and time frames is just for illustration of how the different methods compare in cases with low and high signal-to-noise (left and right column, respectively). The color maps are identical along each column and only stippling and hatching differ on the basis of the different methods. Different methods for stippling and hatching are shown determined from a) from relating the model mean to internal variability, b) as in a) but hatching here indicates high agreement for “small change”, c) by the robustness measure by Knutti and Sedláček (2013) d) by the method proposed by Tebaldi et al. (2011) and e) by the method by Power et al. (2012). Detailed technical explanations for each method are given in the text. The number of CMIP5 models used is indicated in the upper right corner of each panel.

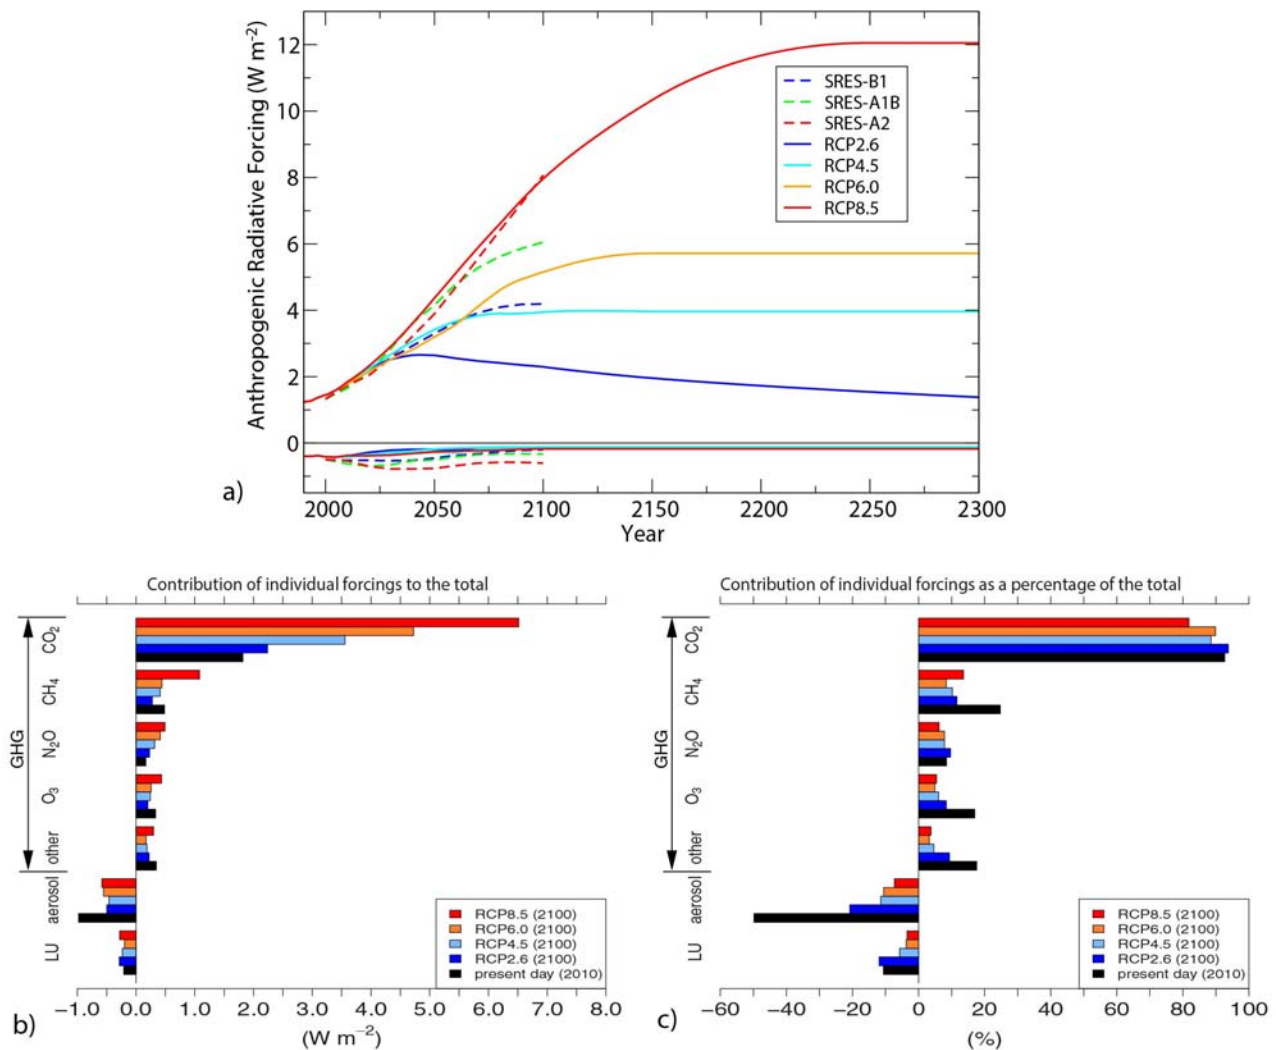

Figure 12.3: (a) Time evolution of the total anthropogenic (positive) and anthropogenic aerosol (negative) radiative forcing relative to preindustrial (~1765) between 2000 and 2300 for RCP scenarios and their extensions (continuous lines), and SRES scenarios (dashed lines) as computed by the integrated assessment models (IAMs) used to develop those scenarios. The four RCP scenarios used in CMIP5 are: RCP2.6 (dark blue), RCP4.5 (light blue), RCP6.0 (orange) and RCP8.5 (red). The three SRES scenarios used in CMIP3 are: B1 (blue, dashed), A1B (green, dashed) and A2 (red, dashed). Positive values correspond to the total anthropogenic radiative forcing. Negative values correspond to the forcing from all anthropogenic aerosol-radiation interactions (i.e., direct effects only). The total radiative forcing of the SRES and RCP families of scenarios differs in 2000 because the number of forcings represented and our knowledge about them have changed since the TAR. The total radiative forcing of the RCP family is computed taking into account the efficacy of the various forcings (Meinshausen et al., 2011a). (b) Contribution of the individual anthropogenic forcings to the total radiative forcing in year 2100 for the four RCP scenarios and at present day (year 2010). The individual forcings are gathered into seven groups: CO₂, CH₄, N₂O, ozone (O₃), other GHGs, aerosol (all effects unlike in (a), i.e., aerosols-radiation and aerosol-cloud interactions, aerosol deposition on snow) and land use (LU). (c) As in b, but the individual forcings are relative to the total radiative forcing (i.e., RF_x/RF_{tot} , in %, with RF_x individual radiative forcings and RF_{tot} total radiative forcing). Note that the radiative forcings in (b) and (c) are not efficacy adjusted, unlike in (a). The values shown in (a) are summarised in Table AII.6.8. The values shown in (b) and (c) have been directly extracted from data files (hosted at <http://tntcat.iiasa.ac.at:8787/RcpDb/>) compiled by the four modelling teams that developed the RCP scenarios and are summarised in Tables AII.6.1 to AII.6.3 for CO₂, CH₄ and N₂O respectively.

Figure 12.4: Global mean radiative forcing (W m^{-2}) between 1980 and 2100 estimated by alternative methods. The baseline is circa 1850 but dependent on the methods. Dashed lines indicate the total anthropogenic plus natural (solar and volcanic) RF for the RCP scenarios as defined by Meinshausen et al. (2011b), taking into account the efficacies of the various anthropogenic forcings (Meinshausen et al., 2011a), normalised by the mean between 1850 and 1859. Solid lines are multi-model mean ERF realised in a subset of CMIP5 models for the concentration-driven historical experiment and RCP scenarios, normalised either with respect to the 1850-1869 base period or with respect to the pre-industrial control simulation (Forster et al., 2013). (The subset of CMIP5 models included is defined by Table 1 of (Forster et al., 2013) but omitting the FGOALS-s2 model, the historical and RCP simulations of which were subsequently withdrawn from the CMIP5 archive.) This CMIP5-based estimate assumes each model has an invariant climate feedback parameter, calculated from abrupt $4 \times \text{CO}_2$ experiments using the method of Gregory et al. (2004). Each individual CMIP5 model's forcing estimate is an average over all available ensemble members, and a 1-sigma inter-model range around the multi-model mean is shaded in light colour. Grey or coloured vertical bars illustrate the 1-sigma range (68% confidence interval) of anthropogenic composition forcing (excluding natural and land-use change forcings, based on ERF for aerosols combined with RF for WMGHG) estimated in ACCMIP models (Shindell et al., 2013) for time slice experiments at 1980, 2000, 2030 (RCP8.5 only) and 2100 (all RCPs). The ACCMIP ranges plotted have been converted from the 5–95% ranges given in Shindell et al. (2013) (Table 8) to a 1-sigma range. Note that the ACCMIP bars at 1980 and 2100 are shifted slightly to aid clarity. The mean ERF diagnosed from 21 CMIP3 models for the SRES A1B scenario, as in Forster and Taylor (2006), is also shown (thick green line) with a 1-sigma range (thinner green lines). The number of models included in CMIP3 and CMIP5 ensemble means is shown colour coded. (See Tables AII.6.8-AII.6.10. Note that the CMIP5 model ranges given in Table AII.6.10 are based on decadal averages and therefore differ slightly from the ranges based on annual data shown in this Figure.)

Figure 12.5: Time series of global annual mean surface air temperature anomalies (relative to 1986–2005) from CMIP5 concentration-driven experiments. Projections are shown for each RCP for the multi model mean (solid lines) and the 5–95% range (± 1.64 standard deviation) across the distribution of individual models (shading). Discontinuities at 2100 are due to different numbers of models performing the extension runs beyond the 21st century and have no physical meaning. Only one ensemble member is used from each model and numbers in the figure indicate the number of different models contributing to the different time periods. No ranges are given for the RCP6.0 projections beyond 2100 as only two models are available.

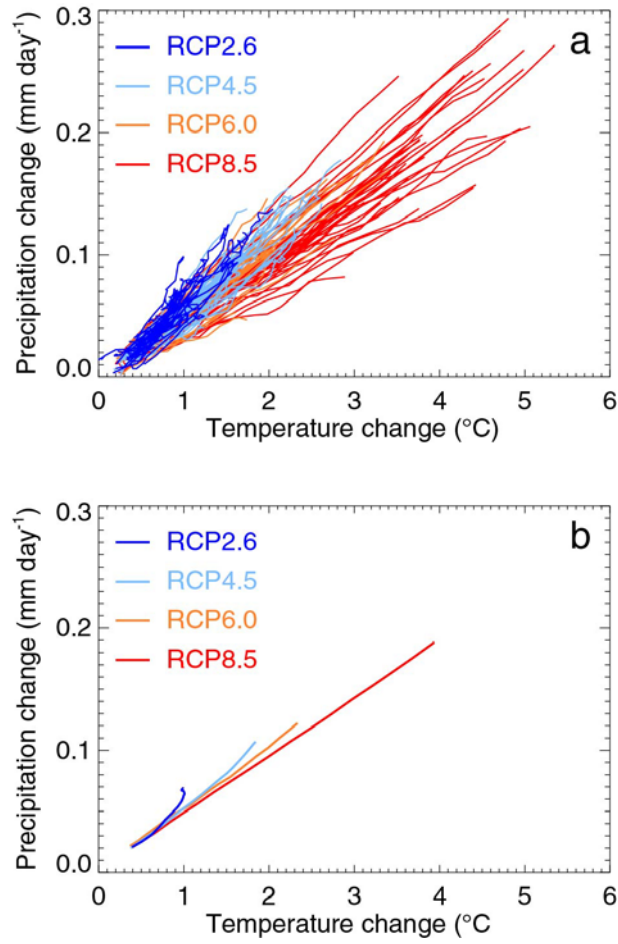

Figure 12.6: Global mean precipitation (mm day⁻¹) versus temperature (°C) changes relative to 1986–2005 baseline period in CMIP5 model concentrations-driven projections for the four RCPs for a) means over decadal periods starting in 2006 and overlapped by 5 years (2006–2015, 2011–2020, up to 2091–2100), each line representing a different model (one ensemble member per model) and b) corresponding multi-model means for each RCP.

Figure 12.7: Percentage changes over the 21st century in global, land and ocean precipitation per °C of global warming in CMIP5 model concentration-driven projections for the four RCP scenarios. Annual mean changes are calculated for each year between 2006 and 2100 from one ensemble member per model relative to its mean precipitation and temperature for the 1986–2005 baseline period, and the gradient of a least-squares fit through the annual data is derived. Land and ocean derived values use global mean temperature in the denominator of dP/dT . Each coloured symbol represents a different model, the same symbol being used for the same model for different RCPs and larger black squares being the multi-model mean. Also shown for comparison are global mean results for ENSEMBLES model concentrations-driven projections for the E1 and A1B scenarios (Johns et al., 2011), in this case using a least-squares fit derived over the period 2000–2099 and taking percentage changes relative to the 1980–1999 baseline period. Changes of precipitation over land and ocean are discussed in Section 12.4.5.2.

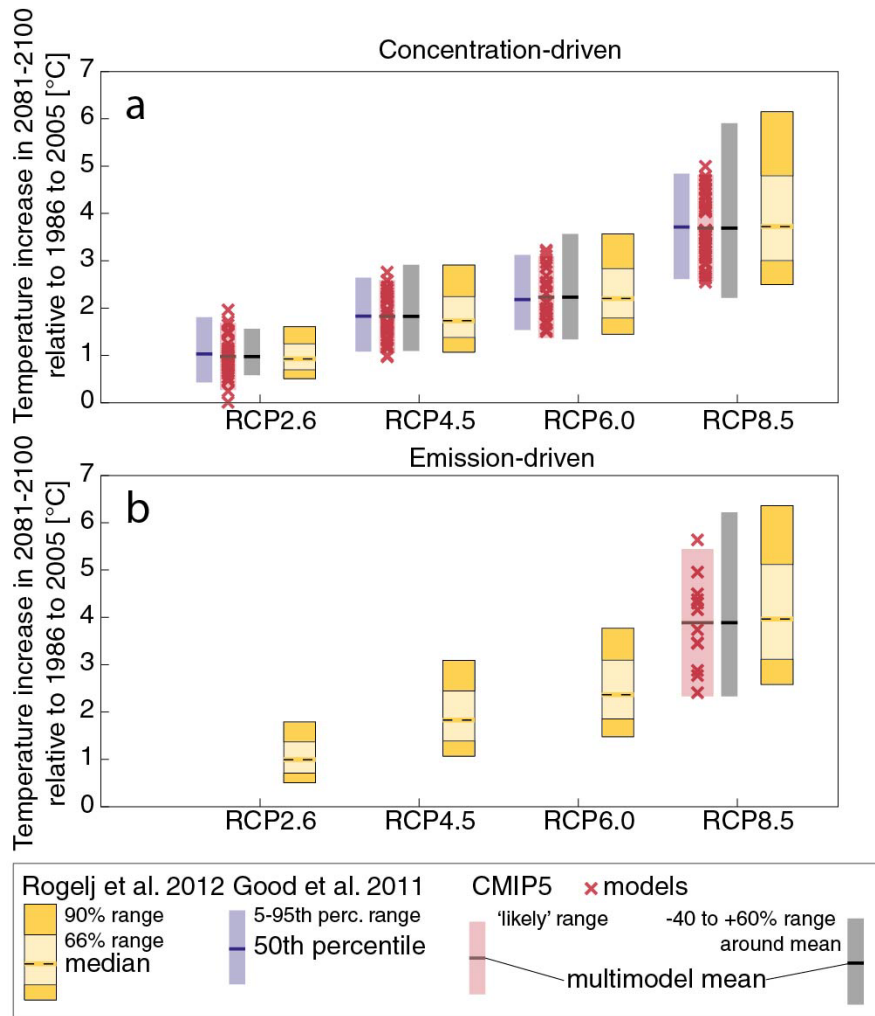

Figure 12.8: Uncertainty estimates for global mean temperature change in 2081–2100 with respect to 1986–2005. Red crosses mark projections from individual CMIP5 models. Red bars indicate mean and 5–95% ranges based on CMIP5 (1.64 standard deviations), which are considered as a *likely range*. Blue bars indicate 5–95% ranges from the pulse response emulation of 21 models (Good et al., 2011). Grey bars mark the range from the mean of CMIP5 minus 40% mean to the mean +60%, assessed as *likely* in AR4 for the SRES scenarios. The yellow bars show the median, 17–83% range and 5–95% range based on Rogelj et al. (2012). See also Figure 12.39 and 12.40.

Annual mean surface air temperature change (RCP4.5: 2081-2100)

Figure 12.9: Surface air temperature change in 2081–2100 displayed as anomalies with respect to 1986–2005 for RCP4.5 from one ensemble member of each of the concentration-driven models available in the CMIP5 archive.

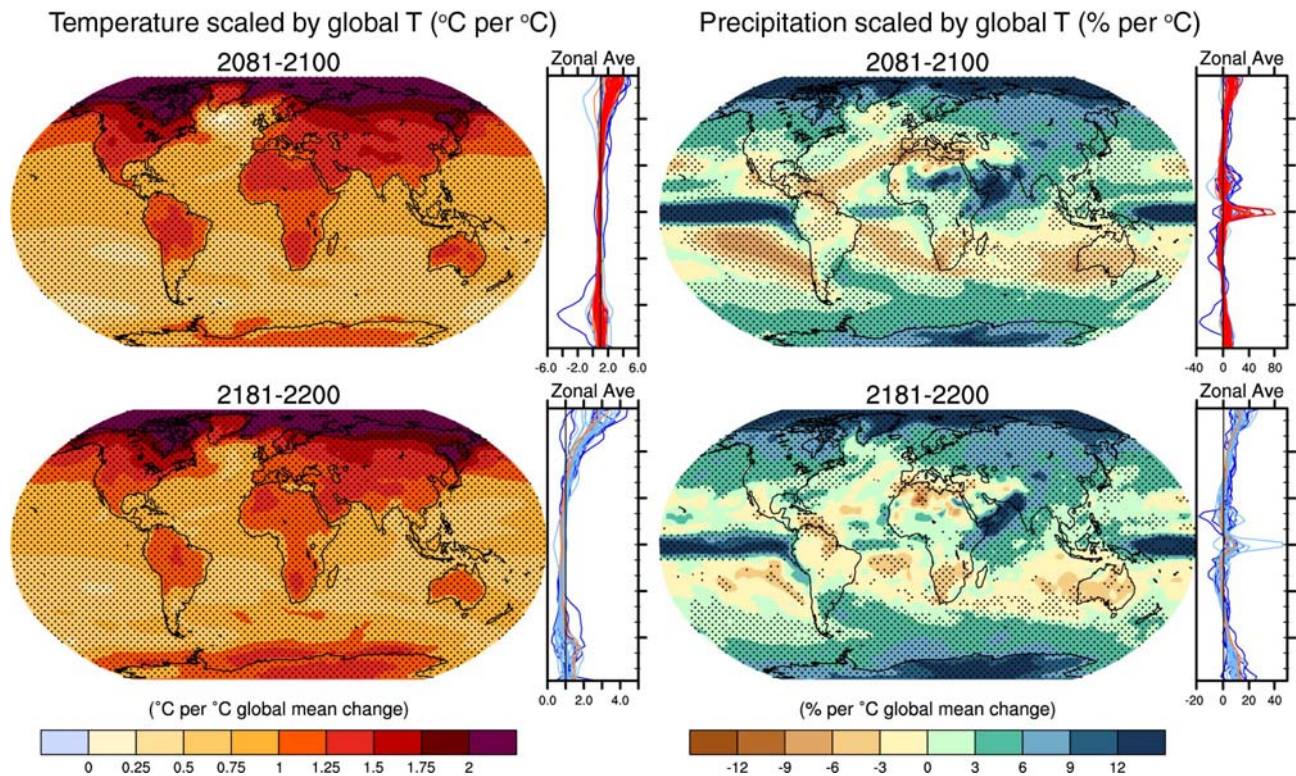

Figure 12.10: Temperature (left) and precipitation (right) change patterns derived from transient simulations from the CMIP5 ensembles, scaled to 1°C of global mean surface temperature change. The patterns have been calculated by computing 20-year averages at the end of the 21st (top) and 22nd (bottom) century and over the period 1986–2005 for the available simulations under all RCPs, taking their difference (percentage difference in the case of precipitation) and normalizing it, grid-point by grid-point, by the corresponding value of global average temperature change for each model and scenario. The normalized patterns have then been averaged across models and scenarios. The colour scale represents $^{\circ}\text{C}$ (in the case of temperature) and % (in the case of precipitation) per 1°C of global average temperature change. Stippling indicates where the mean change averaged over all realisations is larger than the 95% percentile of the distribution of models. Zonal means of the geographical patterns are shown for each individual model for RCP2.6 (blue), 4.5 (light blue), 6.0 (orange) and 8.5 (red). RCP8.5 is excluded from the stabilisation figures. The RCP2.6 simulation of the FIO-ESM model was excluded because it did not show any warming by the end of the 21st century, thus not complying with the method requirement that the pattern be estimated at a time when the temperature change signal from CO_2 increase has emerged.

Annual mean surface air temperature change

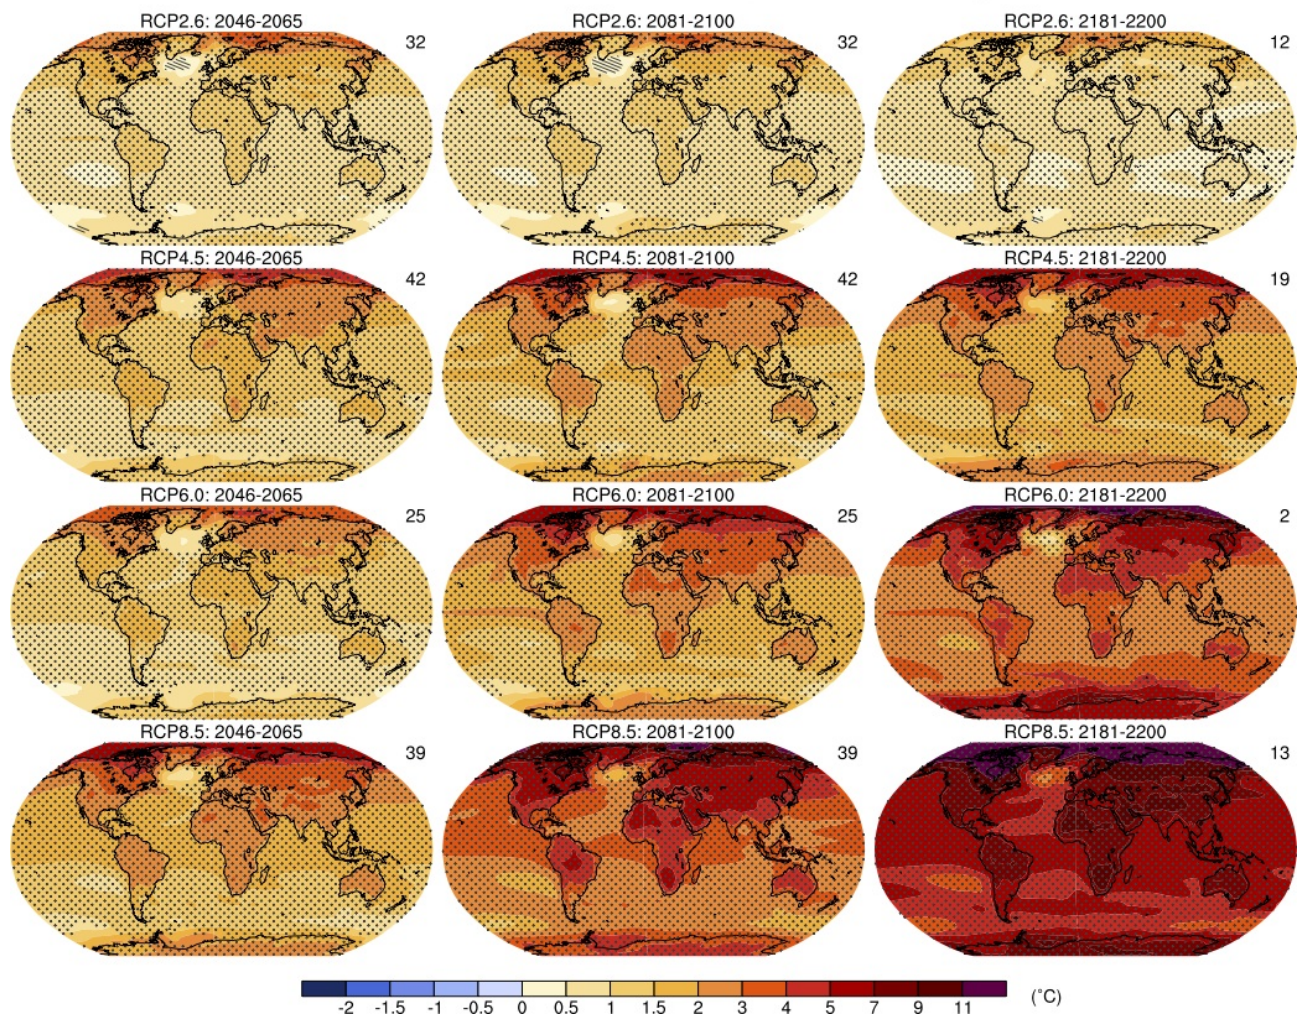

Figure 12.11: Multi model ensemble average of surface air temperature change (compared to 1986–2005 base period) for 2046–2065, 2081–2100, 2181–2200 for RCP2.6, 4.5, 6.0 and 8.5. Hatching indicates regions where the multi model mean change is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean change is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

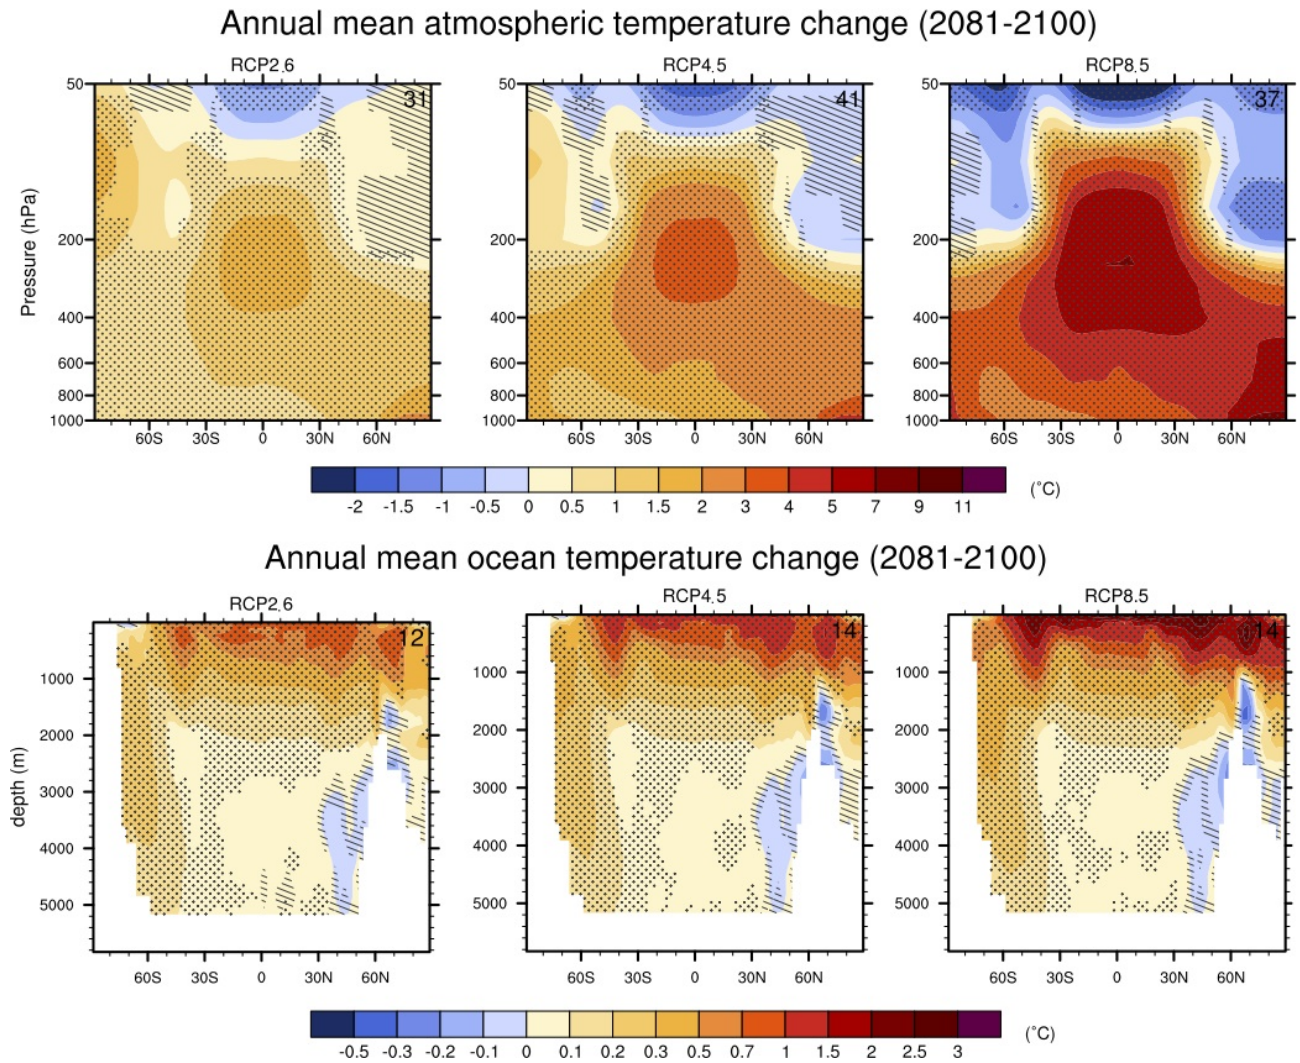

Figure 12.12: CMIP5 multi-model changes in annual mean zonal mean temperature in the atmosphere and ocean relative to 1986–2005 for 2081–2100 under the RCP2.6 (left), RCP4.5 (centre) and RCP8.5 (right) forcing scenarios. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1).

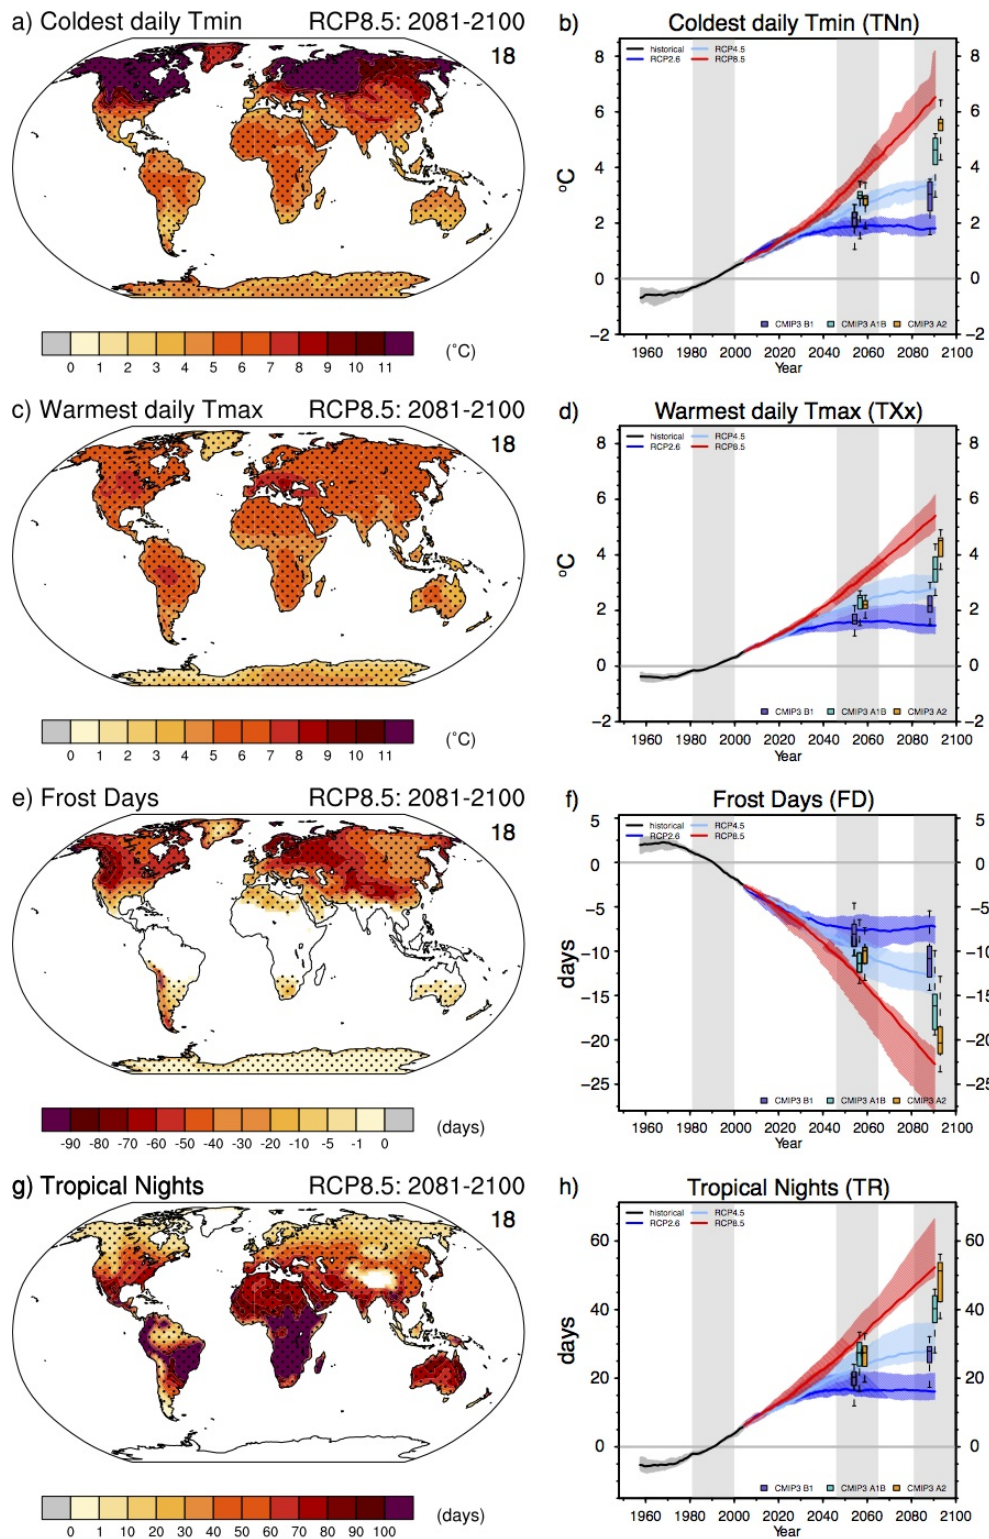

Figure 12.13: CMIP5 multi model mean geographical changes (relative to a 1981–2000 reference period in common with CMIP3) under RCP8.5 and 20-year smoothed time series for RCP2.6, RCP4.5 and RCP8.5 in the (a,b) annual minimum of minimum daily temperature, (c,d) annual maximum of maximum daily temperature, (e,f) frost days (number of days below 0°C) and (g,h) tropical nights (number of days above 20°C). White areas over land indicate regions where the index is not valid. Shading in the time series represents the interquartile ensemble spread (25th and 75th quantiles). The box-and-whisker plots show the interquartile ensemble spread (box) and outliers (whiskers) for 11 CMIP3 model simulations of the SRES scenarios A2 (orange), A1B (cyan), and B1 (purple) globally averaged over the respective future time periods (2046–2065 and 2081–2100) as anomalies from the 1981–2000 reference period. Stippling indicates grid points with changes that are significant at the 5% level using a Wilcoxon signed-ranked test. Updated from Sillmann et al. (2013), excluding the FGOALS-s2 model.

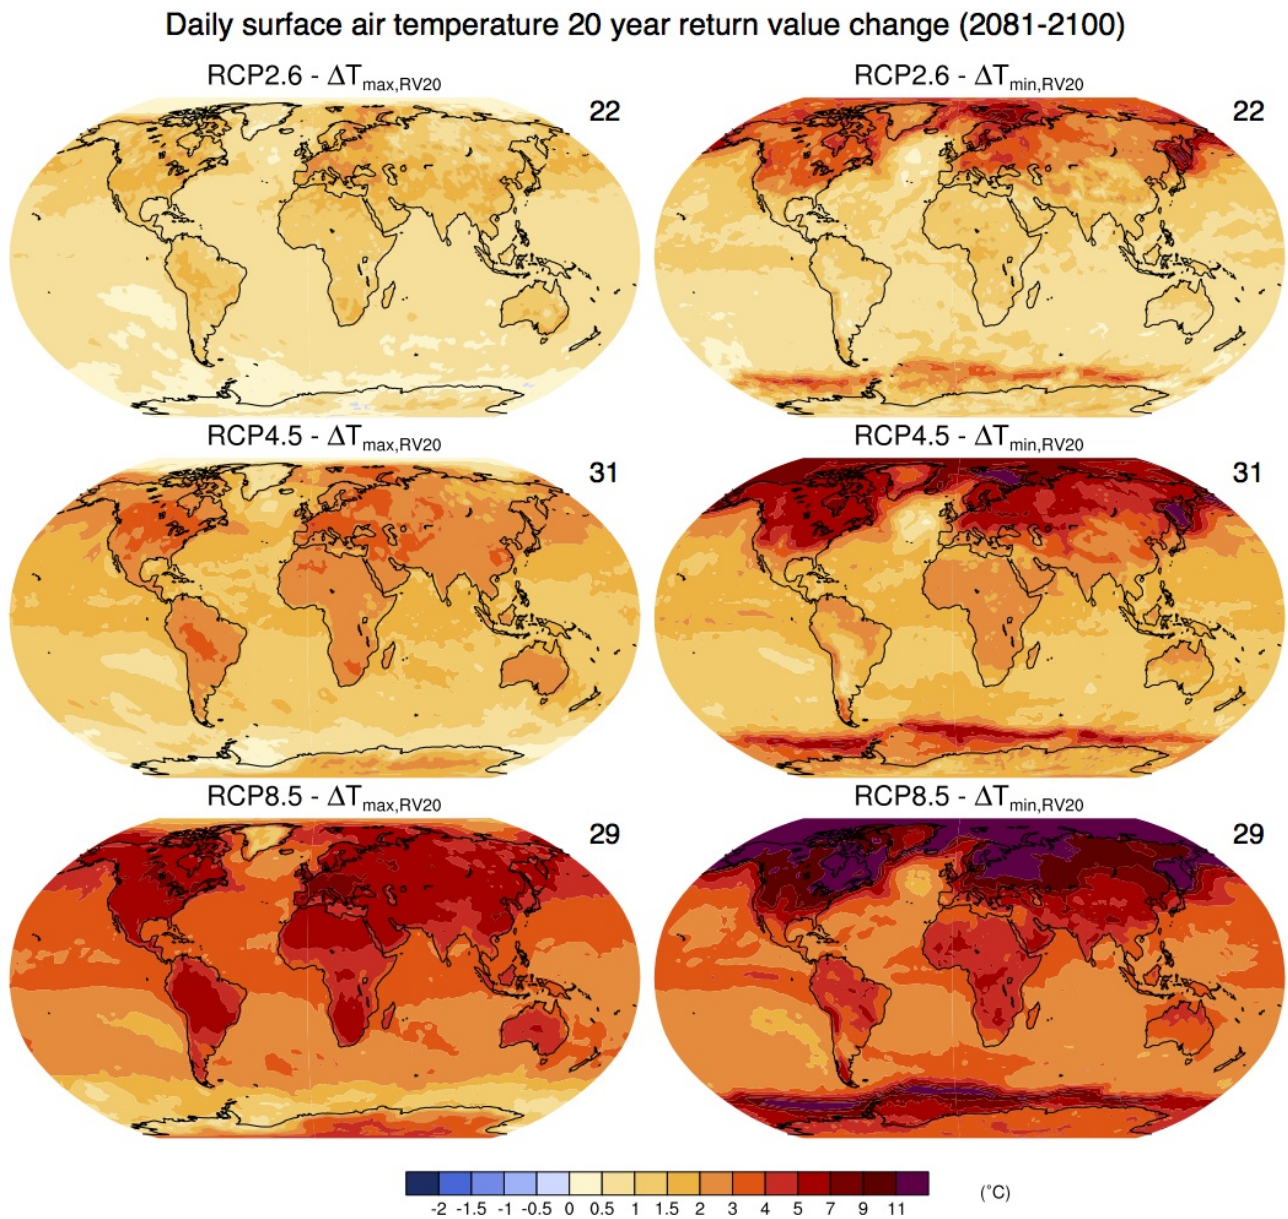

Figure 12.14: The CMIP5 multi-model median change in 20-year return values of annual warm temperature extremes (left hand panels) and cold temperature extremes (right hand panels) as simulated by CMIP5 models in 2081–2100 relative to 1986–2005 in the RCP2.6 (top panels), RCP4.5 (middle panels), and RCP8.5 (bottom panels) experiments.

Annual mean top of atmosphere radiation

Figure 12.15: Time series of global and annual multi model mean (a) net total radiation anomaly at the TOA, (b) net longwave radiation anomaly at the TOA and (c) net shortwave radiation anomaly at the TOA from the CMIP5 concentration-driven experiments for the historical period (black) and the four RCP scenarios. All the fluxes are positive downward and units are W m^{-2} . The anomalies are calculated relative to the 1900–1950 base period as this is a common period to all model experiments with few volcanic eruptions and relatively small trends. One ensemble member is used for each individual CMIP5 model and the \pm standard deviation across the distribution of individual models is shaded.

Figure 12.16: Multi-model CMIP5 average changes in annual mean (left) net total radiation anomaly at the TOA, (middle) net longwave radiation anomaly at the TOA and (right) net shortwave radiation anomaly at the TOA for the RCP4.5 scenario averaged over the periods 2081–2100. All fluxes are positive downward, units are W m^{-2} . The net radiation anomalies are computed with respect to the 1900–1950 base period. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

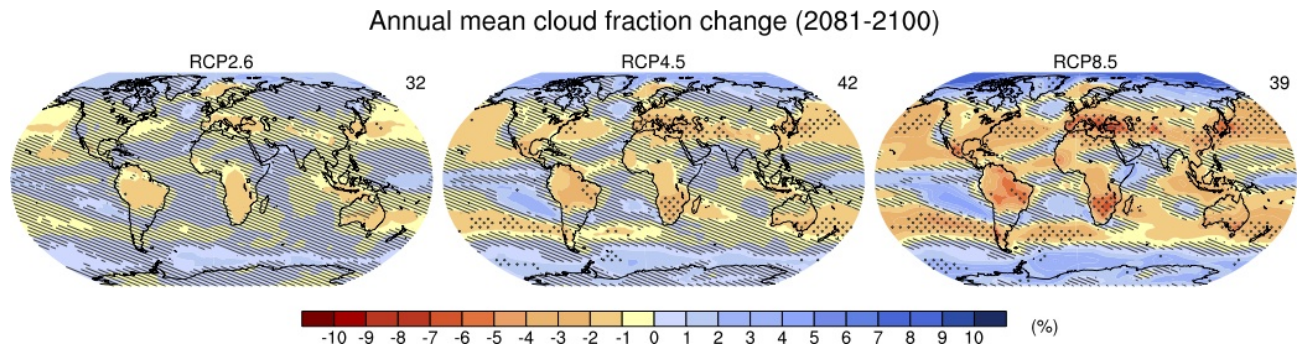

Figure 12.17: CMIP5 multi-model changes in annual mean total cloud fraction (in %) relative to 1986–2005 for 2081–2100 under the RCP2.6 (left), RCP4.5 (centre) and RCP8.5 (right) forcing scenarios. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

Seasonal mean sea level pressure change (2081-2100)

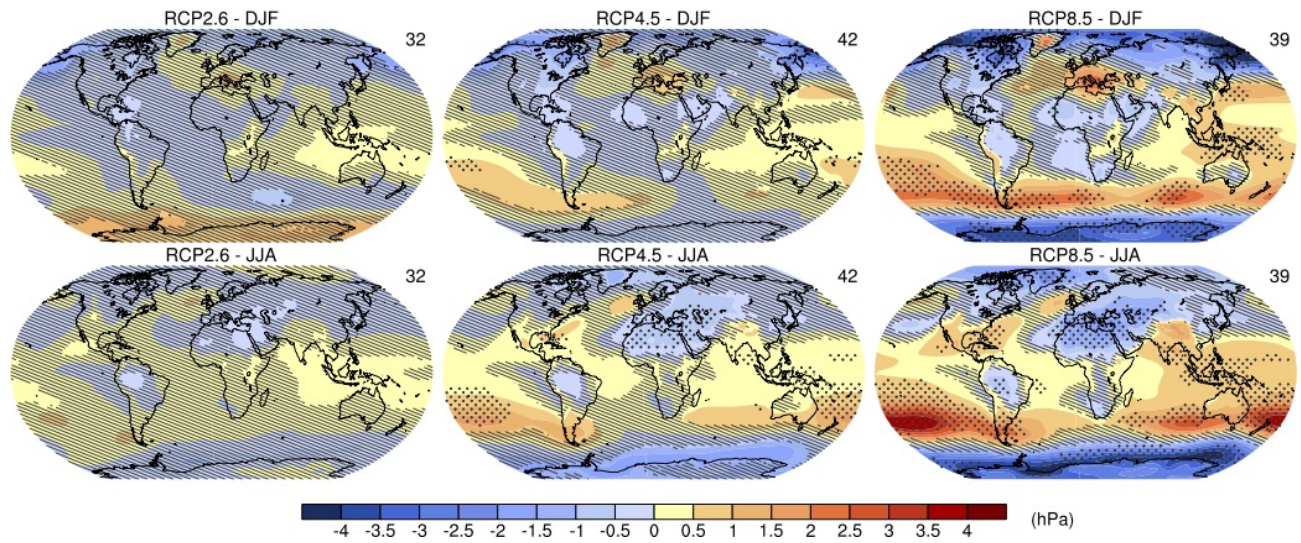

Figure 12.18: CMIP5 multi model ensemble average of DJF (top row) and JJA (bottom row) mean sea level pressure change (2081–2100 minus 1986–2005) for, from left to right, RCP2.6, 4.5 and 8.5. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

Annual mean zonal wind change (2081-2100)

Figure 12.19: CMIP5 multi model ensemble average of zonal and annual mean wind change (2081–2100 minus 1986–2005) for, from left to right, RCP2.6, 4.5 and 8.5. Black contours represent the multi model average for the 1986–2005 base period. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

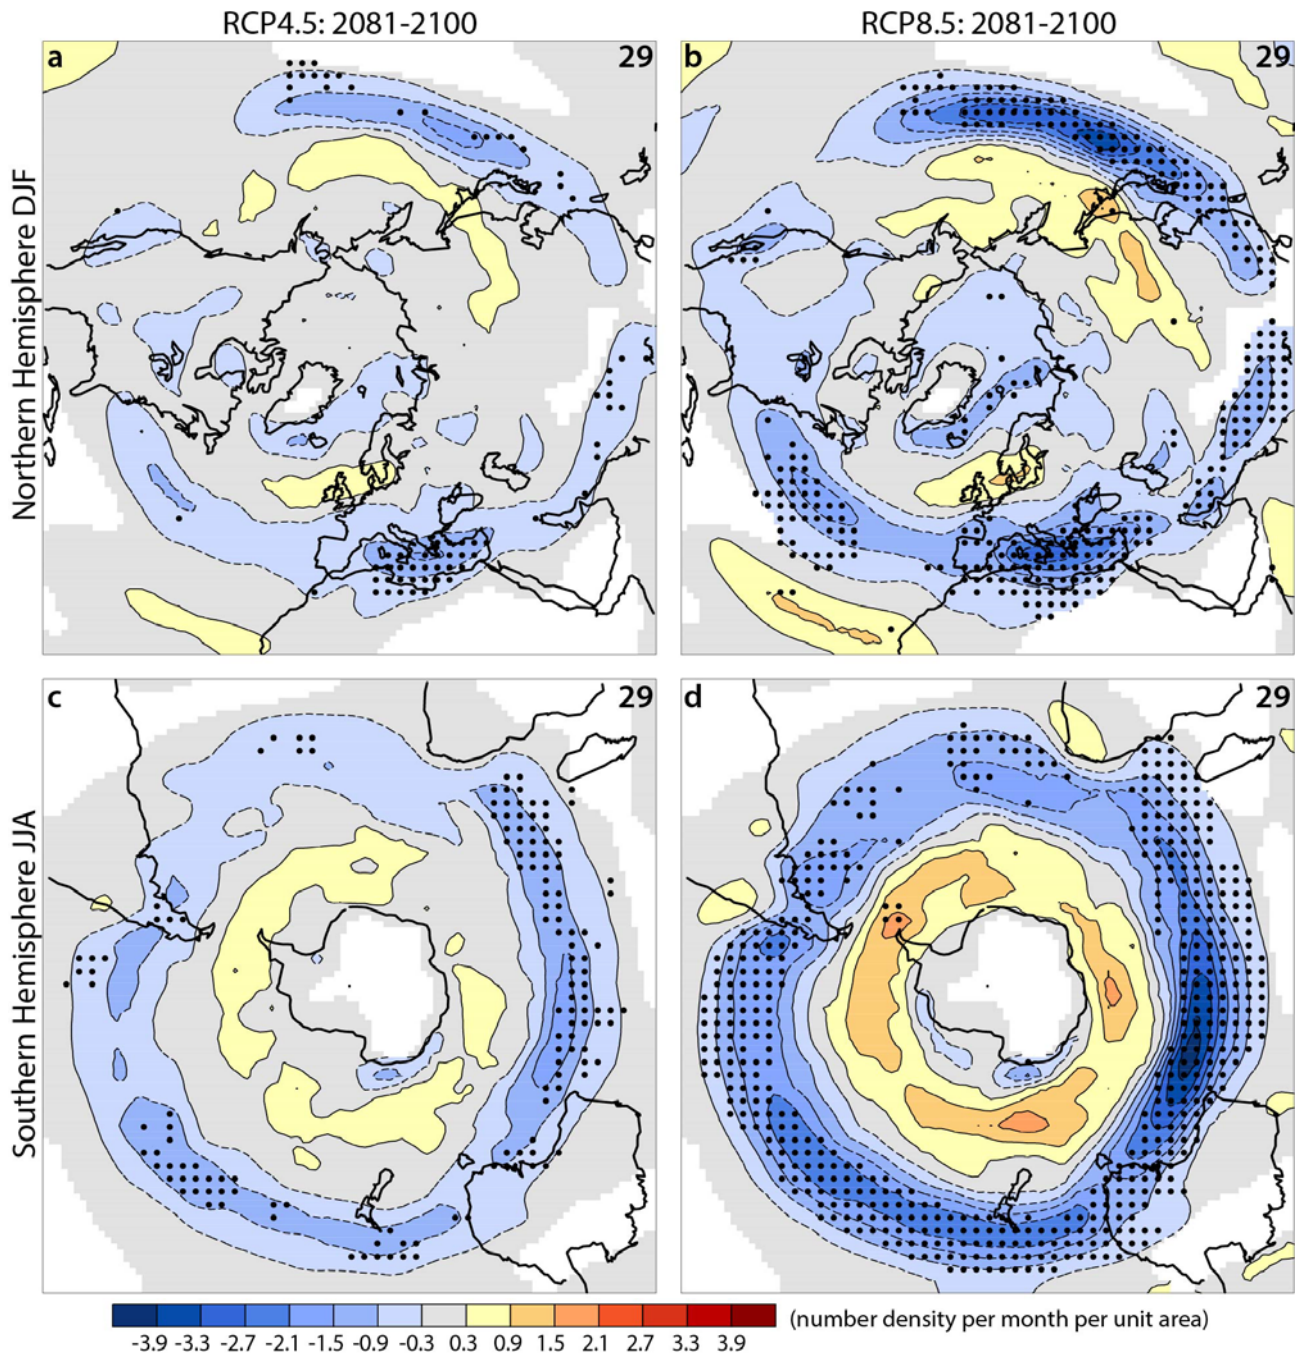

Figure 12:20: Change in winter, extratropical storm track density (2081–2100) – (1986–2005) in CMIP5 multi-model ensembles: (a) RCP4.5 Northern Hemisphere DJF and (b) RCP8.5 Northern Hemisphere DJF (c) RCP4.5 Southern Hemisphere JJA and (d) RCP8.5 Southern Hemisphere JJA. Storm-track computation uses the method of Bengtsson et al. (2006, their Figure 13a) applied to six-hourly 850 hPa vorticity computed from horizontal winds in the CMIP5 archive. The number of models used appears in the upper right of each panel. DJF panels include data for December 1985 and 2080 and exclude December 2005 and December 2100 for in-season continuity. Stippling marks locations where at least 90% of the models agree on the sign of the change; note that this criterion differs from that used for many other figures in this chapter, due to the small number of models providing sufficient data to estimate internal variability of twenty-year means of storm-track statistics. Densities have units (number density/month/unit area), where the unit area is equivalent to a 5° spherical cap ($\sim 10^6 \text{ km}^2$). Locations where the scenario or contemporary-climate ensemble average is below 0.5 density units are left white.

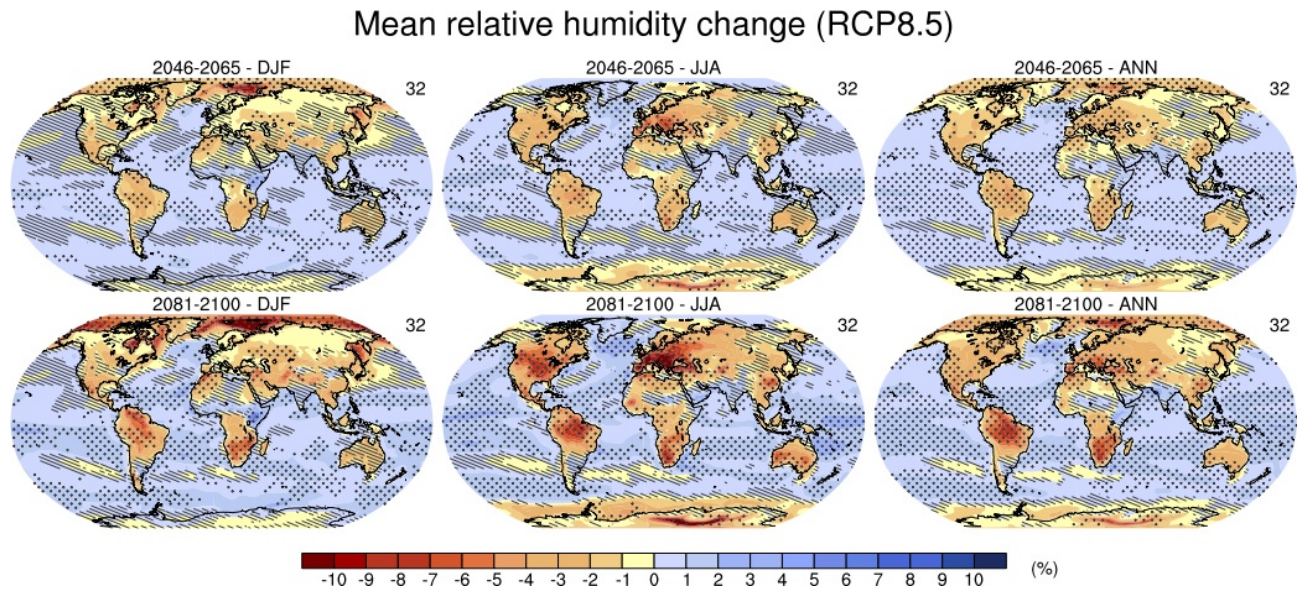

Figure 12.21: Projected changes in near-surface relative humidity from the CMIP5 models under RCP8.5 for the DJF (left), JJA (middle) and annual mean (ANN, right) averages relative to 1986–2005 for the periods 2046–2065 (top row), 2081–2100 (bottom row). The changes are differences in relative humidity percentage (as opposed to a fractional or relative change). Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

Seasonal mean percentage precipitation change (RCP8.5)

Figure 12.22: Multi-model CMIP5 average percentage change in seasonal mean precipitation relative to the reference period 1985–2005 averaged over the periods 2045–2065, 2081–2100 and 2181–2200 under the RCP8.5 forcing scenario. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1).

Annual mean near-surface soil moisture change (2081-2100)

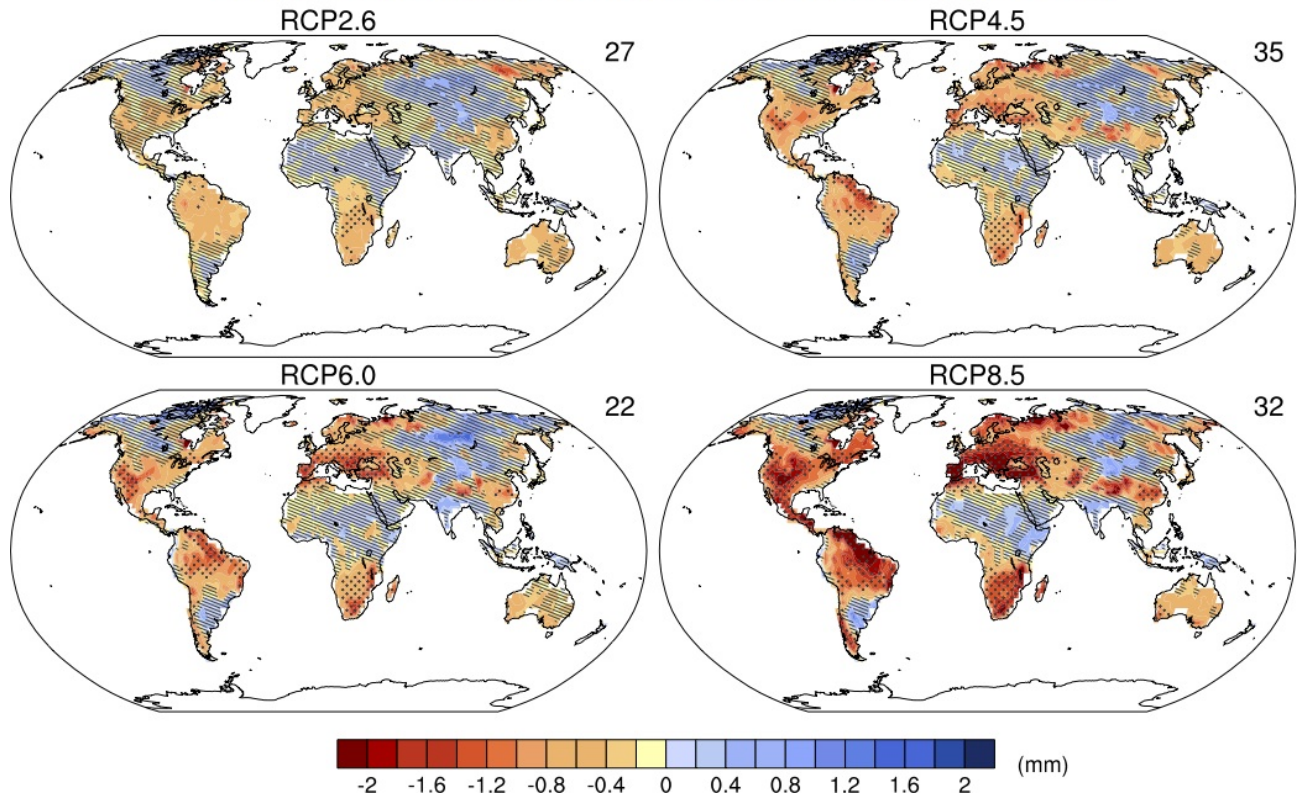

Figure 12.23: Change in annual mean soil moisture (mass of water in all phases in the uppermost 10 cm of the soil) (mm) relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

Annual mean runoff change (2081-2100)

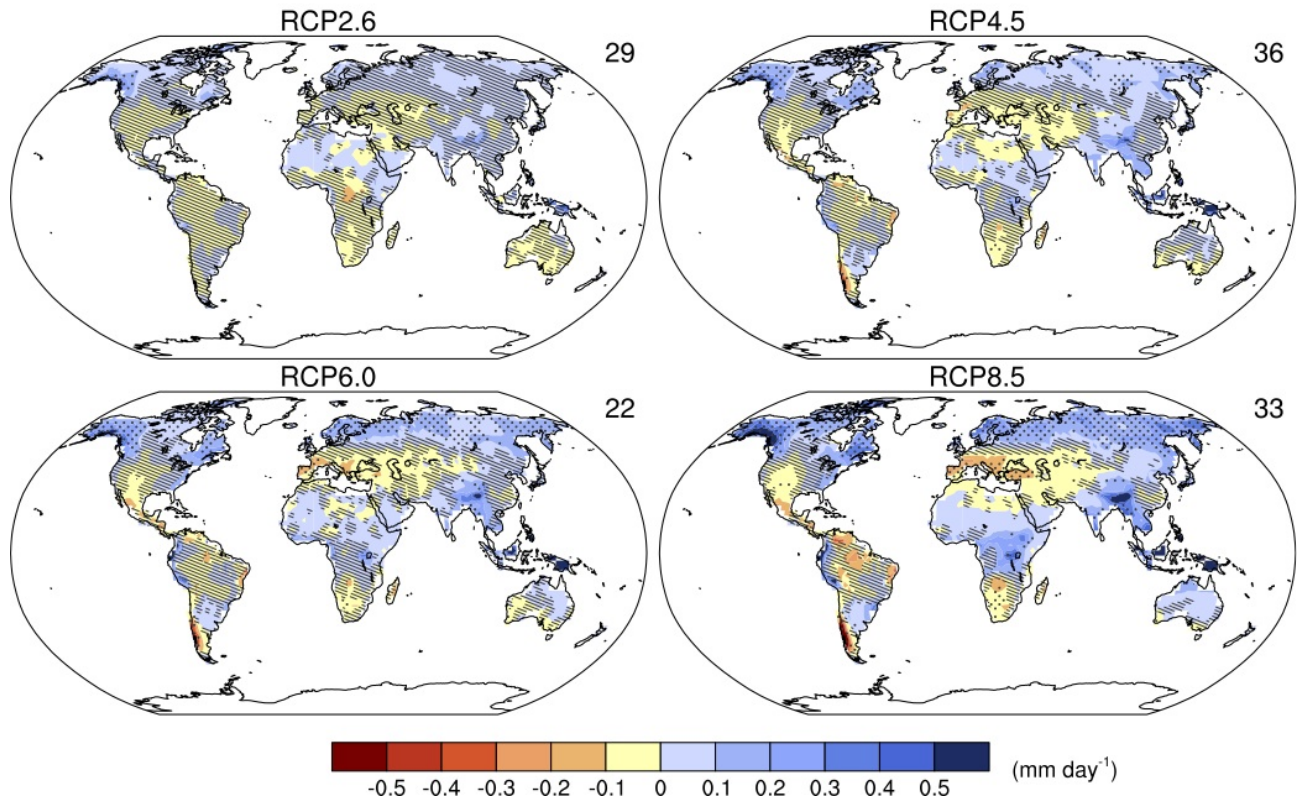

Figure 12.24: Change in annual mean runoff (mm) relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

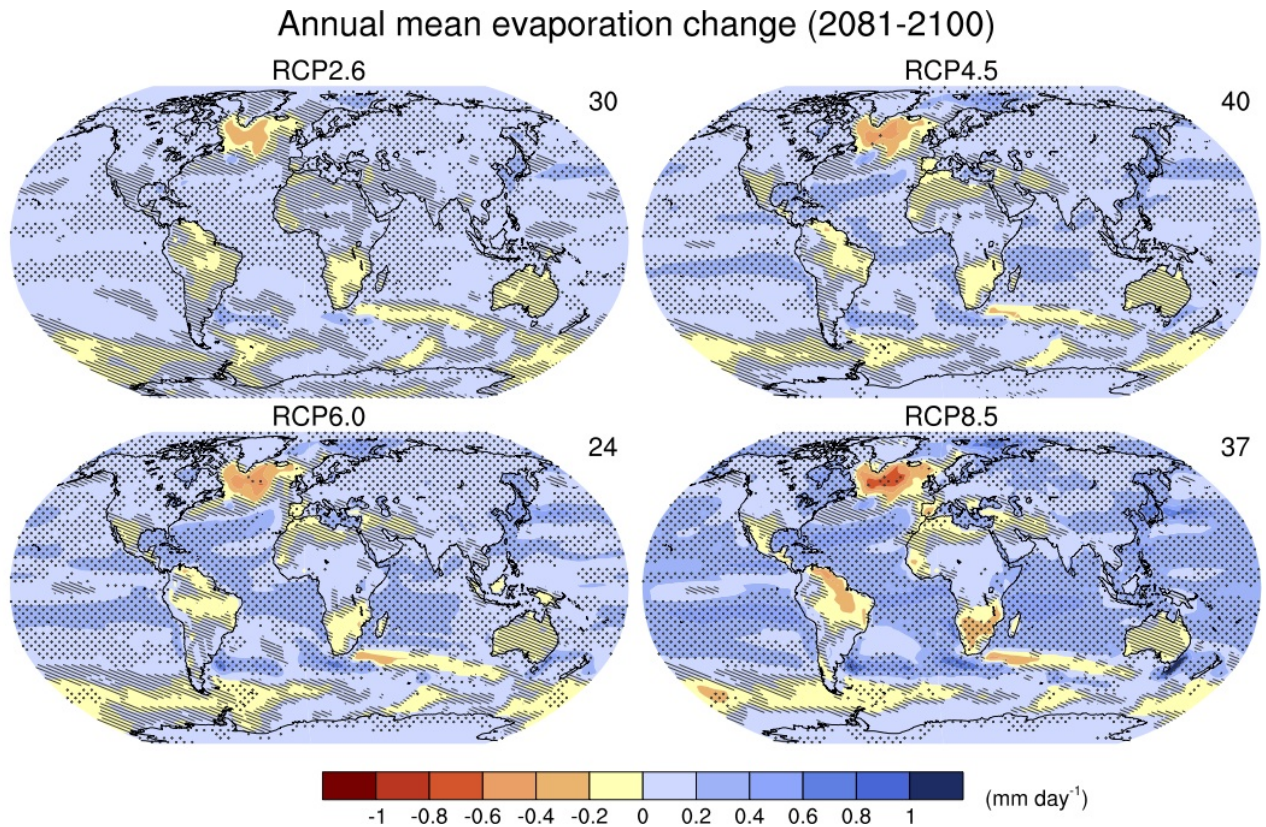

Figure 12.25: Change in annual mean evaporation (mm) relative to the reference period 1986–2005 projected for 2081–2100 from the CMIP5 ensemble. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner of each panel.

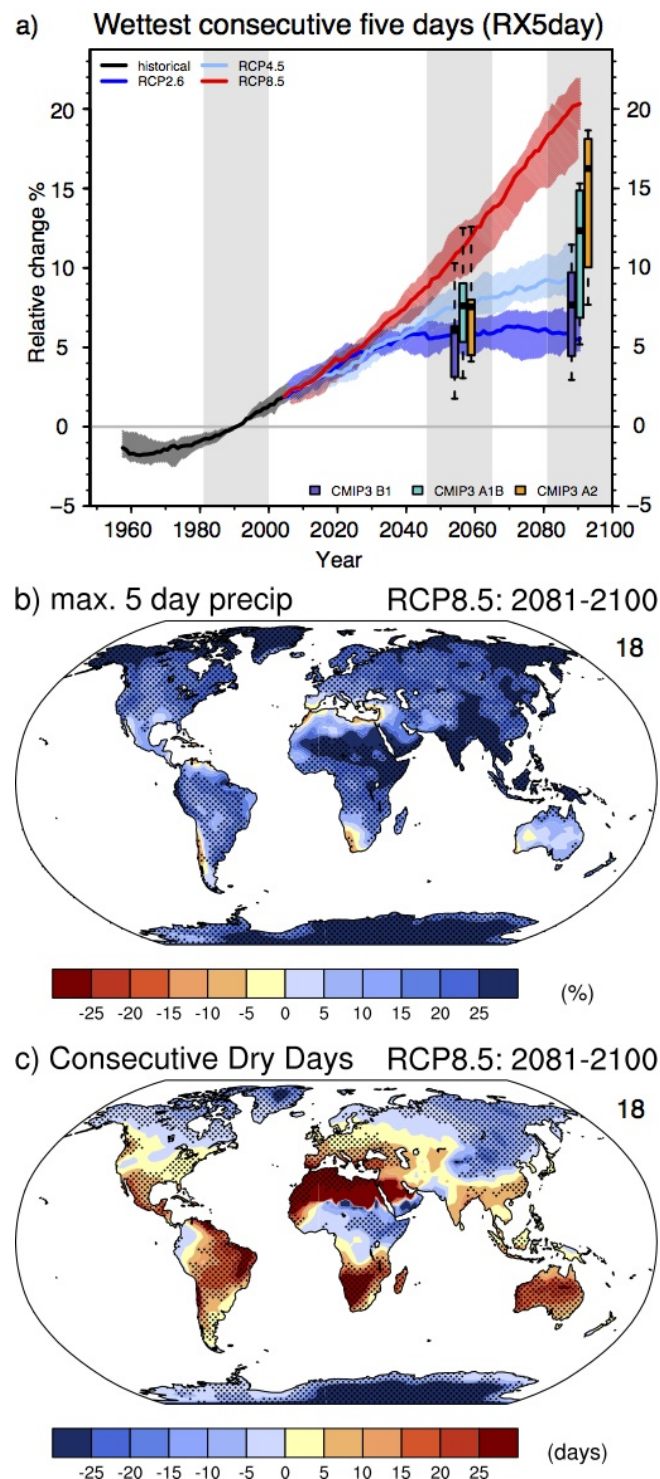

Figure 12.26: a and b) Projected percent changes (relative to the 1981–2000 reference period in common with CMIP3) from the CMIP5 models in RX5day, the annual maximum five-day precipitation accumulation a) Global average percent change over land regions for the RCP2.6, 4.5 and 8.5 scenarios. Shading in the time series represents the interquartile ensemble spread (25th and 75th quantiles). The box-and-whisker plots show the interquartile ensemble spread (box) and outliers (whiskers) for 11 CMIP3 model simulations of the SRES scenarios A2 (orange), A1B (cyan), and B1 (purple) globally averaged over the respective future time periods (2046–2065 and 2081–2100) as anomalies from the 1981–2000 reference period. b) Percent change over the 2081–2100 period in the RCP8.5 scenario. c) Projected change in annual CDD, the maximum number of consecutive dry days when precipitation is less than 1 mm, over the 2081–2100 period in the RCP8.5 scenario (relative to the 1981–2000 reference period) from the CMIP5 models. Stippling indicates gridpoints with changes that are significant at the 5% level using a Wilcoxon signed-ranked test. Updated from Sillmann et al. (2013), excluding the FGOALS-s2 model.

Daily precipitation 20 year return value and return period change (2081-2100)

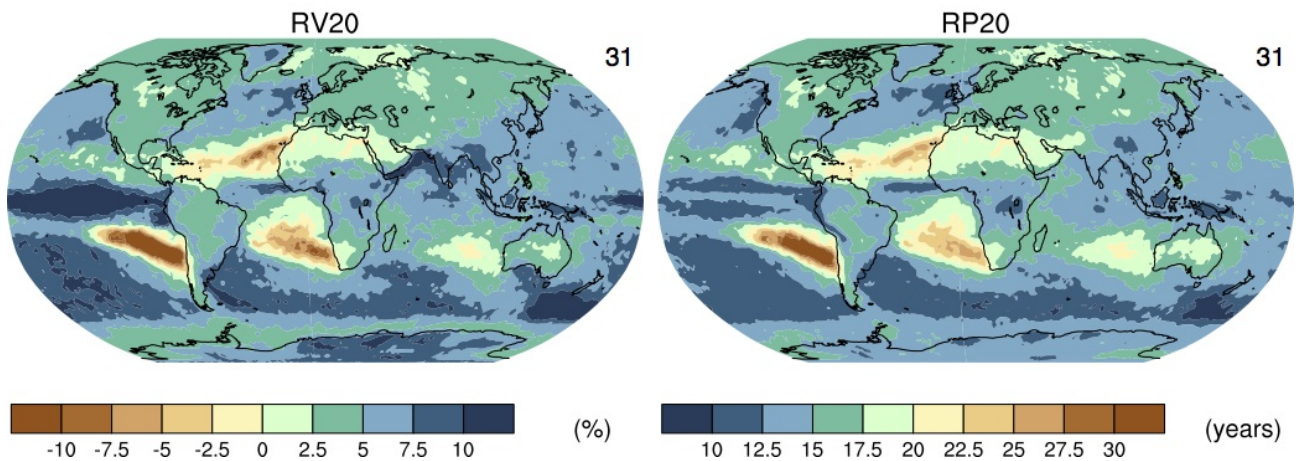

Figure 12.27: Left: The average 2081–2100 CMIP5 multi-model ensemble median percent change in twenty year return values of annual maximum daily precipitation per 1°C of local warming relative to the 1986–2005 reference period. Right: The average 2081–2100 CMIP5 multi-model ensemble median of the return periods (years) of 1986–2005 twenty year return values of annual maximum daily precipitation corresponding to 1°C of local warming. Regions of no change would have return periods of twenty years.

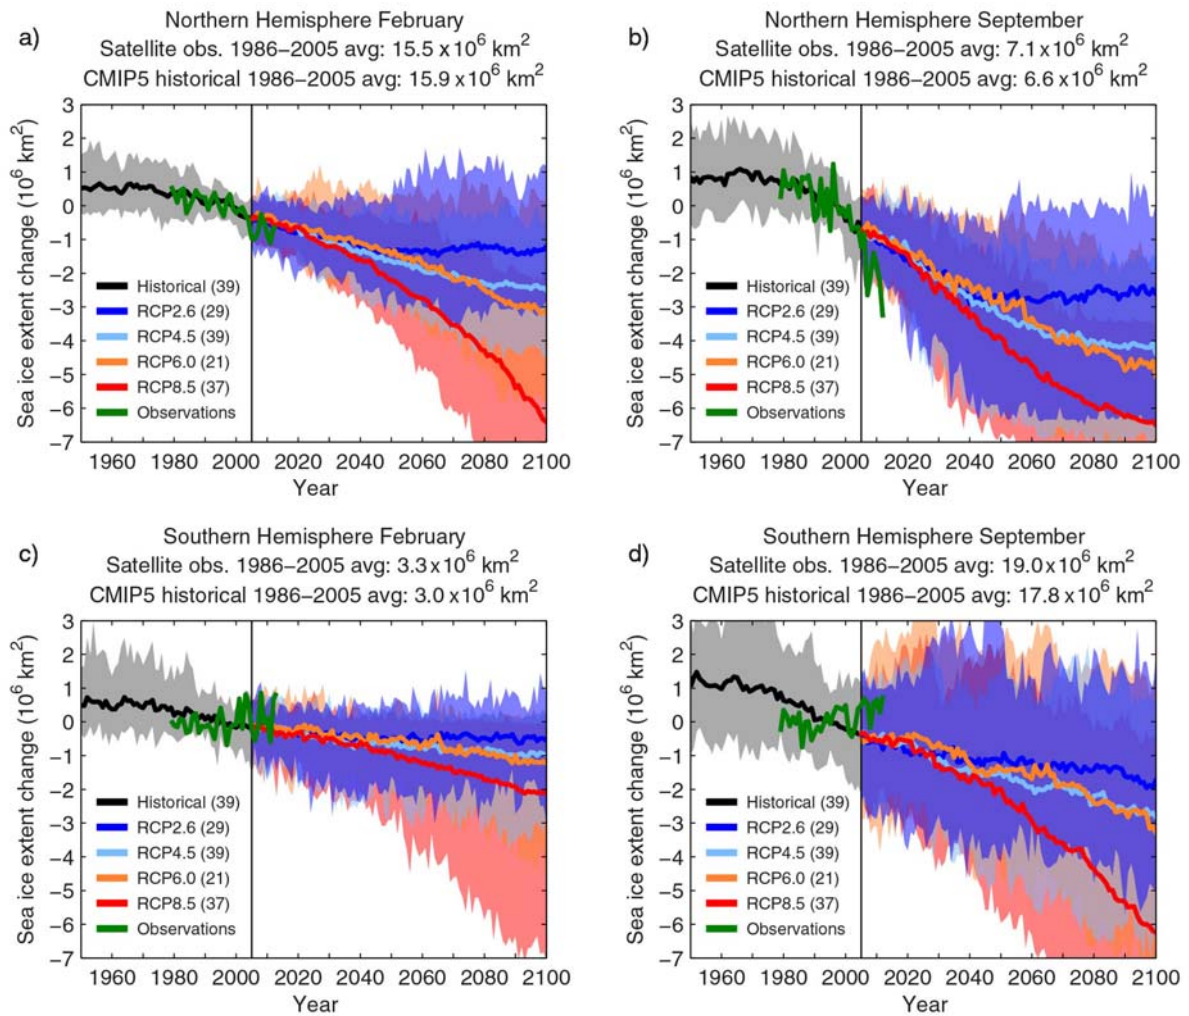

Figure 12.28: Changes in sea ice extent as simulated by CMIP5 models over the second half of the 20th century and the whole 21st century under RCP2.6, RCP4.5, RCP6.0 and RCP8.5 for (a) Northern Hemisphere February, (b) Northern Hemisphere September, (c) Southern Hemisphere February and (d) Southern Hemisphere September. The solid curves show the multi-model means and the shading denotes the 5–95% range of the ensemble. The vertical line marks the end of CMIP5 historical climate change simulations. One ensemble member per model is taken into account in the analysis. Sea ice extent is defined as the total ocean area where sea ice concentration exceeds 15% and is calculated on the original model grids. Changes are relative to the reference period 1986–2005. The number of models available for each RCP is given in the legend. Also plotted (solid green curves) are the satellite data of Comiso and Nishio (2008, updated 2012) over 1979–2012.

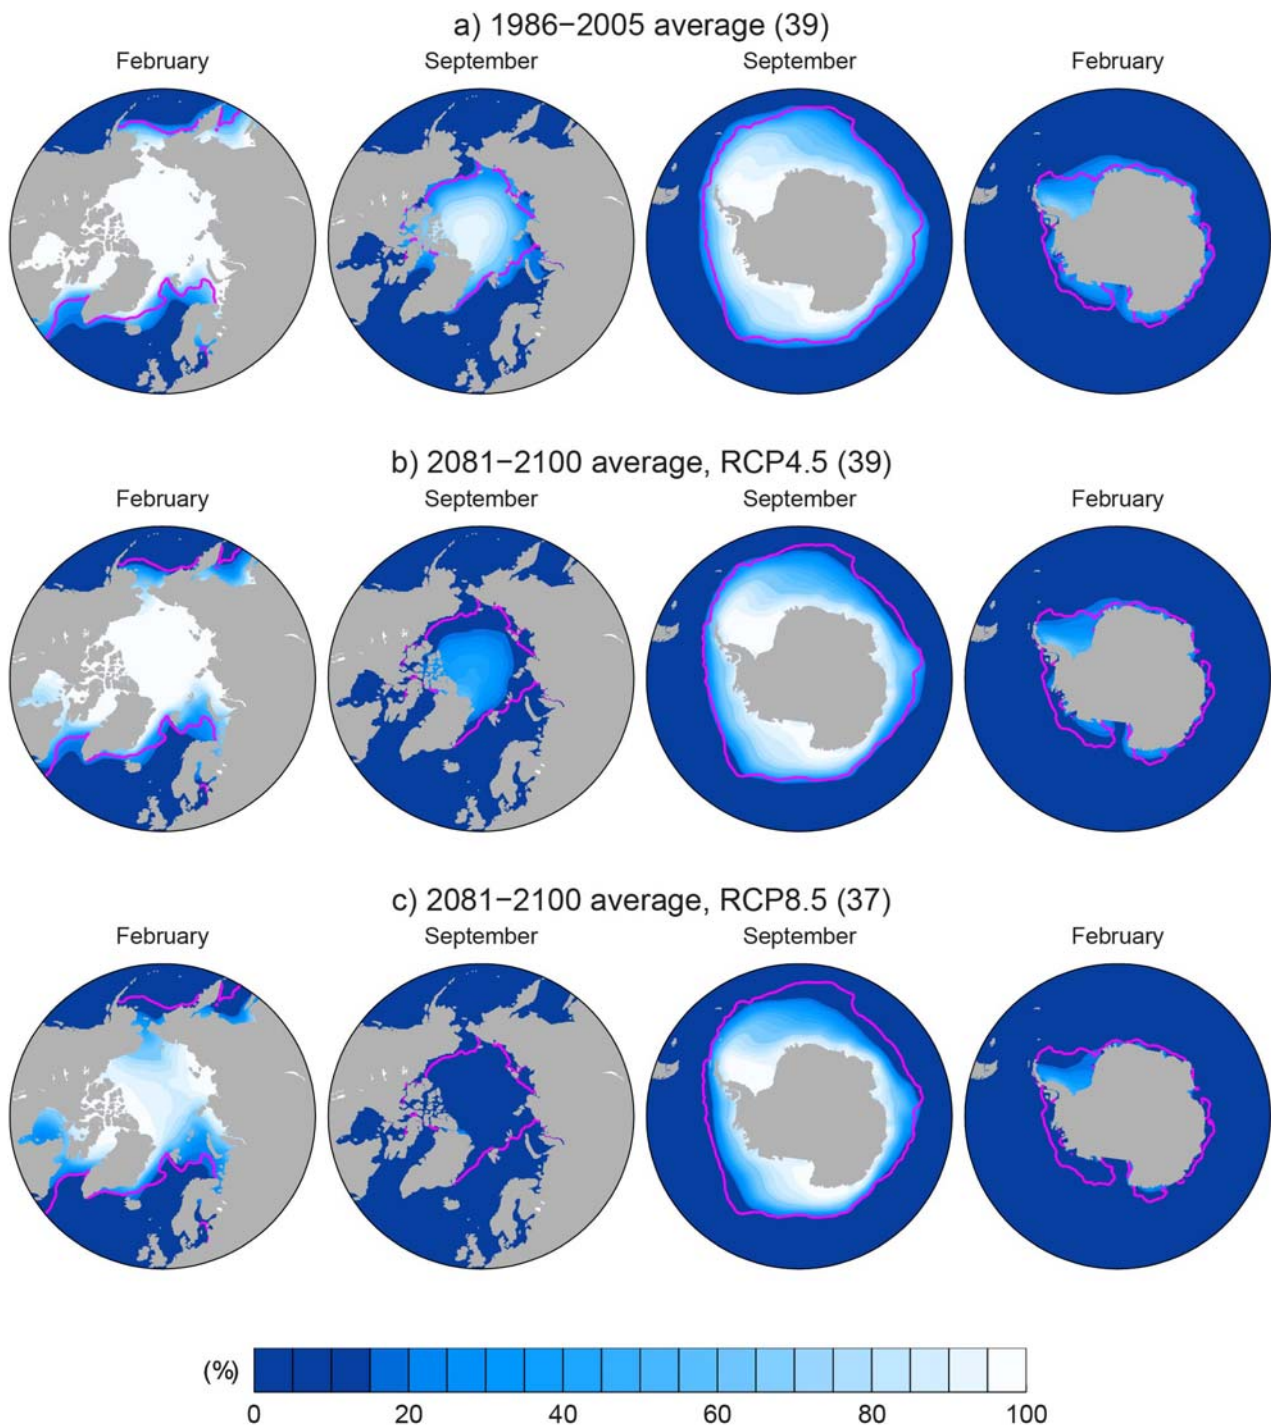

Figure 12.29: February and September CMIP5 multi-model mean sea ice concentrations (%) in the Northern and Southern Hemispheres for the periods (a) 1986–2005, (b) 2081–2100 under RCP4.5 and (c) 2081–2100 under RCP8.5. The model sea ice concentrations are interpolated onto a $1^\circ \times 1^\circ$ regular grid. One ensemble member per model is taken into account in the analysis, and the multi-model mean sea ice concentration is shown where it is larger than 15%. The number of models available for each RCP is given in parentheses. The pink lines indicate the observed 15% sea ice concentration limits averaged over 1986–2005 (Comiso and Nishio, 2008, updated 2012).

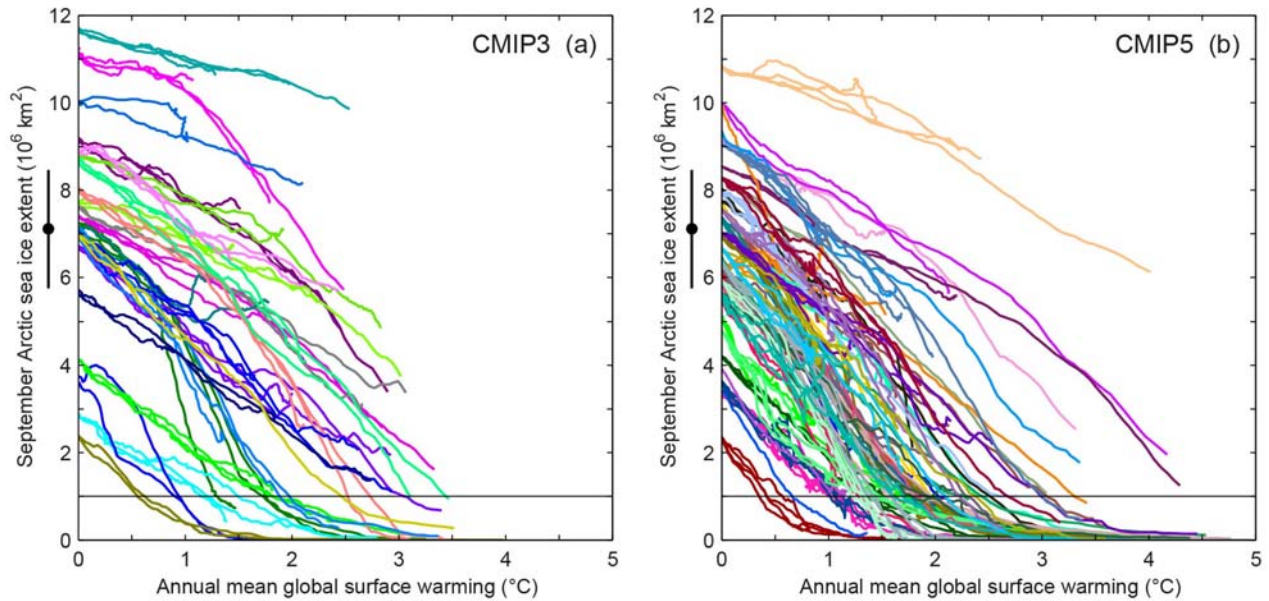

Figure 12.30: September Arctic sea ice extent as a function of the annual mean global surface warming relative to the period 1986–2005 for (a) CMIP3 models (all SRES scenarios) and (b) CMIP5 models (all RCPs). The ice extents and global temperatures are computed on a common latitude-longitude grid for CMIP3 and on the original model grids for CMIP5. One ensemble member per model is taken into account in the analysis. A 21-year running mean is applied to the model output. The full black circle and vertical bar on the left-hand side of the y-axis indicate the mean and ± 2 standard deviations about the mean of the observed September Arctic sea ice extent over 1986–2005, respectively (Comiso and Nishio, 2008, updated 2012). The horizontal line corresponds to a nearly ice-free Arctic Ocean in September.

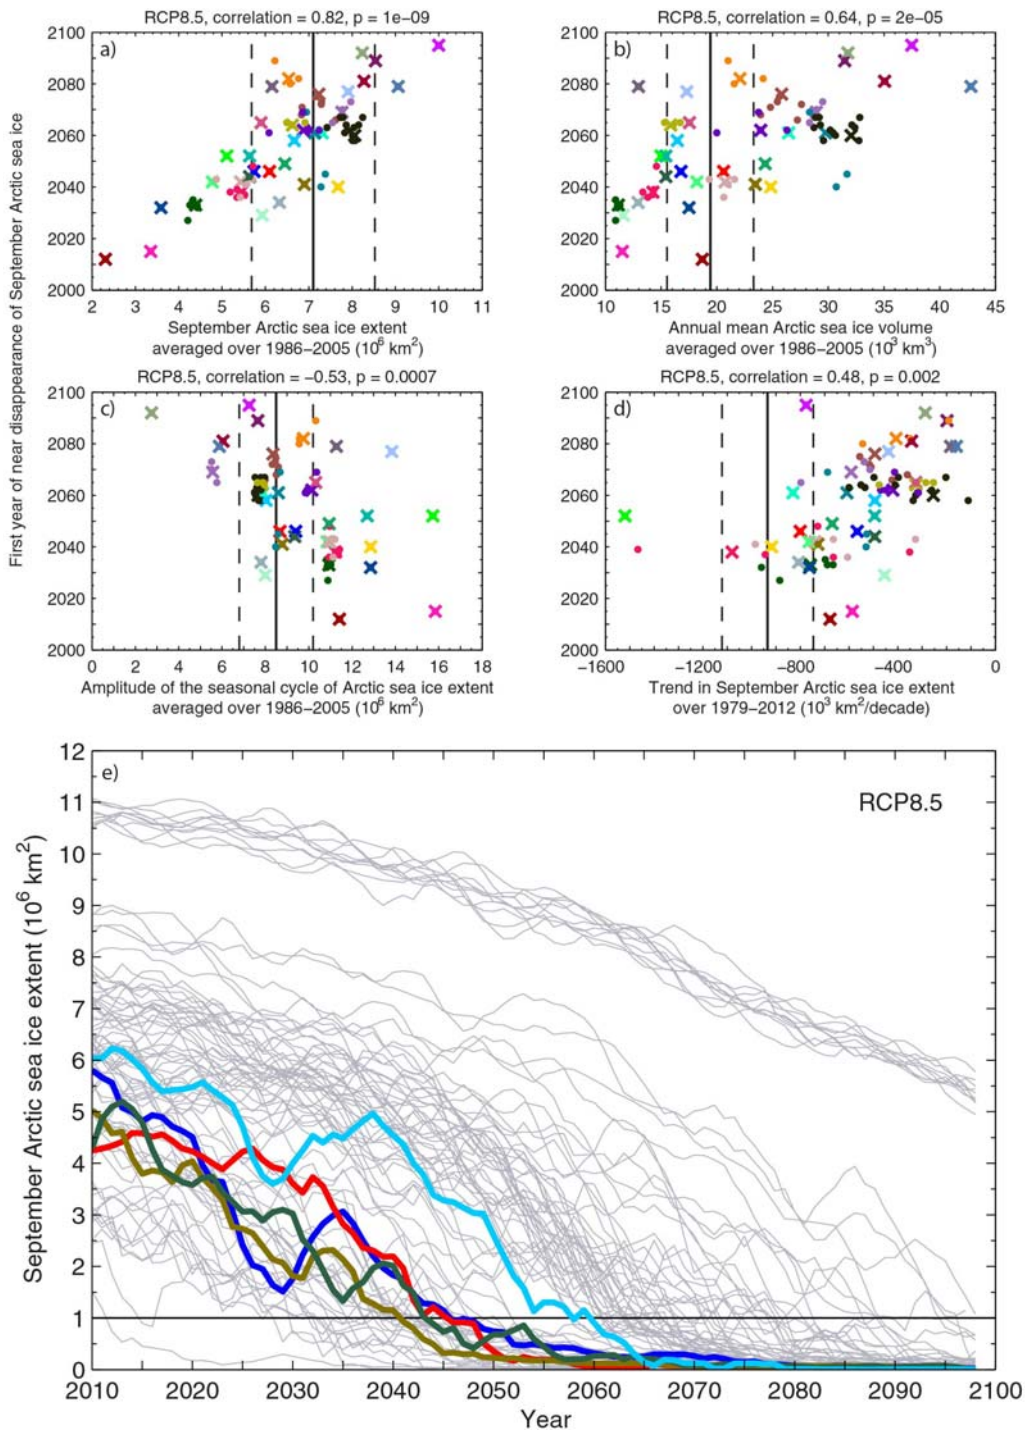

Figure 12.31: (a–d) First year during which the September Arctic sea ice extent falls below $1 \times 10^6 \text{ km}^2$ in CMIP5 climate projections (37 models, RCP8.5) as a function of (a) the September Arctic sea ice extent averaged over 1986–2005, (b) the annual mean Arctic sea ice volume averaged over 1986–2005, (c) the amplitude of the 1986–2005 mean seasonal cycle of Arctic sea ice extent and (d) the trend in September Arctic sea ice extent over 1979–2012. The sea ice diagnostics displayed are calculated on the original model grids. The correlations and one-tailed p -values are computed from the multi-member means for models with several ensemble members (coloured crosses), but the ensemble members of individual models are also depicted (coloured dots). The vertical solid and dashed lines show the corresponding observations or bias-adjusted PIOMAS (Pan-Arctic Ice-Ocean Modelling and Assimilation System) reanalysis data (a, c and d: Comiso and Nishio, 2008, updated 2012; b: Schweiger et al., 2011) and the $\pm 20\%$ interval around these data, respectively. (e) Time series of September Arctic sea ice extent (5-year running mean) as simulated by all CMIP5 models and their ensemble members under RCP8.5 (thin curves). The thick, coloured curves correspond to a subset of five CMIP5 models selected on the basis of panels a–d following Massonnet et al. (2012) (see text for details). Note that each of these models only provides one ensemble member for RCP8.5.

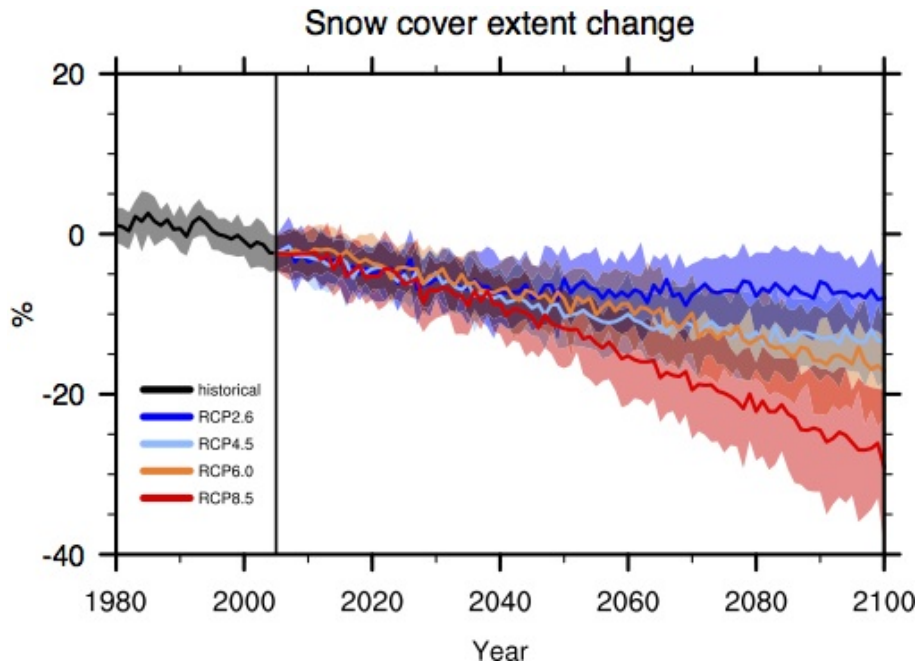

Figure 12.32: Northern Hemisphere spring (March to April average) snow cover extent change (in %) in the CMIP5 ensemble, relative to the simulated extent for the 1986–2005 reference period. Thick lines mark the multi-model average, shading indicates the inter-model spread (one standard deviation). The observed March to April average snow cover extent for the 1986–2005 reference period is $32.6 \cdot 10^6 \text{ km}^2$ (Brown and Robinson, 2011).

Figure 12.33: Northern hemisphere near-surface permafrost area, diagnosed for the available CMIP5 models by Slater and Lawrence (2013) following Nelson and Outcalt (1987) and using 20-year average bias-corrected monthly surface air temperatures and snow depths. Blue: RCP2.6; Light blue: RCP4.5; Orange: RCP6.0; Red: RCP8.5. Thick lines: multi-model average. Shading and thin lines indicate the inter-model spread (one standard deviation). The black line for the historical period is diagnosed from the average of the ERA, JRA, MERRA and CFSRR reanalyses (Slater and Lawrence, 2013). Estimated present permafrost extent is between 12 and 17 million km^2 (Zhang et al., 2000).

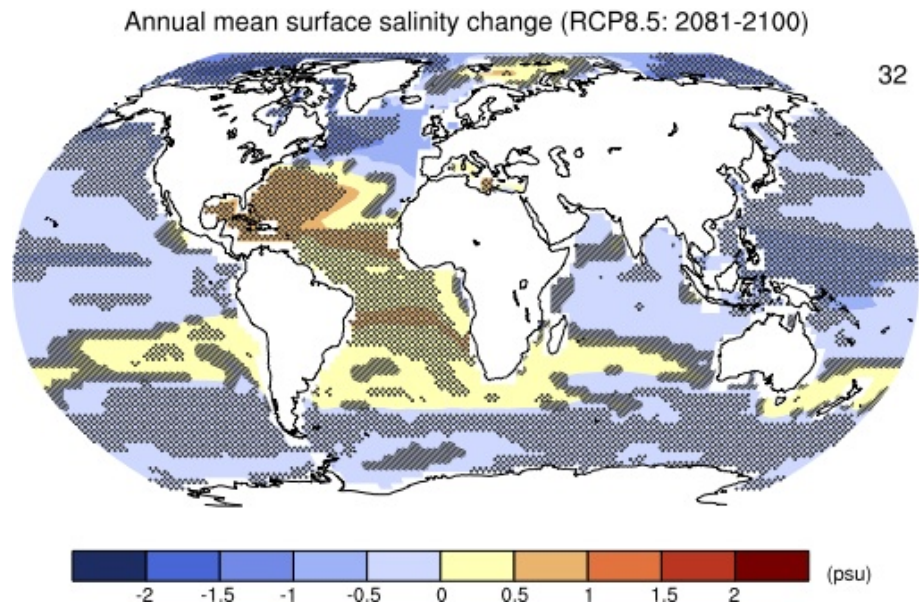

Figure 12.34: Projected sea surface salinity differences 2081–2100 for RCP8.5 relative to 1986–2005 from CMIP5 models. Hatching indicates regions where the multi model mean is less than one standard deviation of internal variability. Stippling indicates regions where the multi model mean is greater than two standard deviations of internal variability and where 90% of the models agree on the sign of change (see Box 12.1). The number of CMIP5 models used is indicated in the upper right corner.

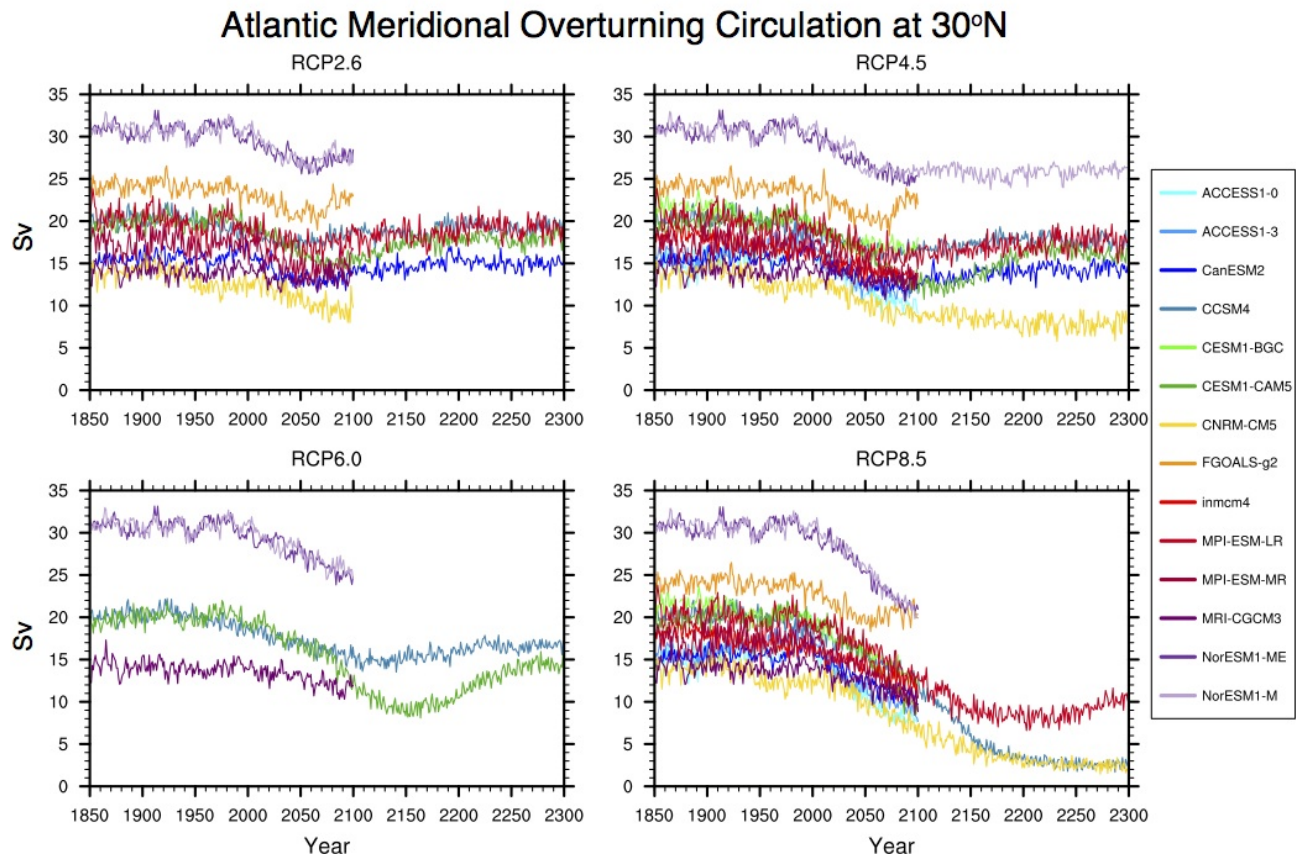

Figure 12.35: Multi model projections of Atlantic meridional overturning circulation (AMOC) strength at 30°N from 1850 through to the end of the RCP extensions. Results are based on a small number of CMIP5 models available. Curves show results from only the first member of the submitted ensemble of experiments.

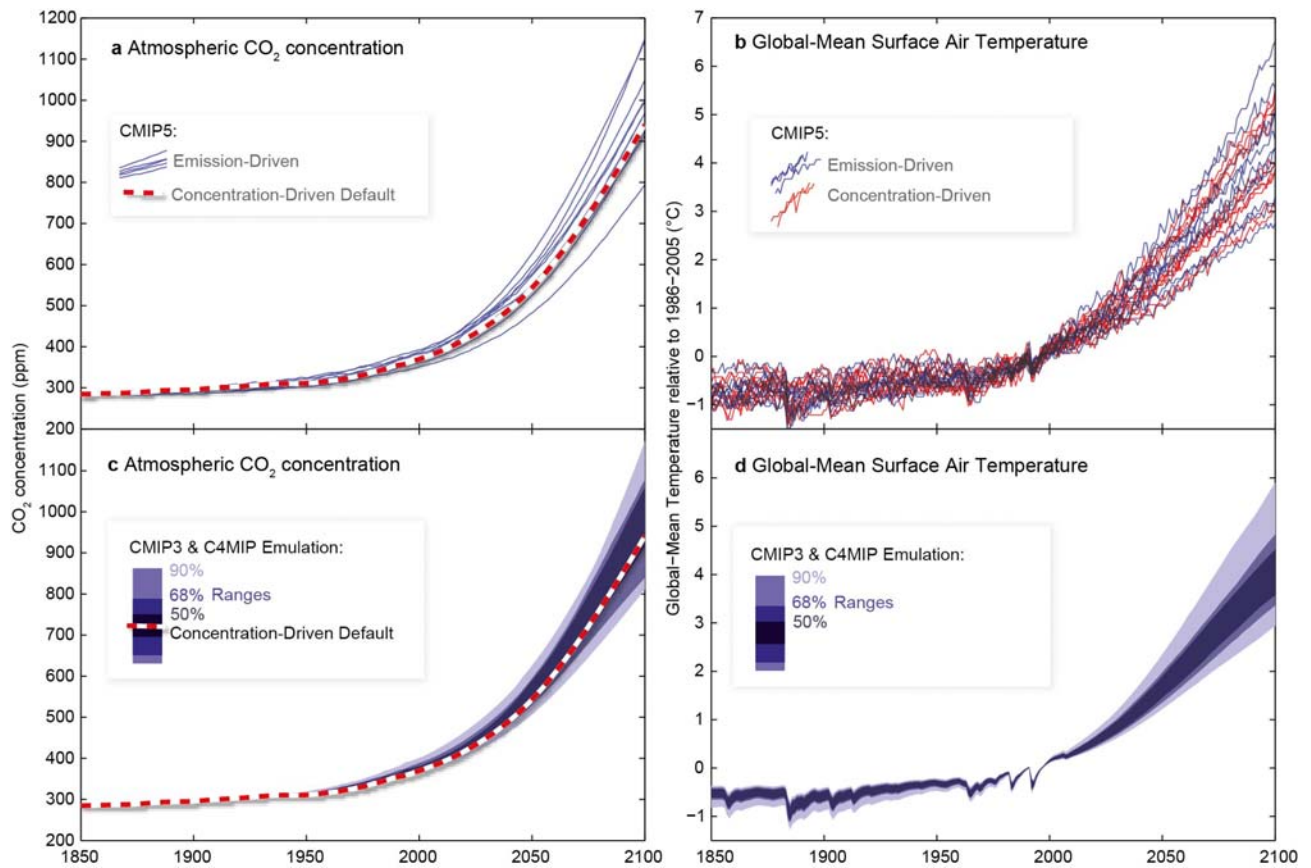

Figure 12.36: Simulated changes in a) atmospheric CO₂ concentration and b) global averaged surface temperature (°C) as calculated by the CMIP5 ESMs for the RCP8.5 scenario when CO₂ emissions are prescribed to the ESMs as external forcing (blue). Also shown (panel b, in red) is the simulated warming from the same ESMs when directly forced by atmospheric CO₂ concentration (panel a, red white line). Panel c and d show the range of CO₂ concentrations and global average surface temperature change simulated by the MAGICC6 simple climate model when emulating the CMIP3 models climate sensitivity range and the C⁴MIP models carbon cycle feedbacks. The default line in panel c is identical to the one in panel a.

Figure 12.37: Uncertainty in global mean temperature from HadCM3 results exploring atmospheric physics and terrestrial carbon cycle parameter perturbations under the SRES A1B scenario (Booth et al., 2012; Murphy et al., 2004). Relative uncertainties in the Perturbed Carbon Cycle (PCC, green plume) and Perturbed Atmospheric Processes (PAP, blue plume) on global mean anomalies of temperature (relative to the 1986–2005 period). The standard simulations from the two ensembles, HadCM3 (blue solid) and HadCM3C (green solid) are also shown. Three bars are shown on the right illustrating the 2100 temperature anomalies associated with the CMIP3/AR4 ensemble (black) the PAP ensemble (blue), and PCC ensemble (green). The ranges indicate the full range, 10th–90th, 25th–75th and 50th percentiles.

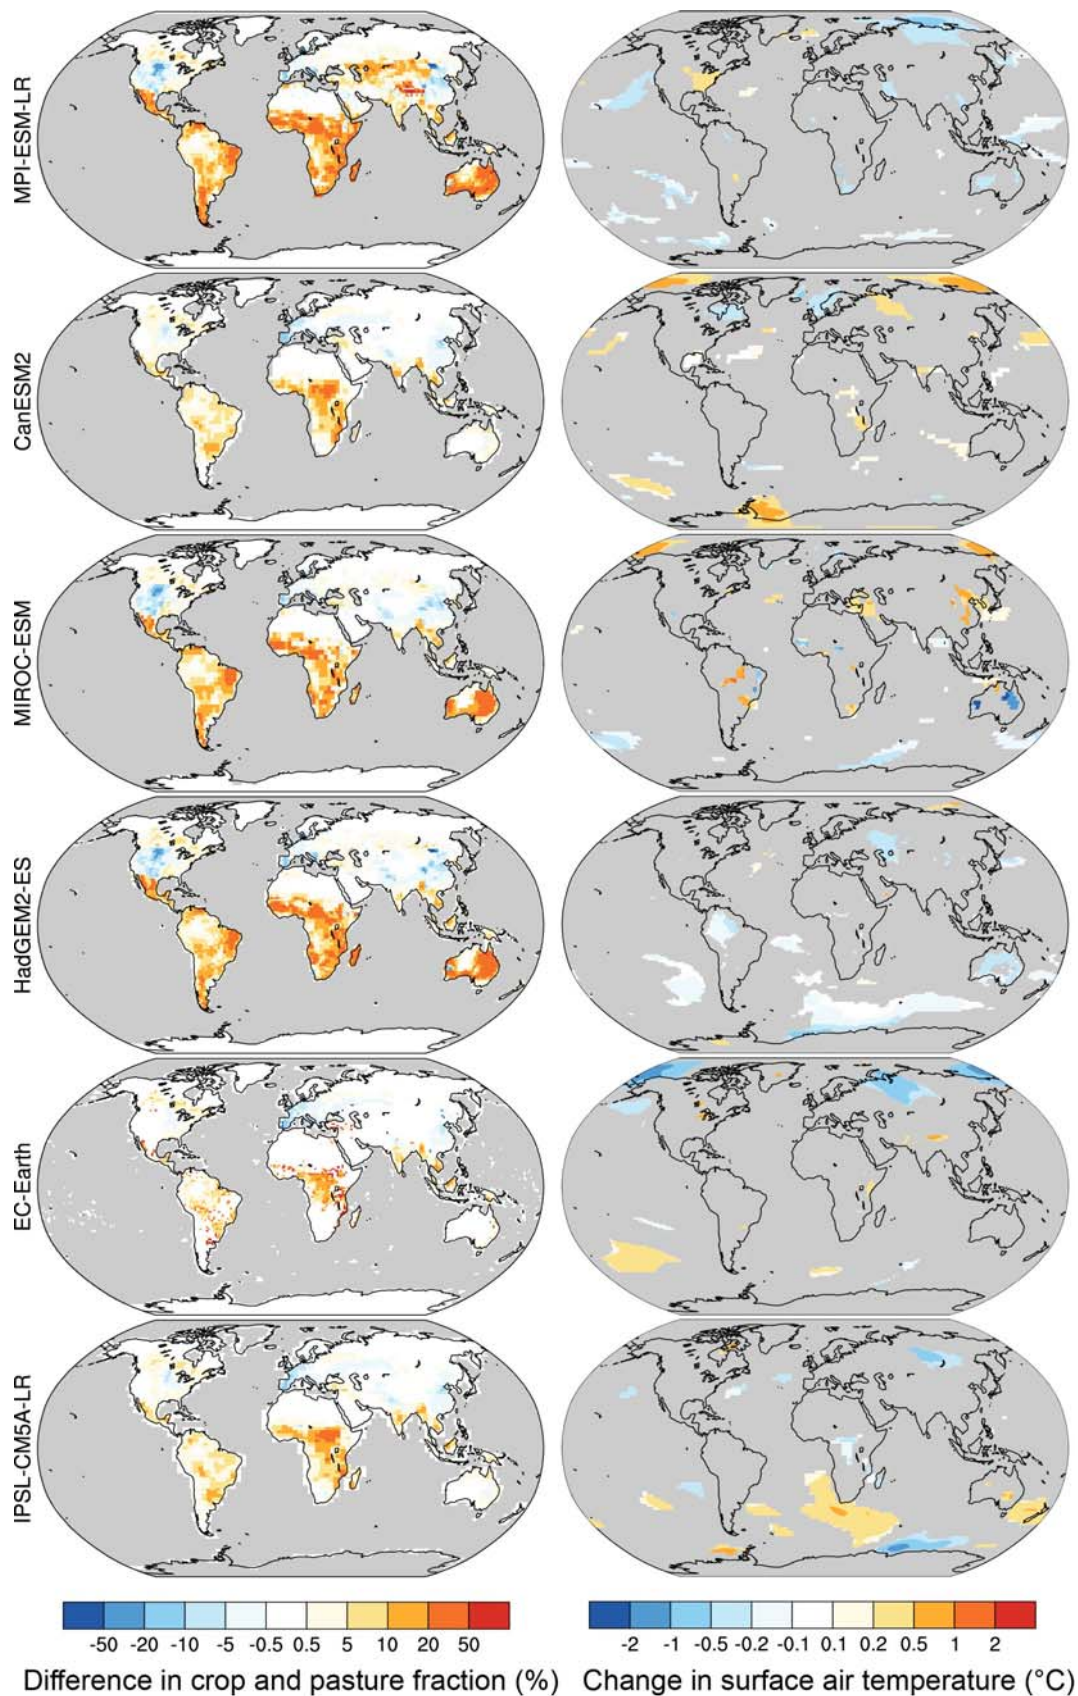

Figure 12.38 Impact of land-use change on surface temperature. LUCID-CMIP5 experiments where 6 ESMs were forced either with or without land-use change beyond 2005 under the RCP8.5 scenario. Left maps of changes in total crop and pasture fraction (%) in the RCP8.5 simulations between 2006 and 2100 as implemented in each ESM. Right maps show the differences in surface air temperature (averaged over the 2071–2100 period) between the simulations with- and without land use change beyond 2005. Only statistically significant changes ($p < 0.05$) are shown.

Figure 12.39: Global mean temperature anomalies at the end of the 21st century from GCM experiments and emulators comparing CMIP3/CMIP5 responses under SRES A1B and RCP6.0. The boxes and whiskers indicate the 5th percentile, mean value – 1 standard deviation, mean, mean value + 1 standard deviation and 95th percentile of the distributions. The first box-and-whiskers on the left is computed directly from the CMIP3 ensemble and corresponds to the numbers quoted in AR4. The emulated SRES A1B projections (second from left) of CMIP5 are obtained by the method of Good et al. (2011) and are calculated for the period 2080-2099 expressed with respect to the AR4 baseline period of 1980–1999. Because of the method, the subset of CMIP5 that are emulated are restricted to those with preindustrial control, abrupt $4 \times \text{CO}_2$, historical, RCP4.5 and RCP8.5 simulations. The emulated RCP6.0 projections of CMIP3 (third from left, see also Figure 12.8) are from Knutti and Sedláček (2013) obtained using the method of Meinshausen et al. (2011b; 2011c) and are calculated for the slightly different future period 2081–2100 to be consistent with the rest of this chapter, and are expressed with respect to the AR5 baseline period of 1986–2005. The box-and-whiskers fourth from the left are a graphical representation of the numbers shown in Table 12.2. The final box-and-whiskers on the right is a combination of CMIP5 model output and emulation of CMIP5 RCP6.0 numbers for those models that did not run RCP6.0.

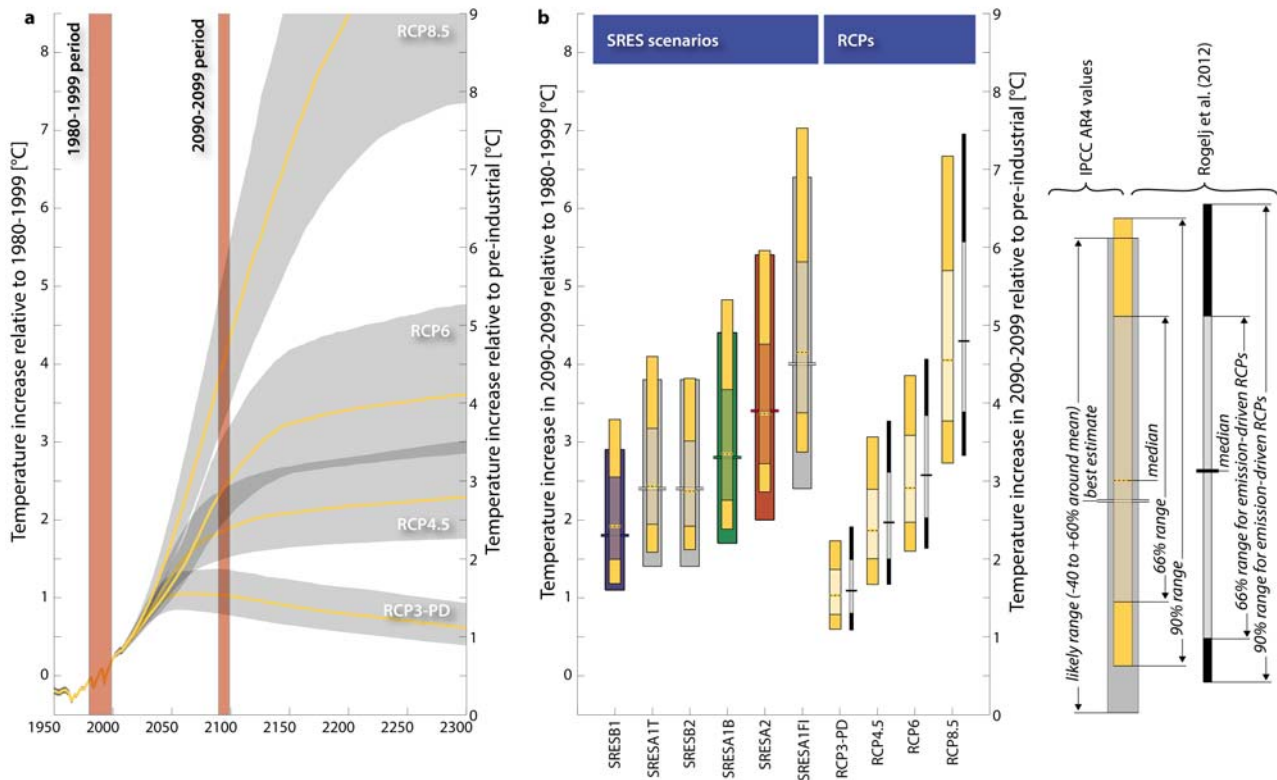

Figure 12.40: Temperature projections for SRES scenarios and the RCPs. (a) Time-evolving temperature distributions (66% range) for the four RCP scenarios computed with the ECS distribution from Rogelj et al. (2012) and a model setup representing closely the carbon-cycle and climate system uncertainty estimates of the AR4 (grey areas). Median paths are drawn in yellow. Red shaded areas indicate time periods referred to in panel b. (b) Ranges of estimated average temperature increase between 2090 and 2099 for SRES scenarios and the RCPs respectively. Note that results are given both relative to 1980–1999 (left scale) and relative to pre-industrial (right scale). Yellow ranges indicate results obtained by Rogelj et al. (2012). Colour-coding of AR4 ranges is chosen to be consistent with AR4 (Meehl et al., 2007). RCP2.6 is labelled as RCP3-PD here.

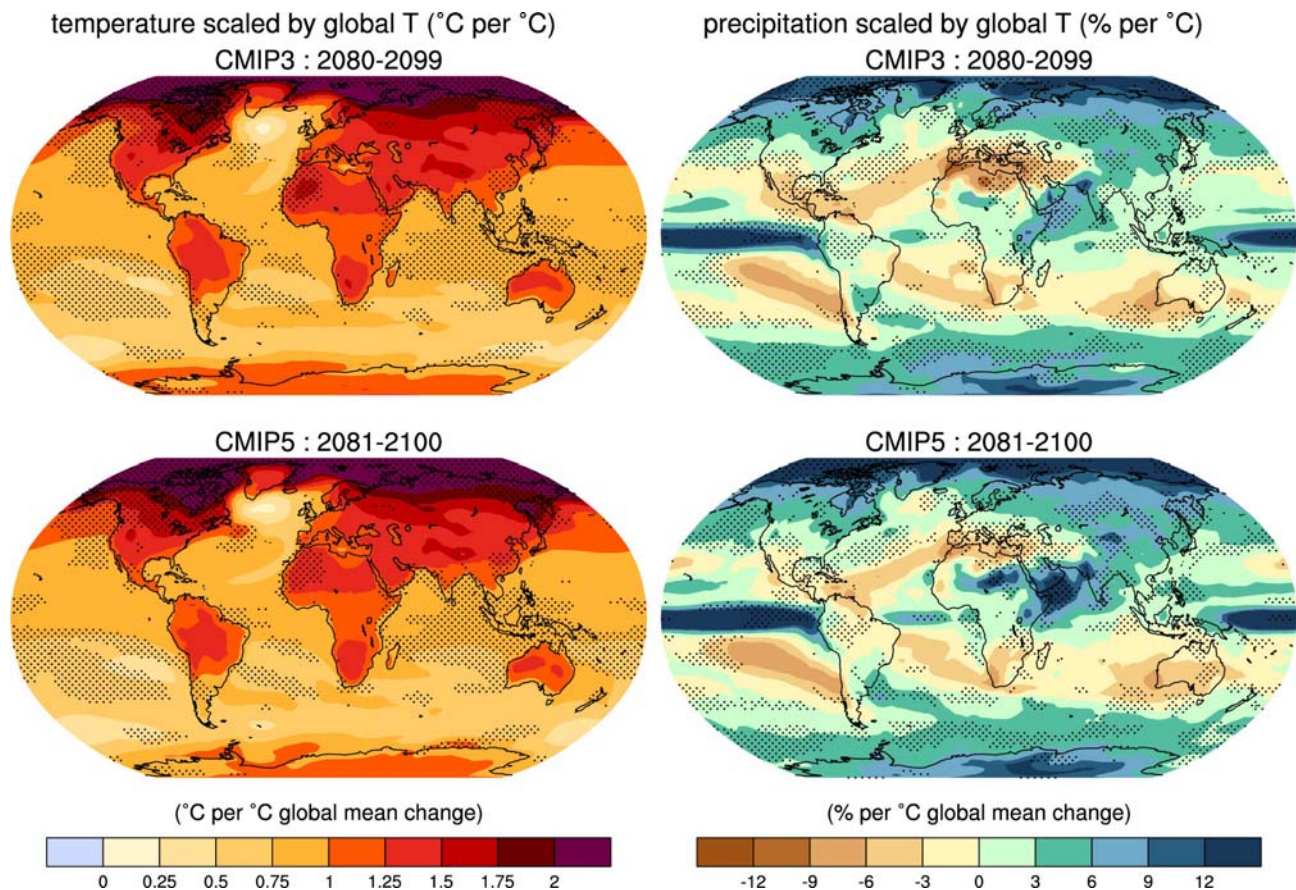

Figure 12.41: Patterns of temperature (left column) and percent precipitation change (right column) for the CMIP3 models average (first row) and CMIP5 models average (second row), scaled by the corresponding global average temperature changes. The patterns are computed in both cases by taking the difference between the averages over the last twenty years of the 21st century experiments (2080–2099 for CMIP3 and 2081–2100 for CMIP5) and the last twenty years of the historic experiments (1980–1999 for CMIP3, 1986–2005 for CMIP5) and rescaling each difference by the corresponding change in global average temperature. This is done first for each individual model, then the results are averaged across models. For the CMIP5 patterns, the RCP2.6 simulation of the FIO-ESM model was excluded because it did not show any warming by the end of the 21st century, thus not complying with the method requirement that the pattern be estimated at a time when the temperature change signal from CO_2 increase has emerged. Stippling indicates a measure of significance of the difference between the two corresponding patterns obtained by a bootstrap exercise. Two subsets of the pooled set of CMIP3 and CMIP5 ensemble members of the same size as the original ensembles, but without distinguishing CMIP3 from CMIP5 members, were randomly sampled 500 times. For each random sample we compute the corresponding patterns and their difference, then the true difference is compared, grid-point by grid-point, to the distribution of the bootstrapped differences, and only grid-points at which the value of the difference falls in the tails of the bootstrapped distribution (less than the 2.5 percentiles or the 97.5 percentiles) are stippled.

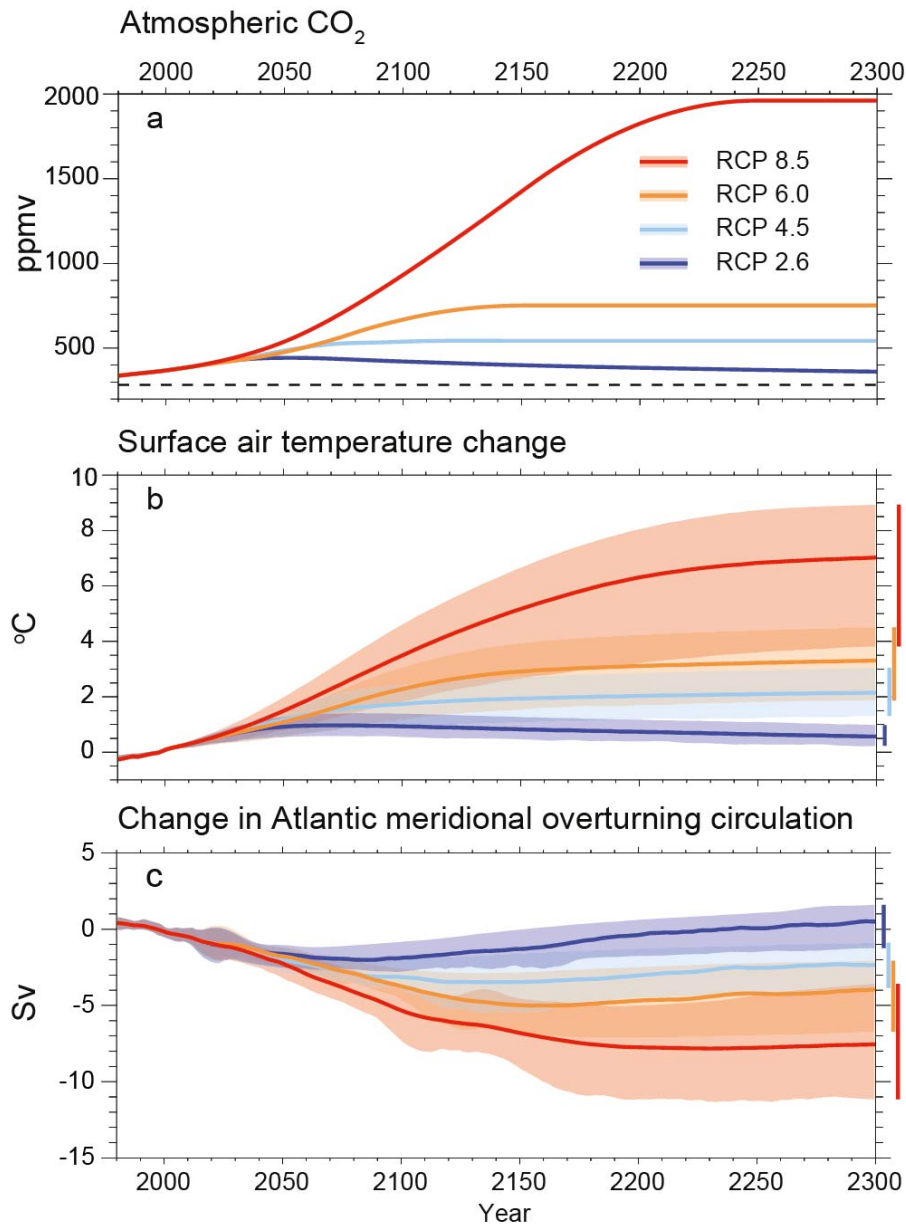

Figure 12.42: a) Atmospheric CO₂, b) projected global mean surface temperature change and c) projected change in the Atlantic meridional overturning circulation, as simulated by EMICs for the four RCPs up to 2300 (Zickfeld et al., 2013). A ten-year smoothing was applied. Shadings and bars denote the minimum to maximum range. The dashed line on panel (a) indicates the pre-industrial CO₂ concentration.

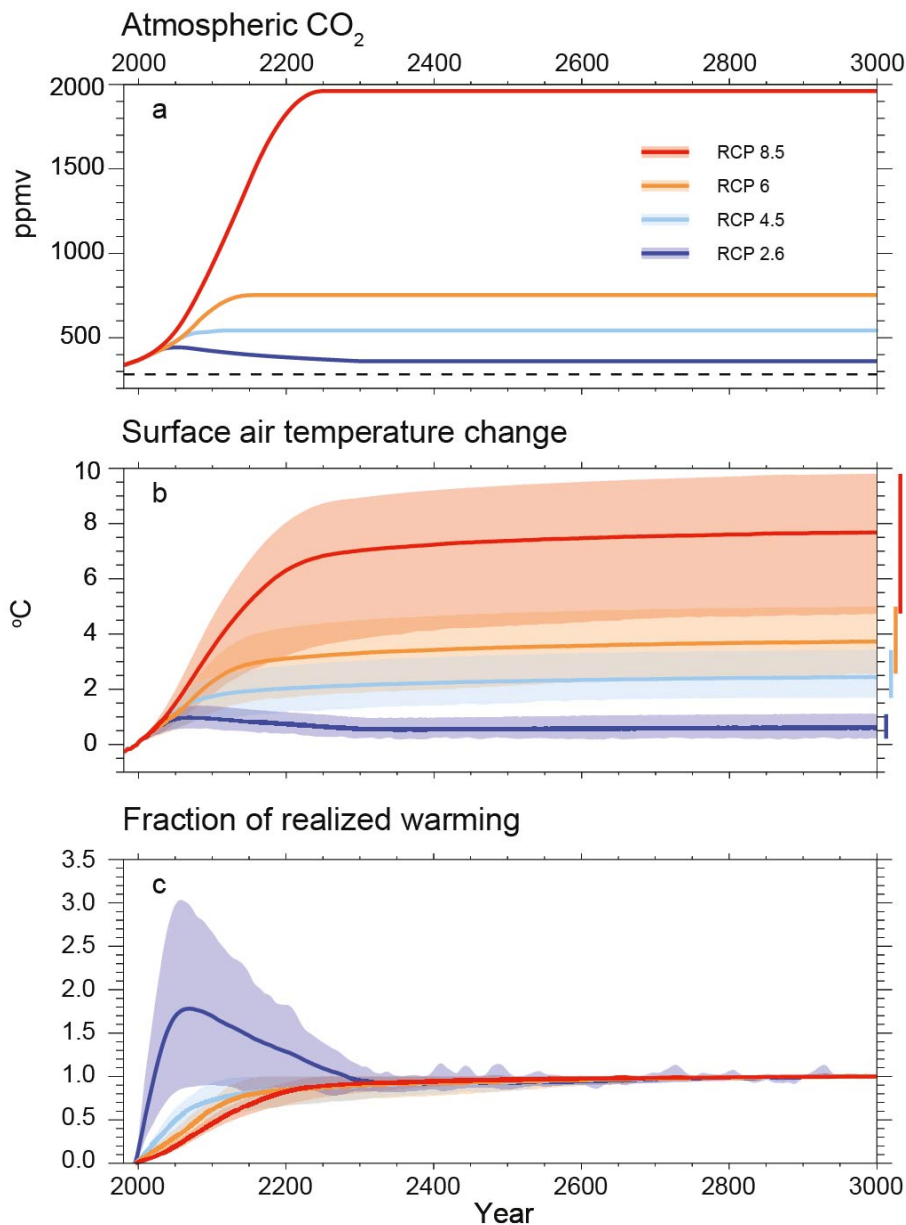

Figure 12.43: a) Atmospheric CO₂, b) projected global mean surface temperature change and c) fraction of realized warming calculated as the ratio of global temperature change at a given time to the change averaged over the 2980–2999 time period, as simulated by EMICs for the 4 RCPs up to 2300 followed by a constant (year 2300 level) radiative forcing up to the year 3000 (Zickfeld et al., 2013). A ten-year smoothing was applied. Shadings and bars denote the minimum to maximum range. The dashed line on panel (a) indicates the pre-industrial CO₂ concentration..

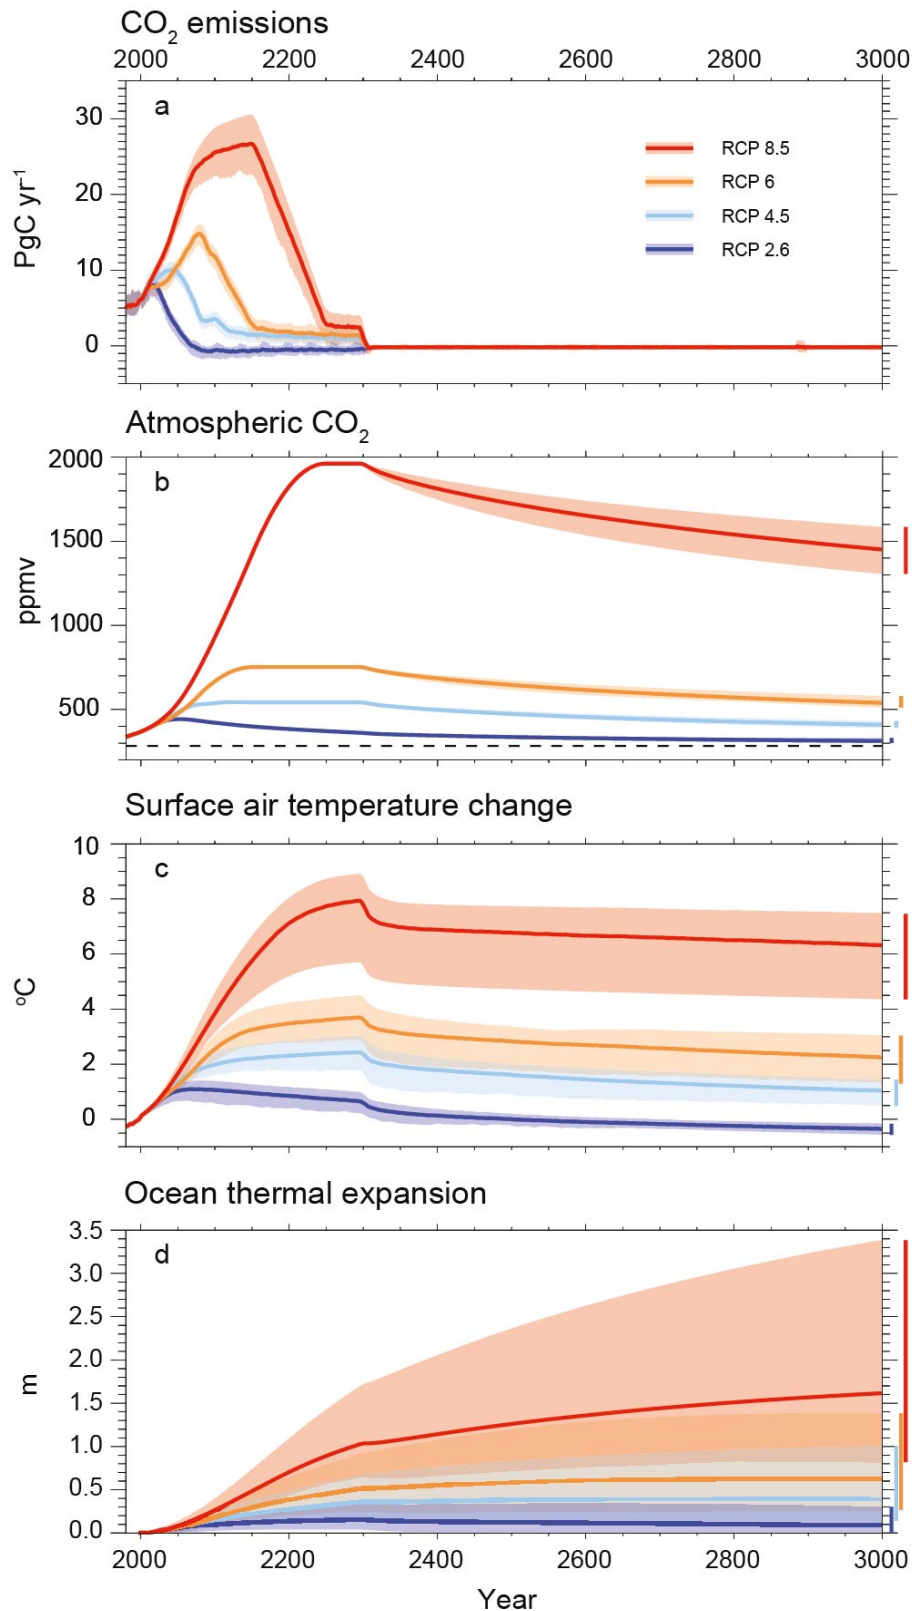

Figure 12.44: a) Compatible anthropogenic CO₂ emissions up to 2300, followed by zero emissions after 2300, b) prescribed atmospheric CO₂ concentration up to 2300 followed by projected CO₂ concentration after 2300, c) global mean surface temperature change and d) ocean thermal expansion as simulated by EMICs for the four concentration driven RCPs with all forcings included (Zickfeld et al., 2013). A 10-year smoothing was applied. The drop in temperature in 2300 is a result of eliminating all non-CO₂ forcings along with CO₂ emissions. Shadings and bars denote the minimum to maximum range. The dashed line on panel (b) indicates the pre-industrial CO₂ concentration.

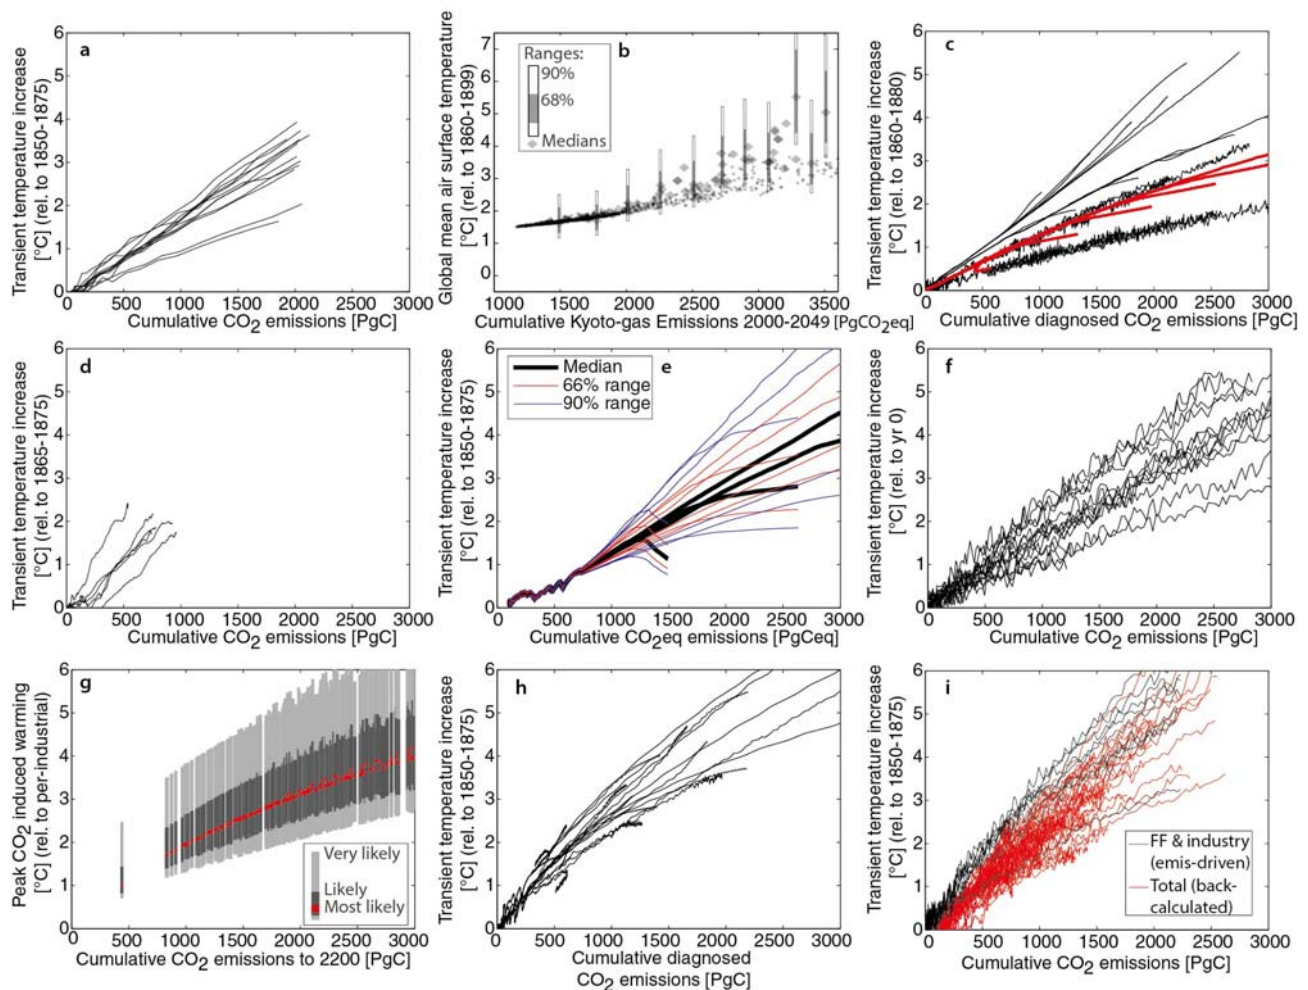

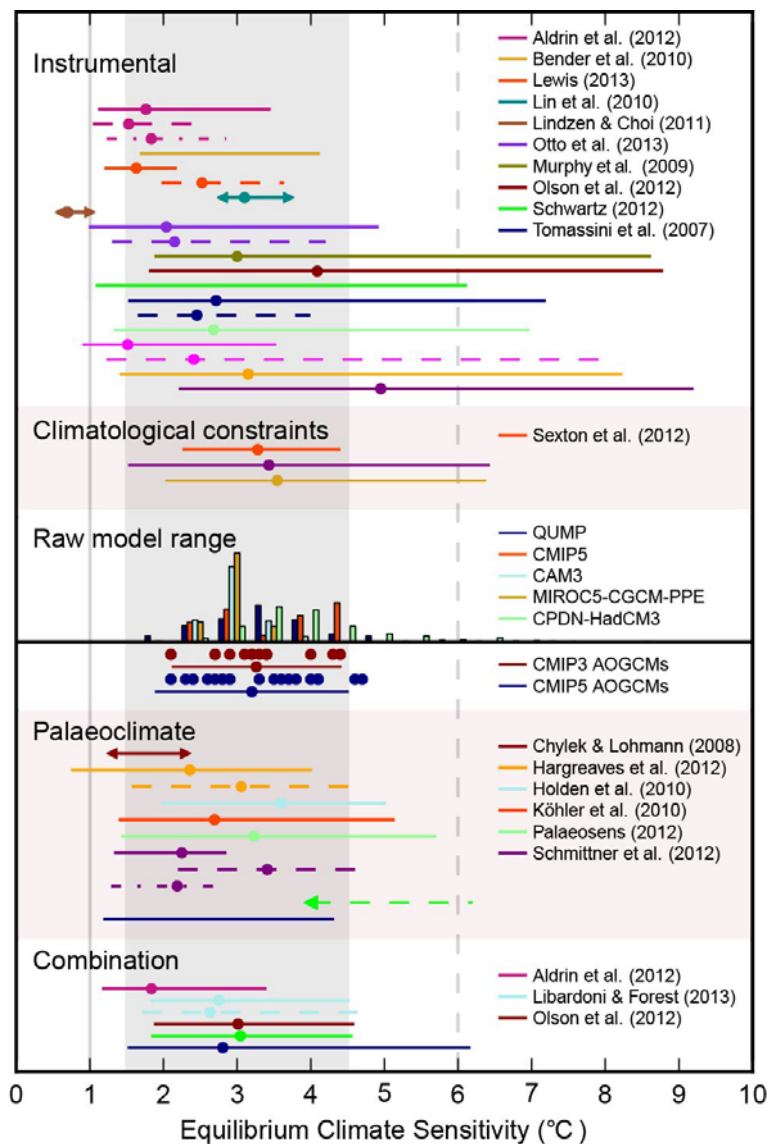

Figure 12.45: Global temperature change vs. cumulative carbon emissions for different scenarios and models. a) Transient global temperature increase vs. cumulative CO₂ emissions for C⁴MIP (Matthews et al., 2009), b) maximum temperature increase until 2100 vs. cumulative Kyoto-gas emissions (CO₂ equivalent, note that all other panels are given in C equivalent) (Meinshausen et al., 2009), c) transient temperature increase vs. cumulative CO₂ emissions for IPCC TAR models (red, IPCC TAR Figure 13.3) and IPCC AR4 EMICs (black, IPCC AR4 Figure 10.35), d) as in panel (a) but for the ENSEMBLES E1 scenario (Johns et al., 2011), e) transient temperature increase for the RCP scenarios based on the MAGICC model constrained to C⁴MIP, observed warming, and the IPCC AR4 climate sensitivity range (Rogelj et al., 2012), f) transient temperature change from the CMIP5 1% yr⁻¹ concentration driven simulations, g) peak CO₂ induced warming vs. cumulative CO₂ emissions to 2200 (Allen et al., 2009; Bowerman et al., 2011), h) transient temperature increase from the new EMIC RCP simulations (Zickfeld et al., 2013) and i) transient temperature change from the CMIP5 historical and RCP8.5 emission driven simulations (black) and transient temperature change in all concentration-driven CMIP5 RCP simulations with back-calculated emissions (red). Note that black lines in panel (i) do not include land-use CO₂ and that warming in panel (i) is higher than in panel (f) due to additional non CO₂ forcings.

Box 12.2, Figure 1: Probability density functions, distributions and ranges for equilibrium climate sensitivity, based on Figure 10.20b plus climatological constraints shown in IPCC AR4 (Meehl et al., 2007, Box 10.2 Figure 1), and results from CMIP5 (Table 9.5). The grey shaded range marks the *likely* 1.5°C–4.5°C range, grey solid line the *extremely unlikely* less than 1°C, the grey dashed line the *very unlikely* greater than 6°C. See Figure 10.20b and Chapter 10 Supplementary Material for full caption and details. Labels refer to studies since AR4.

Box 12.2, Figure 2: Probability density functions, distributions and ranges (5–95%) for the transient climate response from different studies, based on Figure 10.20a, and results from CMIP5 (black histogram, Table 9.5). The grey shaded range marks the *likely* 1°C–2.5°C range, the grey solid line marks the *extremely unlikely* greater than 3°C. See Figure 10.20a and Chapter 10 Supplementary Material for full caption and details.

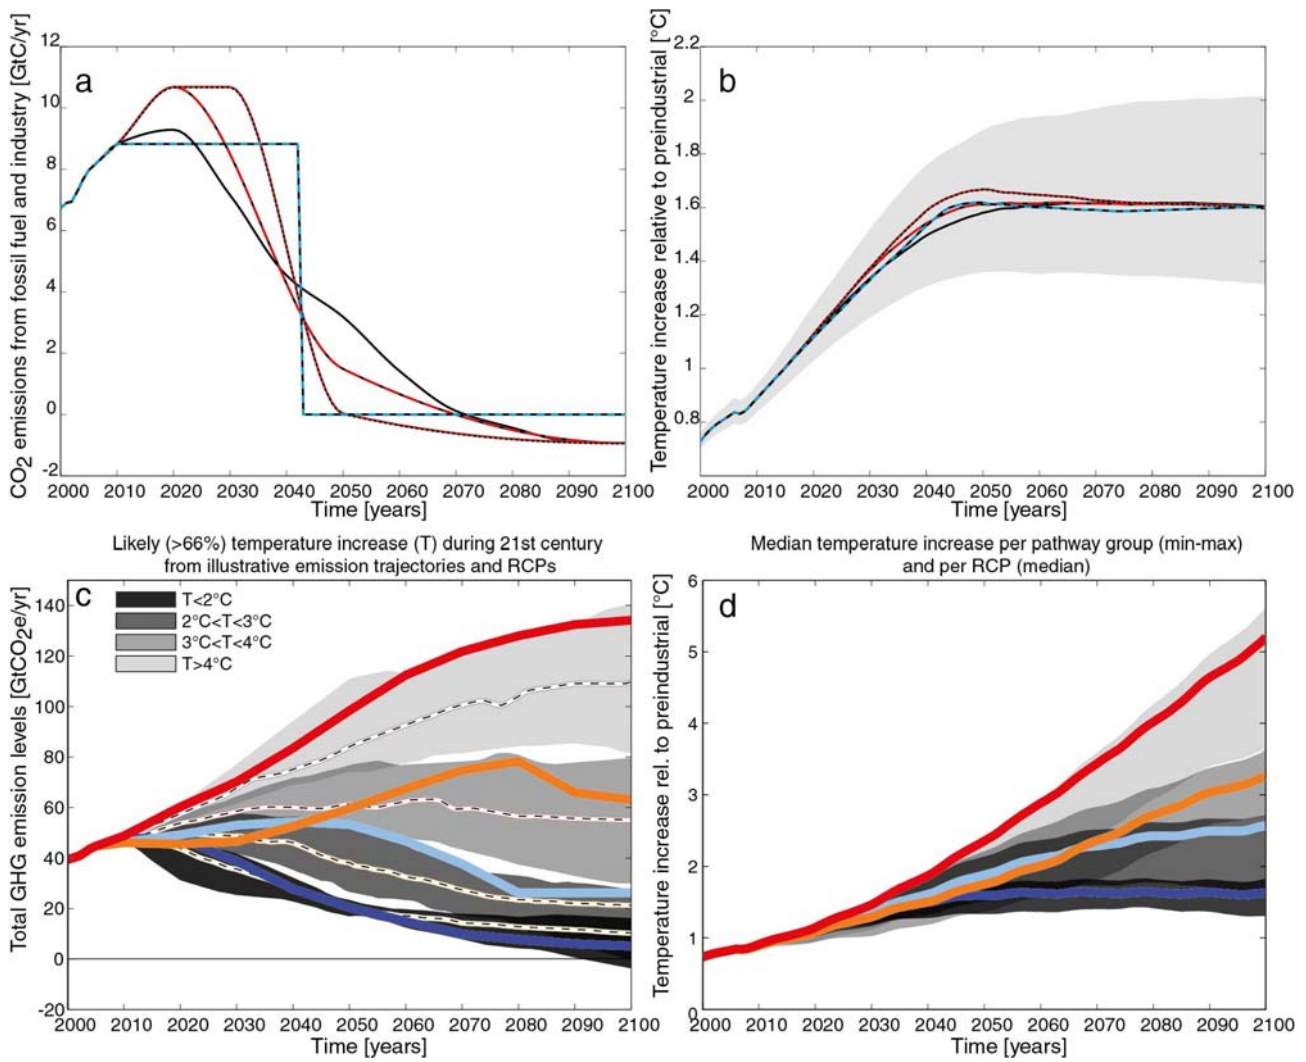

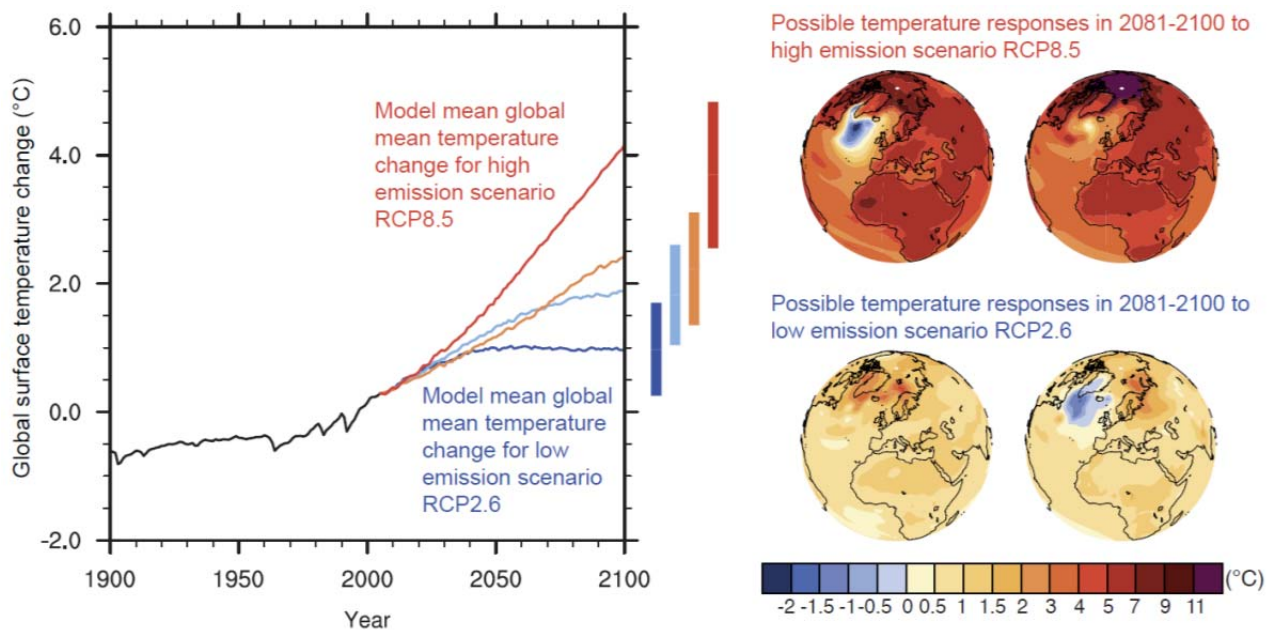

Figure 12.46: a) CO₂ emissions for the RCP2.6 scenario (black) and three illustrative modified emission pathways leading to the same warming, b) global temperature change relative to preindustrial for the pathways shown in panel (a). c) Grey shaded bands show IAM emission pathways over the 21st century. The pathways were grouped based on ranges of *likely* avoided temperature increase in the 21st century. Pathways in the darkest three bands *likely* stay below 2°C, 3°C, 4°C by 2100, respectively (see legend), while those in the lightest grey band are higher than that. Emission corridors were defined by, at each year, identifying the 15th to 85th percentile range of emissions and drawing the corresponding bands across the range. Individual scenarios that follow the upper edge of the bands early on tend to follow the lower edge of the band later on. Black-white lines show median paths per range, d) global temperature relative to preindustrial for the pathways in panel c. Data in panels c, d based on Rogelj et al. (2011). Coloured lines in c, d denote the four RCP scenarios.

FAQ 12.1, Figure 1: Global mean temperature change averaged across all CMIP5 models (relative to 1986–2005) for the four RCP scenarios: RCP2.6 (dark blue), RCP4.5 (light blue), RCP6.0 (orange) and RCP8.5 (red); 32, 42, 25 and 39 models were used respectively for these 4 scenarios. *Likely* ranges for global temperature change by the end of the 21st century are indicated by vertical bars. Note that these ranges apply to the difference between two 20-year means, 2081–2100 relative to 1985–2005, which accounts for the bars being centred at a smaller value than the end point of the annual trajectories. For the highest (RCP8.5) and lowest (RCP2.6) scenario, illustrative maps of surface temperature change at the end of the 21st century (2081–2100 relative to 1986–2005) are shown for three CMIP5 models. These models are chosen to show a rather broad range of response, but this particular set is not representative of any measure of model response uncertainty.

FAQ 12.2, Figure 1: Schematic diagram of projected changes in major components of the water cycle. The blue arrows indicate major types of water movement changes through the Earth's climate system: poleward water transport by extratropical winds, evaporation from the surface and runoff from the land to the oceans. The shaded regions denote areas more likely to become drier or wetter. Yellow arrows indicate an important atmospheric circulation change by the Hadley circulation, whose upward motion promotes tropical rainfall, while suppressing subtropical rainfall. Model projections indicate that the Hadley circulation will shift its downward branch poleward in both the Northern and Southern Hemispheres, with associated drying. Wetter conditions are projected at high latitudes, because a warmer atmosphere will allow greater precipitation, with greater movement of water into these regions.

FAQ 12.3, Figure 1: Projections based on the energy balance carbon cycle model MAGICC for constant atmospheric composition (constant forcing, grey), constant emissions (red) and zero future emissions (blue) starting in 2010, with estimates of uncertainty. Figure adapted from Hare and Meinshausen (2006) based on the calibration of a simple carbon cycle climate model to all CMIP3 and C⁴MIP models (Meinshausen et al., 2011a; Meinshausen et al., 2011c). Results are based on a full transient simulation starting from preindustrial and using all radiative forcing components.

Executive Summary

This chapter considers changes in global mean sea level, regional sea level, sea level extremes and waves. Confidence in projections of global mean sea level rise has increased since the AR4 because of the improved physical understanding and the improved agreement of process-based models with observations, and the inclusion of ice-sheet dynamical changes.

Past Sea Level Change

Paleo sea level records from warm periods during the last 3 million years indicate that global mean sea level exceeded 5 m above present (*very high confidence*)¹ when global temperature was up to 2°C warmer than pre-industrial (*medium confidence*). During the last interglacial period (~129–116 ka), peak global warmth was not more than 2°C above pre-industrial temperatures (*medium confidence*) and global mean sea level was 5 m higher than present (*very high confidence*) to 10 m higher than present (*high confidence*), implying substantial contributions from the Greenland and Antarctic ice sheets. [5.3.4, 5.6.1, 5.6.2, 13.2.1]

Based on proxy and instrumental data, it is *virtually certain*² that the rate of global mean sea level rise has accelerated during the last two centuries, marking the transition from relatively low rates of change during the late Holocene (order tenths of mm yr⁻¹) to modern rates (order mm yr⁻¹). It is *very likely* that the mean rate was 1.7 [1.5 to 1.9] mm yr⁻¹ between 1901 and 2010 for a total sea level rise of 0.19 [0.17 to 0.21] m. Between 1993 and 2010, the rate was *very likely* higher at 3.2 [2.8 to 3.6] mm yr⁻¹; similarly high rates *likely* occurred between 1930 and 1950. It is *likely* that global mean sea level has accelerated since the early 1900s, with estimates ranging from 0.000 to 0.013 [–0.002 to 0.019] mm yr⁻². [3.7.2, 3.7.4, 5.6.3, 13.2.1–13.2.2, Figure 13.3]

Understanding of Sea Level Change

Ocean thermal expansion and glacier melting have been the dominant contributors to 20th century global mean sea level rise. Observations since 1971 indicate that thermal expansion and glaciers (excluding the glaciers in Antarctica) explain 75% of the observed rise (*high confidence*). The contribution of the Greenland and Antarctic ice sheets has increased since the early 1990s, partly from increased outflow induced by warming of the immediately adjacent ocean. Natural and human-induced land water storage changes have made only a small contribution; the rate of groundwater depletion has increased and now exceeds the rate of reservoir impoundment. Since 1993, when observations of all sea level components are available, the sum of contributions equals the observed global mean sea level rise within uncertainties (*high confidence*). [Chapter 3; Chapter 4; 13.3.6; Figure 13.4; Table 13.1]

There is *high confidence* in projections of thermal expansion, *high confidence* in projections of Greenland surface mass balance, and *medium confidence* in projections of Antarctic surface mass balance and glacier mass loss. There has been substantial progress in ice-sheet modelling, particularly for Greenland. Process-based model calculations of contributions to past sea level change from ocean thermal expansion, glacier mass loss and Greenland ice-sheet surface mass balance are consistent with available observational estimates over recent decades. Ice sheet flow-line modelling is able to reproduce observed acceleration of the main outlet glaciers in the Greenland Ice Sheet, thus allowing estimates of the 21st century dynamic response (*medium confidence*). Significant challenges remain in the process-based projection of the dynamics response of marine terminating glaciers and the Antarctic Ice Sheet. Alternative

¹ In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

² In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

means of projection (extrapolation within a statistical framework and informed judgement) provide *medium confidence* in a likely range. There is currently *low confidence* in projecting the onset of large-scale grounding line instability in the marine sectors of the ice sheet. [13.3.1–13.3.3, 13.4.3, 13.4.4]

The sum of thermal expansion simulated by CMIP5 AOGCMs, glacier mass loss computed by global glacier models using CMIP5 climate change simulations, and estimates of land water storage explain 65% of the observed global mean sea level rise for 1901–1990 and 90% for 1971–2010 and 1993–2010 (*high confidence*). When observed climate parameters are used, the glacier models indicate a larger Greenland glacier contribution in the first half of the 20th century such that the sum of thermal expansion, glacier mass loss and changes in land water storage and a small ongoing Antarctic ice-sheet contribution are within 20% of the observations throughout the 20th century. In all periods, the residual is small enough to be attributed to the ice sheets. Model-based estimates of ocean thermal expansion and glacier contributions indicate that the greater rate of rise since 1990 is a response to radiative forcing (both anthropogenic and natural) and increased loss of ice-sheet mass and not part of a natural oscillation (*medium confidence*). [13.3.6; Figures 13.4 and 13.7; Table 13.1]

The Earth's Energy Budget

Independent estimates of effective radiative forcing of the climate system, the observed heat storage, and surface warming combine to give an energy budget for the Earth that is *very likely* closed within uncertainties, and is consistent with the *likely* range of climate sensitivity. The largest increase in the storage of heat in the climate system over recent decades has been in the oceans; this is a powerful observation for the detection and attribution of climate change. [Box 3.1 and Box 13.1]

Global Mean Sea Level Rise Projections

It is *very likely* that the rate of global mean sea level rise during the 21st century will exceed the rate observed during 1971–2010 for all RCP scenarios due to increased ocean warming and loss of mass from glaciers and ice sheets. For the period 2081–2100, compared to 1986–2005, global mean sea level rise is *likely* (*medium confidence*) to be in the 5–95% range of process-based models, which give 0.26–0.54 m for RCP2.6, 0.32–0.62 m for RCP4.5, 0.33–0.62 m for RCP6.0, and 0.45–0.81 m for RCP8.5. For RCP8.5, the rise by 2100 is 0.53–0.97 m with a rate during 2081–2100 of 7–15 mm yr⁻¹. We have considered the evidence for higher projections and have concluded that there is currently insufficient evidence to evaluate the probability of specific levels above the likely range. Based on current understanding, only the collapse of marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause global mean sea level to rise substantially above the likely range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise during the 21st century. [13.5.1, Table 13.5, Figures 13.10 and 13.11]

Some semi-empirical models project a range that overlaps the process-based *likely* range while others project a median and 95-percentile that are about twice as large as the process-based models. In nearly every case, the semi-empirical model 95-percentile is higher than the process-based *likely* range. Despite their successful calibration and evaluation against the observed 20th century sea level record, there is low agreement in their projections and no consensus in the scientific community about the reliability of SEM projections, and there is *low confidence* in their projections [13.5.2-3; Figure 13.12].

It is *virtually certain* that global mean sea level rise will continue beyond 2100, with sea level rise due to thermal expansion to continue for many centuries. Longer term sea level rise depends on future emissions. The few available process-based models indicate global mean sea level rise by 2300 to be less than 1 m for greenhouse gas concentrations that peak and decline and do not exceed 500 ppm CO₂-equivalent but 1–3 m for concentrations above 700 ppm CO₂-equivalent (*medium confidence*). The amount of ocean thermal expansion increases with global warming (0.2–0.6 m °C⁻¹) but the glacier contribution decreases over time as their volume (currently 0.43 m sea level equivalent) decreases. The contribution from the ice sheets will *likely* continue beyond 2100, but *confidence* in projections is *low*. Sea level rise of 1–3 m per degree of warming is expected if the warming is sustained for several millennia (*low confidence*). [13.5.4, Figures 13.13, 13.14]

The available evidence indicates that global warming greater than a certain threshold would lead to the near-complete loss of the Greenland Ice Sheet over a millennium or more, causing a global mean sea level rise of about 7 m. Studies with fixed ice sheet topography indicate the threshold is greater than 2°C but less than 4°C of global mean surface temperature rise with respect to preindustrial. The one study with a dynamical ice sheet suggests the threshold could be as low as 1°C. We are unable to quantify a *likely* range. Whether or not a decrease in the Greenland Ice Sheet mass loss is irreversible also depends on the duration and degree of exceedance of the threshold. [13.4.3.3]

Regional Sea Level Change Projections

It is very likely that in the 21st century and beyond, sea level change will have a strong regional pattern, with some places experiencing significant deviations of local and regional sea level change from the global mean change. Over decadal periods, the rates of regional sea level change as a result of climate variability can differ from the global average rate by more than 100% of the global average rate. By the end of the 21st century, it is *very likely* that over about 95% of the world ocean, regional sea level rise will be positive, while most regions experiencing a sea level fall are located near current and former glaciers and ice sheets. About 70% of the global coastlines are projected to experience a sea level change within 20% of the global mean sea level change. [13.6.5, Figures 13.18–13.20]

Projections of 21st Century Sea Level Extremes and Surface Waves

It is very likely that there will be a significant increase in the occurrence of future sea level extremes by 2050 and 2100. This increase will primarily be the result of an increase in mean sea level (*high confidence*), with the frequency of a particular sea level extreme increasing by an order of magnitude or more in some regions by the end of the 21st century. There is *low confidence* in region-specific projections of storminess and associated storm surges. [13.7.2, Figure 13.25]

It is likely (*medium confidence*) that annual mean significant wave heights will increase in the Southern Ocean as a result of enhanced wind speeds. Southern Ocean generated swells are *likely* to affect heights, periods, and directions of waves in adjacent basins. It is *very likely* that wave heights and the duration of the wave season will increase in the Arctic Ocean as a result of reduced sea-ice extent. In general, there is *low confidence* in region-specific projections due to the *low confidence* in tropical and extratropical storm projections, and to the challenge of downscaling future wind fields from coarse-resolution climate models. [13.7.3; Figure 13.26]

13.1 Components and Models of Sea Level Change

13.1.1 Introduction and Chapter Overview

Changes in sea level occur over a broad range of temporal and spatial scales, with the many contributing factors making it an integral measure of climate change (Milne et al., 2009; Church et al., 2010). The primary contributors to contemporary sea level change are the expansion of the ocean as it warms and the transfer of water currently stored on land, particularly from land ice (glaciers and ice sheets) (Church et al., 2011b). Observations indicate the largest increase in the storage of heat in the climate system over recent decades has been in the oceans (Section 3.2) and thus sea level rise from ocean warming is a central part of the Earth's response to increasing greenhouse gas concentrations.

The First IPCC Assessment laid the groundwork for much of our current understanding of sea level change (Warrick and Oerlemans, 1990). This included the recognition that sea level had risen during the 20th century, that the rate of rise had increased compared to the 19th century, that ocean-thermal expansion and the mass loss from glaciers were the main contributors to the 20th century rise, that during the 21st century the rate of rise was projected to be faster than during the 20th century, that sea level will not rise uniformly around the world, and that sea level would continue to rise well after greenhouse gas emissions were reduced. They also concluded that no major dynamic response of the ice sheets was expected during the 21st century, leaving ocean-thermal expansion and the melting of glaciers as the main contributors to the 21st century rise. The Second Assessment Report came to very similar conclusions (Warrick et al., 1996).

By the time of the Third Assessment Report, coupled atmosphere-ocean general circulation models (AOGCMs) and ice sheet models largely replaced energy-balance climate models as the primary techniques supporting the interpretation of observations and the projections of sea level (Church et al., 2001). This approach allowed consideration of the regional distribution of sea level change in addition to the global average change. By the time of the Fourth Assessment Report (AR4), there were more robust observations of the variations in the rate of global average sea level rise for the 20th century, some understanding of the variability in the rate of rise, and the satellite altimeter record was long enough to reveal the complexity of the time-variable spatial distribution of sea level (Bindoff et al., 2007). Nevertheless, three central issues remained. First, the observed sea level rise over decades was larger than the sum of the individual contributions estimated from observations or with models (Rahmstorf et al., 2007; Rahmstorf et al., 2012b), although in general the uncertainties were large enough that there was no significant contradiction. Second, it was not possible to make confident projections of the regional distribution of sea level rise. Third, there was insufficient understanding of the potential contributions from the ice sheets. In particular, the AR4 recognised that existing ice-sheet models were unable to simulate the recent observations of ice-sheet accelerations and that understanding of ice-sheet dynamics was too limited to assess the likelihood of continued acceleration or to provide a best estimate or an upper bound for their future contributions.

Despite changes in the scenarios between the four Assessments, the sea level projections for 2100 (compared to 1990) for the full range of scenarios were remarkably similar, with the reduction in the upper end in more recent reports reflecting the smaller increase in radiative forcing in recent scenarios due to smaller greenhouse gas (GHG) emissions and the inclusion of aerosols, and a reduction in uncertainty in projecting the contributions: 31 to 110 cm in the FAR, 13 to 94 cm in the SAR, 9 to 88 cm in the TAR, and 18 to 59 cm in AR4 (not including a possible additional allowance for a dynamic ice-sheet response).

Results since the AR4 show that for recent decades, sea level has continued to rise (Section 3.7). Improved and new observations of the ocean (Section 3.7) and the cryosphere (Chapter 4) and their representation in models have resulted in better understanding of 20th century sea level rise and its components (this chapter). Records of past sea level changes constrain long-term land-ice response to warmer climates as well as extend the observational record to provide a longer context for current sea level rise (Section 5.6).

This chapter provides a synthesis of past and contemporary sea level change at global and regional scales. Drawing on the published refereed literature, including as summarised in earlier chapters of this Assessment, we explain the reasons for contemporary change, and assess *confidence* in and provide global and regional projections of *likely* sea level change for the 21st century and beyond. We discuss the primary factors that cause regional sea level to differ from the global average and how these may change in the

future. In addition, we address projected changes in surface waves and the consequences of sea level and climate change for extreme sea level events.

13.1.2 Fundamental Definitions and Concepts

The height of the ocean surface at any given location, or sea level, is measured either with respect to the surface of the solid Earth (relative sea level, RSL) or a geocentric reference such as the reference ellipsoid (geocentric sea level). RSL is the more relevant quantity when considering the coastal impacts of sea level change, and it has been measured using tide gauges during the past few centuries (Sections 13.2.2 and 3.7) and estimated for longer time spans from geological records (Sections 13.2.1 and 5.6). Geocentric sea level has been measured over the past two decades using satellite altimetry (Sections 13.2.2 and 3.7).

A temporal average for a given location, known as Mean Sea Level (MSL; see Glossary), is applied to remove shorter period variability. Apart from Section 13.7, which considers high-frequency changes in ocean surface height, the use of ‘sea level’ elsewhere in this chapter refers to MSL. It is common to average MSL spatially to define Global Mean Sea Level (GMSL; see Glossary). In principle, integrating RSL change over the ocean area gives the change in ocean water volume, which is directly related to the processes that dominate sea level change (changes in ocean temperature and land-ice volume). In contrast, a small correction (-0.15 to -0.5 mm yr⁻¹) needs to be subtracted from altimetry observations to estimate ocean water volume change (Tamisiea, 2011). Local RSL change can differ significantly from GMSL because of spatial variability in changes of the sea-surface and ocean-floor height (see FAQ 13.1 and Section 13.7).

13.1.3 Processes Affecting Sea Level

This chapter focuses on processes within the ocean, atmosphere, land ice, and hydrological cycle that are climate sensitive and are expected to contribute to sea level change at regional to global scales in the coming decades to centuries (Figure 13.1). Figure 13.2 is a navigation aid for the different sections of this chapter and sections of other chapters that are relevant to sea level change.

[INSERT FIGURE 13.1 HERE]

Figure 13.1: Climate sensitive processes and components that can influence global and regional sea level and are considered in this chapter. Changes in any one of the components or processes shown will result in a sea level change. The term ‘ocean properties’ refers to ocean temperature, salinity and density, which influence and are dependent on ocean circulation. Both relative and geocentric sea level vary with position. Note that the geocenter is not shown.

[INSERT FIGURE 13.2 HERE]

Figure 13.2: Schematic representation of key linkages between processes and components that contribute to sea level change and are considered in this report. Colouring of individual boxes indicates the types of models and approaches used in projecting the contribution of each process or component to future sea level change. The diagram also serves as an index to the sections in this report that are relevant to the assessment of sea level projections via the section numbers given at the bottom of each box. Note gravity and solid Earth effects change the shape of the ocean floor and surface and thus are required to infer changes in ocean water volume from both relative and geocentric sea level observations.

Changes in ocean currents, ocean density and sea level are all tightly coupled such that changes at one location impact local sea level and sea level far from the location of the initial change, including changes in sea level at the coast in response to changes in deep-ocean temperature (Landerer et al., 2007; Yin et al., 2010). While both temperature and salinity changes can contribute significantly to regional sea level change (Church et al., 2010), only temperature change produces a significant contribution to global average ocean volume change due to thermal expansion/contraction (Gregory and Lowe, 2000). Regional atmospheric pressure anomalies also cause sea level to vary through atmospheric loading (Wunsch and Stammer, 1997). All of these climate-sensitive processes cause sea level to vary on a broad range of space and time scales from relatively short lived events, such as waves and storm surges, to sustained changes over several decades or centuries that are associated with atmospheric and ocean modes of climate variability (White et al., 2005; Miller and Douglas, 2007; Zhang and Church, 2012).

Water and ice mass exchange between the land and the oceans leads to a change in GMSL. A signal of added mass to the ocean propagates rapidly around the globe such that all regions experience a sea level change within days of the mass being added (Lorbacher et al., 2012). In addition, an influx of freshwater changes

ocean temperature and salinity and thus changes ocean currents and local sea level (Stammer, 2008; Yin et al., 2009), with signals taking decades to propagate around the global ocean. The coupled atmosphere-ocean system can also adjust to temperature anomalies associated with surface freshwater anomalies through air-sea feedbacks, resulting in dynamical adjustments of sea level (Okumura et al., 2009; Stammer et al., 2011). Water mass exchange between land and the ocean also results in patterns of sea level change called ‘sea level fingerprints’ (Clark and Lingle, 1977; Conrad and Hager, 1997; Mitrovica et al., 2001) due to change in the gravity field and vertical movement of the ocean floor associated with visco-elastic Earth deformation (Farrell and Clark, 1976). These changes in mass distribution also affect the Earth’s inertia tensor and therefore rotation, which produces an additional sea level response (Milne and Mitrovica, 1998).

There are other processes that affect sea level but are not associated with contemporary climate change. Some of these result in changes that are large enough to influence the interpretation of observational records and sea level projections at regional and global scales. In particular surface mass transfer from land ice to oceans during the last deglaciation contributes significantly to present-day sea level change due to the ongoing visco-elastic deformation of the Earth and the corresponding changes of the ocean floor height and gravity (referred to as glacial isostatic adjustment, GIA) (Lambeck and Nakiboglu, 1984; Peltier and Tushingham, 1991). Ice sheets also have long response times and so continue to respond to past climate change (Section 13.1.5).

Anthropogenic processes that influence the amount of water stored in the ground or on its surface in lakes and reservoirs, or cause changes in land-surface characteristics that influence runoff or evapotranspiration rates, will perturb the hydrological cycle and cause sea level change (Sahagian, 2000; Wada et al., 2010). Such processes include water impoundment (dams, reservoirs), irrigation schemes, and ground water depletion (Section 13.4.5).

Sea level changes due to tectonic and coastal processes are beyond the scope of this chapter. With the exception of earthquakes, which can cause rapid local changes and tsunamis (Broerse et al., 2011) and secular RSL changes due to post-seismic deformation (Watson et al., 2010), tectonic processes cause, on average, relatively low rates of sea level change (order 0.1 mm yr^{-1} or less) (Moucha et al., 2008). Sediment transfer and compaction (including from ground water depletion) in the coastal zone are particularly important in deltaic regions (Blum and Roberts, 2009; Syvitski et al., 2009). While they can dominate sea level change in these localised areas, they are less important as a source of sea level change at regional and global scales and so are not considered further in this chapter (See they are discussed in WGII Chapter 5). Estimates of sediment delivery to the oceans (Syvitski and Kettner, 2011) suggest a contribution to GMSL rise of order 0.01 mm yr^{-1} .

13.1.4 Models Used to Interpret Past and Project Future Changes in Sea Level

Atmosphere-ocean general circulation models (AOGCMs) have components representing the ocean, atmosphere, land and cryosphere and simulate sea-surface height changes relative to the geoid resulting from the natural forcings of volcanic eruptions and changes in solar irradiance, and from anthropogenic increases in greenhouse gases and aerosols (Chapter 9). AOGCMs also exhibit internally generated climate variability, including such modes as the El Niño Southern Oscillation (ENSO), the Pacific Decadal Oscillation (PDO), the North Atlantic Oscillation (NAO), and others which affect sea level (White et al., 2005; Zhang and Church, 2012). Critical components for global and regional changes in sea level are changes in surface wind stress and air-sea heat and freshwater fluxes (Lowe and Gregory, 2006; Timmermann et al., 2010; Suzuki and Ishii, 2011) and the resultant changes in ocean density and circulation, for instance in the strength of the Atlantic meridional overturning circulation (AMOC) (Yin et al., 2009; Lorbacher et al., 2010; Pardaens et al., 2011a). As in the real world, ocean density, circulation, and sea level are dynamically connected in AOGCMs and evolve together. Offline models are required for simulating glacier and ice-sheet changes (Section 13.1.4.1).

Geodynamic surface-loading models are used to simulate the RSL response to past and contemporary changes in surface water and land-ice mass redistribution and contemporary atmospheric pressure changes. The sea surface height component of the calculation is based solely on water mass conservation and perturbations to gravity, with no considerations of ocean dynamic effects. Application of these models has focused on annual and interannual variability driven by contemporary changes in the hydrological cycle and

atmospheric loading (Clarke et al., 2005; Tamisiea et al., 2010), and on secular trends associated with past and contemporary changes in land ice and hydrology (Lambeck et al., 1998; Mitrovica et al., 2001; Peltier, 2004; Riva et al., 2010).

Semi-empirical models (SEMs) project sea level based on statistical relationships between observed GMSL and global mean temperature (Rahmstorf, 2007a; Vermeer and Rahmstorf, 2009; Grinsted et al., 2010) or total radiative forcing (Jevrejeva et al., 2009; Jevrejeva et al., 2010). The form of this relationship is motivated by physical considerations, and the parameters are determined from observational data—hence the term “semi-empirical” (Rahmstorf et al., 2012a). SEMs do not explicitly simulate the underlying processes, and they use a characteristic response time that could be considerably longer than the timescale of interest (Rahmstorf, 2007a) or explicitly determined by the model (Grinsted et al., 2010).

Storm-surge and wave-projection models are used to assess how changes in storminess and MSL impact sea level extremes and wave climates. The two main approaches involve dynamical (Lowe et al., 2010) and statistical models (Wang et al., 2010). The dynamical models are forced by near-surface wind and mean sea level pressure fields derived from regional or global climate models (Lowe et al., 2010).

In this chapter, we use the term “process-based models” (see Glossary) to refer to sea level and land-ice models (Section 13.1.5.1) that aim to simulate the underlying processes and interactions, in contrast to “semi-empirical models” which do not. While these two approaches are distinct, semi-empirical methods are often employed in components of the process-based models (e.g., glacier models in which surface mass balance is determined by a Degree Day method (Braithwaite and Olesen, 1989)).

13.1.4.1 Models Used to Project Changes in Ice Sheets and Glaciers

The representation of glaciers and ice sheets within AOGCMs is not yet at a stage where projections of their changing mass are routinely available. Additional process-based models use output from AOGCMs to evaluate the consequences of projected climate change on these ice masses.

The overall contribution of an ice mass to sea level involves changes to either its surface mass balance (SMB) or changes in the dynamics of ice flow that affect outflow (i.e., solid ice discharge) to the ocean. SMB is primarily the difference between snow accumulation and the melt and sublimation of snow and ice (ablation). An assessment of observations related to this mass budget can be found in Section 4.4.2. Although some ice-sheet models used in projections incorporate both effects, most studies have focussed on either SMB or flow dynamics. It is assumed that the overall contribution can be found by summing the contributions calculated independently for these two sources, which is valid if they do not interact significantly. While this can be addressed using a correction term to SMB in ice-sheet projections over the next century, such interactions become more important on longer time scales when, for example, changes in ice-sheet topography may significantly affect SMB or dynamics.

Projecting the sea level contribution of land ice requires comparing the model results with a base state that assumes no significant sea level contribution. This base state is taken to be either the preindustrial period or, because of our scant knowledge of the ice sheets before the advent of satellites, the late 20th century. In reality, even at these times, the ice sheets are likely to have been contributing to sea level change (Huybrechts et al., 2011; Box and Colgan, 2013) and this contribution, although difficult to quantify, should be included in the observed sea level budget (Gregory et al., 2013b) and the projections.

Regional climate models (RCMs), which incorporate or are coupled to sophisticated representations of the mass and energy budgets associated with snow and ice surfaces, are now the primary source of ice-sheet SMB projections. A major source of uncertainty lies in the ability of these schemes to adequately represent the process of internal refreezing of melt water within the snowpack (Bougamont et al., 2007; Fausto et al., 2009). These models require information on the state of the atmosphere and ocean at their lateral boundaries, which are derived from reanalysis data sets or AOGCMs for past climate, or from AOGCM projections of future climate.

Models of ice dynamics require a fairly complete representation of stresses within an ice mass in order to represent the response of ice flow to changes at the marine boundary and the governing longitudinal stresses

(Schoof, 2007b). For Antarctica, there is also a need to employ high spatial resolution (<1 km) to capture the dynamics of grounding line migration robustly so that results do not depend to an unreasonable extent on model resolution (Durand et al., 2009; Goldberg et al., 2009; Morlighem et al., 2010; Cornford et al., 2013; Pattyn et al., 2013). One-dimensional flowline models have been developed to the stage that modelled iceberg calving is comparable with observations (Nick et al., 2009). The success of this modelling approach relies on the ability of the model's computational grid to evolve to continuously track the migrating calving front. Although this is relatively straightforward in a one-dimensional model, this technique is difficult to incorporate into three-dimensional ice sheet models that typically use a computational grid that is fixed in time.

The main challenge faced by models attempting to assess sea level change from glaciers is the small number of glaciers for which mass budget observations are available (~380) (Cogley, 2009a) (see Sections 4.3.1 and 4.3.4) as compared to the total number (the World Glacier Inventory contains more than 181,500) (Arendt et al., 2012). Statistical techniques are used to derive relations between observed SMB and climate variables for the small sample of surveyed glaciers, and then these relations are used to upscale to regions of the world. These techniques often include volume-area scaling to estimate glacier volume from their more readily observable areas. Although tidewater glaciers may also be affected by changes in outflow related to calving, the complexity of the associated processes means that most studies limit themselves to assessing the effects of SMB changes.

13.2 Past Sea Level Change

13.2.1 The Geological Record

Records of past sea level change provide insight into the sensitivity of sea level to past climate change as well as context for understanding current changes and evaluating projected changes. Since the AR4, important progress has been made in understanding the amplitude and variability of sea level during past intervals when climate was warmer than pre-industrial, largely through better understanding of and accounting for the effects of proxy uncertainties and GIA on coastal sequences (Kopp et al., 2009; Raymo et al., 2011; Dutton and Lambeck, 2012; Lambeck et al., 2012; Raymo and Mitrovica, 2012; Kopp et al., 2013) (Chapter 5). Here we summarize the constraints provided by the record of past sea level variations during times when global temperature was similar to or warmer than today.

13.2.1.1 The Middle Pliocene

During the warm intervals of the middle Pliocene (3.3 to 3.0 Ma), there is *medium confidence* that global mean surface temperatures were 2°C–3.5°C warmer than for pre-industrial climate (Section 5.3.1). There are multiple lines of evidence that GMSL during these middle Pliocene warm periods was higher than today, but low agreement on how high it reached (Section 5.6.1). The most robust lines of evidence come from proximal sedimentary records that suggest periodic deglaciation of the WAIS and parts of the EAIS (Naish et al., 2009; Passchier, 2011) and from ice-sheet models that suggest near-complete deglaciation of GIS, WAIS and partial deglaciation of the EAIS (Pollard and DeConto, 2009; Hill et al., 2010; Dolan et al., 2011). The assessment by Chapter 5 suggests that GMSL was above present, but that it did not exceed 20 m above present, during the middle Pliocene warm periods (*high confidence*).

13.2.1.2 Marine Isotope Stage 11

During marine isotope stage 11 (MIS 11; 401–411 ka ago), Antarctic ice-core and tropical Pacific paleo-temperature estimates suggest that the global temperature was 1.5°C–2.0°C warmer than pre-industrial (*low confidence*) (Masson-Delmotte et al., 2010). Studies of the magnitude of sea level highstands from raised shorelines attributed to MIS 11 have generated highly divergent estimates. Since the AR4, studies have accounted for GIA effects (Raymo and Mitrovica, 2012) or reported elevations from sites where the GIA effects are estimated to be small (Muhs et al., 2012; Roberts et al., 2012). From this evidence, our assessment is that MIS 11 GMSL reached 6–15 m higher than present (*medium confidence*), requiring a loss of most or all of the present Greenland and West Antarctic Ice Sheets plus a reduction in the EAIS of up to 5 m equivalent sea level if sea level rise was at the higher end of the range.

13.2.1.3 The Last Interglacial Period

New data syntheses and model simulations since the AR4 indicate that during the Last Interglacial Period (LIG, ~129–116 ka), global mean annual temperature was not more than 2°C above pre-industrial (*medium confidence*). Data syntheses suggest peak global warmth was 1°C–2°C above pre-industrial temperatures, with peak global annual sea surface temperatures that were 0.7°C ± 0.6°C warmer (*medium confidence*) (Section 5.3.4). There is robust evidence and high agreement that under this warmer climate, sea level was higher than present. There have been a large number of estimates of the magnitude of LIG GMSL rise from localities around the globe, but they are generally from a small number of RSL reconstructions, and do not consider GIA effects, which can be substantial (Section 5.6.2). Since the AR4, two approaches have addressed GIA effects in order to infer LIG sea level from RSL observations at coastal sites. Kopp et al. (2009, 2013) obtained a probabilistic estimate of GMSL based on a large and geographically broadly distributed database of LIG sea level indicators. Their analysis accounted for GIA effects (and their uncertainties) as well as uncertainties in geochronology, the interpretation of sea level indicators, and regional tectonic uplift and subsidence. Kopp et al. (2013) concluded that GMSL was 6.4 m (95% probability) and 7.7 m (67% probability) higher than present, and with a 33% probability that it exceeded 8.8 m. The other approach, taken by Dutton and Lambeck (2012), used data from far-field sites that are tectonically stable. Their estimate of 5.5–9 m LIG GMSL is consistent with the probabilistic estimates made by Kopp et al. (2009, 2013). Chapter 5 thus concluded there is *very high confidence* that the maximum GMSL during the LIG was at least 5 m higher than present and *high confidence* it did not exceed 10 m. The best estimate is 6 m higher than present. Chapter 5 also concluded from ice-sheet model simulations and elevation changes derived from a new Greenland ice core that the Greenland Ice Sheet *very likely* contributed between 1.4 and 4.3 m sea level equivalent. This implies with *medium confidence* a contribution from the Antarctic Ice Sheet to the global mean sea level during the last interglacial period, but this is not yet supported by observational and model evidence.

There is *medium confidence* for a sea level fluctuation of up to 4 m during the LIG, but regional sea level variability and uncertainties in sea level proxies and their ages cause differences in the timing and amplitude of the reported fluctuation (Kopp et al., 2009; Thompson et al., 2011; Kopp et al., 2013). For the time interval during the LIG in which GMSL was above present, there is *high confidence* that the maximum 1000-year average rate of GMSL rise associated with the sea level fluctuation exceeded 2 m kyr⁻¹ but that it did not exceed 7 m kyr⁻¹ (Chapter 5) (Kopp et al., 2013). Faster rates lasting less than a millennium cannot be ruled out by these data. Therefore, there is *high confidence* that there were intervals when rates of GMSL rise during the LIG exceeded the 20th century rate of 1.7 [1.5 to 1.9] mm yr⁻¹.

13.2.1.4 The Late Holocene

Since the AR4, there has been significant progress in resolving the sea level history of the last 7000 years. From ~7 to 3 ka, RSL records indicate that GMSL *likely* rose 2–3 m to near present-day levels (Chapter 5). Based on local sea level records spanning the last 2000 years, there is *medium confidence* that fluctuations in GMSL during this interval have not exceeded ~ ±0.25 m on time scales of a few hundred years (Section 5.6.3, Figure 13.3a). The most robust signal captured in salt marsh records from both northern and southern hemispheres supports the AR4 conclusion for an acceleration that marks the transition from relatively low rates of change during the late Holocene (order tenths of mm yr⁻¹) to modern rates (order mm yr⁻¹) (Section 5.6.3, Figure 13.3b). However, there is variability in the magnitude and the timing (1840–1920) of this acceleration in both paleo and instrumented (tide gauge) records (Section 3.7). By combining paleo sea level records with tide gauge records at the same localities, Gehrels and Woodworth (2013) concluded that sea level began to rise above the late Holocene background rate between 1905 and 1945 CE, consistent with the conclusions by Lambeck et al. (2004).

[INSERT FIGURE 13.3 HERE]

Figure 13.3: (a) Paleo sea level data for last 3000 years from Northern and Southern Hemisphere sites. The effects of glacial isostatic adjustment (GIA) have been removed from these records. Light green = Iceland (Gehrels et al., 2006), purple = Nova Scotia (Gehrels et al., 2005), bright blue = Connecticut (Donnelly et al., 2004), blue = Nova Scotia (Gehrels et al., 2005), red = United Kingdom (Gehrels et al., 2011), green = North Carolina (Kemp et al., 2011), brown = New Zealand (Gehrels et al., 2008), gray = mid-Pacific Ocean (Woodroffe et al., 2012). (b) Paleo sea level data from salt marshes since 1700 from Northern and Southern Hemisphere sites compared to sea level reconstruction from tide gauges (blue time series with uncertainty) (Jevrejeva et al., 2008). The effects of GIA have been removed from these

records. Green and light green = North Carolina (Kemp et al., 2011), orange = Iceland (Gehrels et al., 2006), purple = New Zealand (Gehrels et al., 2008), dark green = Tasmania (Gehrels et al., 2012), brown = Nova Scotia (Gehrels et al., 2005). (c) Yearly average GMSL reconstructed from tide gauges (1900–2010) by three different approaches. Orange from Church and White (2011), blue from Jevrejeva et al. (2008), green from Ray and Douglas (2011) (see Section 13.7). (d) Altimetry data sets from five groups (CU, NOAA, GSFC, AVISO, CSIRO) with mean of the five shown as bright blue line (see Section 13.7). (e) Comparison of the paleo data from salt marshes (purple symbols, from panel b), with tide gauge and altimetry data sets (same line colors as in panels c and d). All paleo data were shifted by mean of 1700–1850 derived from the Sand Point, North Carolina data. The Jevrejeva et al. (2008) tide gauge data were shifted by their mean for 1700–1850; other two tide gauge data sets were shifted by same amount. The altimeter time series has been shifted vertically upwards so that their mean value over the 1993–2007 period aligns with the mean value of the average of all three tide gauge time series over the same period.

13.2.2 The Instrumental Record (~1700–2012)

The instrumental record of sea level change is mainly comprised of tide gauge measurements over the past two to three centuries (Figure 13.3b) and, since the early 1990s, of satellite-based radar altimeter measurements (Figure 13.3c).

13.2.2.1 The Tide Gauge Record (~1700–2012)

The number of tide gauges has increased since the first sites at some northern Europe ports were installed in the 18th century; Southern Hemisphere measurements only started in the late 19th century. Section 3.7 assesses 20th century sea level rise estimates from tide gauges (Douglas, 2001; Church and White, 2006; Jevrejeva et al., 2006; Holgate, 2007; Jevrejeva et al., 2008; Church and White, 2011; Ray and Douglas, 2011), and concludes that even though different strategies were developed to account for inhomogeneous tide gauge data coverage in space and time, and to correct for vertical crustal motions (also sensed by tide gauges, in addition to sea level change and variability), it is *very likely* that long-term trend estimates in GMSL are 1.7 [1.5 to 1.9] mm yr⁻¹ between 1900 and 2010 for a total sea level rise of 0.19 [0.17–0.21] m (Figure 13.3c). Interannual and decadal-scale variability is superimposed on the long-term MSL trend, but Chapter 3 noted that discrepancies between the various published MSL records are present at these shorter time scales.

Section 3.7 also concludes that it is *likely* that the rate of sea level rise increased from the 19th century to the 20th century. Taking this evidence in conjunction with the proxy evidence for a change of rate (Sections 5.6.3, 13.2.1, Figure 13.3b), it is *virtually certain* that the rate of global mean sea level rise has accelerated during the last two centuries. Because of the presence of low-frequency variations (e.g., multidecadal variations seen in some tide gauge records; Chambers et al. (2012), sea level acceleration results are sensitive to the choice of the analysis time span. When a 60-year oscillation is modeled along with an acceleration term, the estimated acceleration in GMSL (twice the quadratic term) computed over 1900–2010 ranges from: 0.000 [–0.002 to 0.002] mm yr⁻² (90% confidence) in the Ray and Douglas (2011) record, 0.013 [0.007 to 0.019] mm yr⁻² in the Jevrejeva et al. (2008) record, and 0.012 [0.009 to 0.015] mm yr⁻² (90% confidence) in the Church and White (2011) record. For comparison, Church and White (2011) estimated the acceleration term to be 0.009 [0.004 to 0.014] mm yr⁻² over the 1880–2009 time span when the 60-year cycle is not considered.

13.2.2.2 The Satellite Altimeter Record (1993–2012)

The high-precision satellite altimetry record started in 1992 and provides nearly global ($\pm 66^\circ$) sea level measurements at 10-day intervals. Ollivier et al. (2012) showed that Envisat, which observes to $\pm 82^\circ$ latitude, provides comparable GMSL estimates. Although there are slight differences at interannual time scales in the altimetry-based GMSL time series produced by different groups (Masters et al., 2012), there is very good agreement on the 20-year long GMSL trend (Figure 13.3d). After accounting for the ~ -0.3 mm yr⁻¹ correction related to the increasing size of the global ocean basins due to GIA (Peltier, 2009), a GMSL rate of 3.2 [2.8 to 3.6] mm yr⁻¹ over 1993–2012 is found by the different altimetry data processing groups. The current level of precision is derived from assessments of all source of errors affecting the altimetric measurements (Ablain et al., 2009) and from tide gauge comparisons (Beckley et al., 2010; Nerem et al., 2010). Chapter 3 concluded that the higher GMSL trend since 1993 compared to mean rates over the 20th century is real (*high confidence*), and that it is *likely* that GMSL rose between 1920 and 1950 at a rate

comparable to that observed since 1993. This higher rate is also seen in tide gauge data over the same period, but on the basis of observations alone it does not necessarily reflect a recent acceleration, considering the previously reported multi-decadal variations of mean sea level. The rapid increase in GMSL since 2011 is related to the recovery from the 2011 La Niña event (Section 13.3.5) (Boening et al., 2012).

[START FAQ 13.1 HERE]

FAQ 13.1: Why Does Local Sea Level Change Differ from the Global Average?

Shifting surface winds, the expansion of warming ocean water, and the addition of melting ice can alter ocean currents which, in turn, lead to changes in sea level that vary from place to place. Past and present variations in the distribution of land ice affect the shape and gravitational field of the Earth, which also cause regional fluctuations in sea level. Additional variations in sea level are caused by the influence of more localised processes such as sediment compaction and tectonics.

Along any coast, vertical motion of either the sea or land surface can cause changes in sea level relative to the land (known as relative sea level). For example, a local rise can be caused by an increase in sea surface height, or by a decrease in land height. Over relatively short time spans (hours to years), the influence of tides, storms and climatic variability—such as El Niño—dominates sea level variations. Earthquakes and landslides can also have an effect by causing changes in land height and, sometimes, tsunamis. Over longer time spans (decades to centuries), the influence of climate change—with consequent changes in volume of ocean water and land ice—is the main contributor to sea level change in most regions. Over these longer time scales, various processes cause vertical motion of the land surface, which can also result in substantial changes in relative sea level.

Since the 1970s, satellites have measured the height of the ocean surface relative to the center of the Earth (known as geocentric sea level). These measurements show differing rates of geocentric sea level rise around the world during the past two decades (see FAQ 13.1, Figure 1). For example, in the western Pacific Ocean, rates were about three times greater than the global mean value of about three millimeters a year. In contrast, those in the eastern Pacific Ocean are lower than the global mean value, with much of the west coast of the Americas experiencing a fall in sea surface height from 1993 to 2012.

Much of the spatial variation shown in FAQ 13.1, Figure 1 is a result of natural climate variability—such as El Niño and the Pacific Decadal Oscillation—over time scales from about a year to several decades. These climate variations alter surface winds, ocean currents, temperature and salinity, and hence affect sea level. The influence of these processes will continue during the 21st century, and will be superimposed on the spatial pattern of sea level change associated with longer term climate change, which also arises through changes in surface winds, ocean currents, temperature and salinity, as well as ocean volume. However, in contrast to the natural variability, the longer term trends accumulate over time and so are expected to dominate over the 21st century. The resulting rates of geocentric sea level change over this longer period may therefore exhibit a very different pattern to that shown in FAQ 13.1, Figure 1.

Tide gauges measure relative sea level, and so they include changes resulting from vertical motion of both the land and the sea surface. Over many coastal regions, vertical land motion is small, and so the long-term rate of sea level change recorded by coastal and island tide gauges is similar to the global mean value (see records at San Francisco and Pago Pago in FAQ 13.1, Figure 1). In some regions, vertical land motion has had an important influence. For example, the steady fall in sea level recorded at Stockholm (FAQ 13.1, Figure 1) is caused by uplift of this region after the melting of a large (>1 km thick) continental ice sheet at the end of the last Ice Age, between ~20,000 and ~9,000 years ago. Such on-going land deformation as a response to the melting of ancient ice sheets is a significant contributor to regional sea level changes in North America and northwest Eurasia, which were covered by large continental ice sheets during the peak of the last Ice Age.

In other regions, this process can also lead to land subsidence, which elevates relative sea levels, as it has at Charlottetown, where a relatively large increase has been observed, compared to the global mean rate (FAQ 13.1, Figure 1). Vertical land motion due to movement of the Earth's tectonic plates can also cause departures from the global mean sea level trend in some areas—most significantly, those located near active

subduction zones, where one tectonic plate slips beneath another. For the case of Antofagasta (FAQ 13.1, Figure 1) this appears to result in steady land uplift and therefore relative sea level fall.

In addition to regional influences of vertical land motion on relative sea level change, some processes lead to land motion that is rapid, but highly localised. For example, the greater rate of rise relative to the global mean at Manila (FAQ 13.1, Figure 1) is dominated by land subsidence caused by intensive ground water pumping. Land subsidence due to natural and anthropogenic processes, such as the extraction of ground water or hydrocarbons, is common in many coastal regions, in particular in large river deltas.

It is commonly assumed that melting ice from glaciers, or the Greenland and Antarctic ice sheets, would cause globally uniform sea level rise, much like filling a bath tub with water. In fact, such melting results in regional variations in sea level due to a variety of processes, including changes in ocean currents, winds, the Earth's gravity field, and land height. For example, computer models that simulate these latter two processes predict a regional fall in relative sea level around the melting ice sheets, because the gravitational attraction between ice and ocean water is reduced, and the land tends to rise as the ice melts (FAQ 13.1, Figure 2). However, further away from the ice sheet melting, sea level rise is enhanced, compared to the global average value.

In summary, a variety of processes drive height changes of the ocean surface and ocean floor, resulting in distinct spatial patterns of sea level change at local to regional scales. The combination of these processes produces a complex pattern of total sea level change, which varies through time as the relative contribution of each process changes. The global average change is a useful single value which reflects the contribution of climatic processes—land-ice melting and ocean warming, and represents a good estimate of sea level change at many coastal locations. At the same time, however, where the various regional processes result in a strong signal, there can be large departures from the global average value.

[INSERT FAQ 13.1, FIGURE 1 HERE]

FAQ13.1, Figure 1: Map of rates of change in sea surface height (geocentric sea level) for the period 1993–2012 from satellite altimetry. Also shown are relative sea level changes (grey lines) from selected tide gauge stations for the period 1950–2012. For comparison, an estimate of global mean sea level change is also shown (red lines) with each tide gauge time series. The relatively large, short-term oscillations in local sea level (grey lines) are due to the natural climate variability described in the main text. For example, the large, regular deviations at Pago Pago are associated with the El Niño-Southern Oscillation.

13.3 Contributions to Global Mean Sea Level Rise During the Instrumental Period

In order to assess our understanding of the causes of observed changes and our confidence in projecting future changes, we compare observational estimates of contributions with results derived from AOGCM experiments, beginning in the late 19th century, forced with estimated past time-dependent anthropogenic changes in atmospheric composition, and natural forcings due to volcanic aerosols and variations in solar irradiance (Section 10.1). This period and these simulations are often referred to as “historical”.

13.3.1 Thermal Expansion Contribution

13.3.1.1 Observed

Important progress has been realized since AR4 in quantifying the observed thermal expansion component of global mean sea level rise. This progress reflects (1) the detection of systematic depth-varying biases affecting historical expendable bathythermograph data (Gouretski and Koltermann, 2007) (Chapter 3), (2) the newly available Argo ocean (temperature and salinity) data with almost global coverage (not including

ice-covered regions and marginal seas) of the oceans down to 2000 m since 2004–2005, and (3) estimates of the deep-ocean contribution using ship-based data collected during the World Ocean Circulation Experiment and revisit cruises (Johnson and Gruber, 2007; Johnson et al., 2007; Purkey and Johnson, 2010; Kouketsu et al., 2011).

For the period 1971–2010, the rate for the 0–700 m depth range is 0.6 [0.4–0.8] mm yr⁻¹ (Section 3.7.2 and Table 3.1). Including the deep-ocean contribution for the same period increases the value to 0.8 [0.5–1.1] mm yr⁻¹ (Figure 13.4a). Over the altimetry period (1993–2010), the rate for the 0–700 m depth range is 0.8 [0.5–1.1] mm yr⁻¹ and 1.1 [0.8–1.4] mm yr⁻¹ when accounting for the deep ocean (Section 3.7.2 and Table 3.1).

13.3.1.2 Modelled

GMSL rise due to thermal expansion is approximately proportional to the increase in ocean heat content (Section 13.4.1). Historical GMSL rise due to thermal expansion simulated by CMIP5 models is shown in Table 13.1 and Figure 13.4a. The model spread is due to uncertainty in radiative forcing and modelled climate response (Sections 8.5.2, 9.4.2.2, 9.7.2.3, 13.4.1).

In the time-mean of several decades, there is a negative volcanic forcing if there is more volcanic activity than is typical of the long term, and a positive forcing if there is less. In the decades after major volcanic eruptions, the rate of expansion is temporarily enhanced, as the ocean recovers from the cooling caused by the volcanic forcing (Church et al., 2005; Gregory et al., 2006) (Figure 13.4a). During 1961–1999, a period when there were several large volcanic eruptions, the CMIP3 simulations with both natural and anthropogenic forcing have substantially smaller increasing trends in the upper 700 m than those with anthropogenic forcing only (Domingues et al., 2008) because the natural volcanic forcing tends to cool the climate system, thus reducing ocean heat uptake (Levitus et al., 2001). The models including natural forcing are closer to observations, though with a tendency to underestimate the trend by about 10% (Sections 9.4.2.2, 10.4.1).

Gregory (2010) and Gregory et al. (2013a) proposed that the AOGCMs underestimate ocean heat uptake in their historical simulations because their control experiments usually omit volcanic forcing, so the imposition of historical volcanic forcing on the simulated climate system represents a time-mean negative forcing relative to the control climate. The apparent long persistence of the simulated oceanic cooling following the 1883 eruption of Krakatau (Delworth et al., 2005; Gleckler et al., 2006a; Gleckler et al., 2006b; Gregory et al., 2006) is a consequence of this bias, which also causes a model-dependent underestimate of up to 0.2 mm yr⁻¹ of thermal expansion on average during the 20th century (Gregory et al., 2013a; Gregory et al., 2013b). This implies that CMIP5 results may be similarly underestimated, depending on the details of the individual model control runs. Church et al. (2013) proposed a correction of 0.1 mm yr⁻¹ to the model mean rate, which we apply in the sea level budget in Table 13.1 and Figure 13.7. The corrected CMIP5 model-mean rate for 1971–2010 is close to the central observational estimate; the model-mean rate for 1993–2010 exceeds the central observational estimate but they are not statistically different given the uncertainties (Table 13.1, Figure 13.4a). This correction is not made to projections of thermal expansion because it is very small compared with the projected increase in the rate (Section 13.5.1).

In view of the improvement in observational estimates of thermal expansion, the good agreement of historical model results with observational estimates, and their consistency with understanding of the energy budget and radiative forcing of the climate system (Box 13.1), we have *high confidence* in the projections of thermal expansion using AOGCMs.

[INSERT FIGURE 13.4 HERE]

Figure 13.4: Comparison of modelled and observed components of global mean sea level change since 1900. Changes in glaciers, ice sheets and land water storage are shown as positive sea level rise when mass is added to the ocean. (a) Ocean thermal expansion. Individual CMIP5 AOGCM simulations are shown in grey, the AOGCM average is black, observations in teal with the 5–95% uncertainties shaded. (b) Glaciers (excluding Antarctic peripheral glaciers). Model simulations by Marzeion et al. (2012a) with input from individual AOGCMs are shown in grey with the average of these results in bright purple. Model simulations by Marzeion et al. (2012a) forced by observed climate are shown in light blue. The observational estimates by Cogley (2009b) are shown in green (dashed) and by Leclercq et al. (2011) in red (dashed). (c) Changes in land water storage (yellow/orange, the sum of groundwater depletion and reservoir

storage) start at zero in 1900. The Greenland Ice sheet (green), the Antarctic Ice Sheet (blue) and the sum of the ice-sheets (red), start at zero at the start of the record 1991. (d) The rate of change (19 year centred trends) for the terms in (a) to (c), and for the ice sheets (5 year centred trends). All curves in (a) and (b) are shown with zero time-mean over the period 1986–2005 and the colours in (d) are matched to earlier panels. Updated from Church et al. (2013).

Table 13.1: Global mean sea level budget (mm yr^{-1}) over different time intervals from observations and from model-based contributions. Uncertainties are 5–95%. The AOGCM historical integrations end in 2005; projections for RCP4.5 are used for 2006–2010. The modelled thermal expansion and glacier contributions are computed from the CMIP5 results, using the model of Marzeion et al. (2012a) for glaciers. The land water contribution is due to anthropogenic intervention only, not including climate-related fluctuations.

Source	1901–1990	1971–2010	1993–2010
Observed contributions to GMSLR

Glaciers except in Greenland and Antarctica	0.63 [0.37 to 0.89]	0.62 [0.41 to 0.84]	0.78 [0.43 to 1.13]
Glaciers in Greenland	0.07 [–0.02 to 0.16]	0.10 [0.05 to 0.15]	0.14 [0.06 to 0.23]
Total including land water storage	1.0 [0.5 to 1.4]	1.8 [1.3 to 2.3]	2.8 [2.1 to 3.5]
Residual^b	0.5 [0.1 to 1.0]	0.2 [–0.4 to 0.8]	0.4 [–0.4 to 1.2]

Notes:

(a) This contribution is not included in the total, because glaciers in Greenland are included in the observational assessment of the Greenland ice sheet.

(b) Observed GMSL rise – modelled thermal expansion – modelled glaciers – observed land water storage.

13.3.2 Glaciers

13.3.2.1 Observed

“Glaciers” are defined here as all land-ice masses, including those peripheral to (but not including) the Greenland and Antarctic ice sheets. The term “glaciers and ice caps” was applied to this category in AR4. Changes in aggregate glacier volume have conventionally been determined by various methods of repeat mapping of surface elevation to detect elevation (and thus volume) change. Mass changes are determined by compilation and upscaling of limited direct observations of surface mass balance (SMB). Since 2003, GRACE space gravity observations have been used to detect mass change of the world’s glaciers.

The combined records indicate that a net decline of global glacier volume began in the 19th century, before significant anthropogenic radiative forcing had started, and was probably the result of warming associated with the termination of the Little Ice Age (Crowley, 2000; Gregory et al., 2006; Gregory et al., 2013b). Global rates of glacier volume loss did not increase significantly during much of the 20th century (Figure 4.12). In part this may have been because of an enhanced rate of loss of due to unforced high-latitude variability early in the century, while anthropogenic warming was still comparatively small (Section 13.3.2.2). It is *likely* that anthropogenic forcing played a statistically significant role in acceleration of global glacier losses in the latter decades of the 20th century relative to rates in the 19th century (Section 10.5.2.2). It is also *likely* that, during the 20th century, the progressive loss of glacier area significantly restricted the rate of mass loss (Gregory et al., 2013b).

The earliest sea level assessments recognized that glaciers have been significant contributors to GMSL rise (Meier, 1984). As assessed in Chapter 4, observations, improved methods of analysis, and a new, globally complete inventory, indicate that glaciers, including those around the ice-sheet peripheries, *very likely* continue to be significant contributors to sea level, but are also highly variable on annual to decadal time

scales. It is assumed that all glacier losses contribute to sea level rise, but the potential role of terrestrial interception of runoff, either in lakes formed following future ice retreat or in groundwater, has yet to be evaluated. For the period 2003–2009, the sea level contribution of all glaciers globally, *including* those glaciers surrounding the periphery of the two ice sheets, is 0.71 [0.64–0.79] mm yr⁻¹ sea level equivalent (SLE) (Section 4.3.3, Table 4.4). Depending upon the method used, however, loss-rate measurements of the two ice sheets can be very difficult to separate from losses from the peripheral glaciers. To avoid double counting, total cryospheric losses are determined by adding estimates of glacier losses excluding the peripheral glaciers to losses from the ice sheets plus their peripheral glaciers. The sea level contribution of all glaciers *excluding* those glaciers surrounding the periphery of the two ice sheets was 1901–1990: 0.54 [0.48–0.61] mm yr⁻¹ SLE; for 1971–2009: 0.62 [0.25–1.00] mm yr⁻¹ SLE; for 1993–2009: 0.76 [0.43–1.09] mm yr⁻¹ SLE; for 2005–2009: 0.83 [0.70–0.97] mm yr⁻¹ SLE (Section 4.3.3.4).

13.3.2.2 Modelled

Global glacier mass balance models are calibrated using data from the few well-observed glaciers. Approximately 100 glacier mass balance records are available in any given year over the past half-century; only 17 glaciers exist with records of 30 years or more (Dyurgerov and Meier, 2005; Kaser et al., 2006; Cogley, 2012). Confidence in these models for projections of future change (Section 13.4.2) depends on their ability to reproduce past observed glacier change using corresponding climate observations as forcing (Raper and Braithwaite, 2005; Meier et al., 2007; Bahr et al., 2009; Radić and Hock, 2011; Marzeion et al., 2012b; 2012a; Giesen and Oerlemans, 2013). Model validation is challenging due to the scarcity of independent observations (unused in model calibration) but uncertainties have been evaluated by methods such as cross-validation of hindcast projections for individual glaciers drawn from the sample of glacier observations averaged for calibration (Marzeion et al., 2012a; Radić et al., 2013).

Confidence in the use of AOGCM climate simulations as input to glacier projections is gained from the agreement since the mid-20th century of glacier models forced by AOGCM simulations with glacier models forced by observations (Marzeion et al., 2012a) (Figure 13.4b). In the earlier 20th century, around the 1930s, glaciers at high northern latitudes lost mass at an enhanced rate (Oerlemans et al., 2011; Leclercq et al., 2012); in the model, observed forcings produced larger glacier losses than did AOGCM forcings (Marzeion et al., 2012a) (Figure 13d). This is judged *likely* to be due to an episode of unforced, regionally variable warming around Greenland (Box, 2002; Chylek et al., 2004) rather than to radiative forcing of the climate system, and is consequently not reproduced by AOGCM experiments (Section 10.2). In our analysis of the budget of GMSL rise (Section 13.3.6), we take the difference between the simulations using AOGCM forcing and the simulation using observations as an estimate of the influence of unforced climate variability on global glacier mass balance (Figure 13.4b).

There is *medium confidence* in the use of glacier models to make global projections based on AOGCM results. The process-based understanding of glacier surface mass balance, the consistency of models and observations of glacier changes, and the evidence that AOGCM climate simulations can provide realistic input all give confidence, which on the other hand is limited because the set of well-observed glaciers is a very small fraction of the total.

13.3.3 Greenland and Antarctic Ice Sheets

13.3.3.1 Observed Mass Balance

The Greenland Ice Sheet's mass balance comprises its surface mass balance and outflow, whereas Antarctica's mass budget is dominated by accumulation and outflow in the form of calving and ice flow into floating (and therefore sea level neutral) ice shelves. Knowledge of the contribution of the Greenland and Antarctic ice sheets to observed sea level changes over the last two decades comes primarily from satellite and airborne surveys. Three main techniques are employed: the mass balance, volumetric, and gravimetric methods (Section 4.4.1).

Observations indicate that the Greenland contribution (all rates quoted here are 5–95%) to GMSL has *very likely* increased from 0.09 [–0.02–0.20] mm yr⁻¹ for 1992–2001 to 0.59 [0.43–0.76] mm yr⁻¹ for 2002–2011 (Section 4.4.2.2, Figure 13.4). The average rate of the Antarctica contribution to sea level rise *likely*

increased from 0.08 [−0.10–0.27] mm yr^{−1} for 1992–2001 to 0.40 [0.20–0.61] mm yr^{−1} for 2002–2011 (Section 4.4.2.3). For the budget period 1993–2010, the combined contribution of the ice sheets is 0.60 [0.42–0.78] mm yr^{−1}. For comparison, the AR4's assessment for the period 1993–2003 was 0.21 ± 0.07 mm yr^{−1} for Greenland and 0.21 ± 0.35 mm yr^{−1} for Antarctica.

13.3.3.2 Modelled Surface Mass Balance

Projections of changes in the SMB of the Antarctic and Greenland ice sheets are obtained from regional climate model (RCM) or downscaled AOGCM simulations (Sections 13.4.3.1 and 13.4.4.1). A spatial resolution of a few 10s km or finer is required in order to resolve the strong gradients in SMB across the steep slopes of the ice-sheet margins. While simulations of SMB at particular locations may have errors of 5–20% compared with in-situ observations, there is good agreement between methods involving RCMs and observational methods of evaluating ice-sheet mass balance (Shepherd et al., 2012). In the present climate, for both Greenland and Antarctica, the mean SMB over the ice-sheet area is positive, giving a negative number when expressed as sea level equivalent (SLE).

In Greenland, the average and standard deviation of accumulation (precipitation minus sublimation) estimates for 1961–1990 is -1.62 ± 0.21 mm yr^{−1} SLE from the models in Table 13.2, agreeing with published observation-based accumulation maps, for example -1.42 ± 0.11 mm yr^{−1} SLE by Bales et al. (2009) and -1.63 ± 0.23 mm yr^{−1} SLE by Burgess et al. (2010). For SMB (accumulation minus runoff, neglecting drifting snow erosion, which is small), the models give -0.92 ± 0.26 mm yr^{−1} SLE for 1961–1990 (Table 13.2).

All of these models indicate that Greenland Ice Sheet SMB showed no significant trend from the 1960s to the 1980s, then started becoming less positive (becoming less negative expressed as SLE) in the early 1990s, on average by 3% yr^{−1}. This results in a statistically significant and increasing (i.e., becoming more positive) contribution to the rate of GMSL rise (SMB trend column of Table 13.2, Figure 13.5). The largest trends are found in models with coupled snow and atmosphere simulations using the RACMO2 and MAR models. Van den Broeke et al. (2009) concluded that the mass loss during 2000–2008 is equally split between SMB and dynamical change. Rignot et al. (2011) indicated that SMB change accounts for about 60% of the mass loss since 1992 and Sasgen et al. (2012) showed that SMB change, simulated by RACMO2 (Ettema et al., 2009, an earlier version of the model in Table 13.2), accounts for about 60% of the observed rate of mass loss during 2002–2010, with an observational estimate of the increase in ice outflow accounting for the remainder. This satisfactory consistency, within uncertainties, in estimates for the Greenland Ice Sheet mass budget gives confidence in SMB simulations of the past, and hence also in the similar models used for projections of SMB changes (Section 13.4.3.1).

This recent trend towards increasingly less positive SMB is caused almost entirely by increased melting and subsequent runoff, with variability in accumulation being comparatively small (Sasgen et al., 2012; Vernon et al., 2013) (Figure 13.5). This tendency is related to pronounced regional warming, which may be attributed to some combination of anthropogenic climate change and anomalous regional variability in recent years (Hanna et al., 2008; 2012; Fettweis et al., 2013). Greenland SMB models forced by boundary conditions from AOGCM historical simulations (Rae et al., 2012; Fettweis et al., 2013) do not show statistically significant trends towards increasing contributions to GMSL, implying that the dominant contribution is internally generated regional climate variability, which is not expected to be reproduced by AOGCM historical simulations (Section 10.2). We have *high confidence* in projections of future warming in Greenland because of the agreement of models in predicting amplified warming at high northern latitudes (Sections 12.4.3.1, 14.7.2) for well-understood physical reasons, although there remains uncertainty in the size of the amplification, and we have *high confidence* in projections of increasing surface melting (Section 13.4.3.1) because of the sensitivity to warming demonstrated by SMB models of the past.

Table 13.2: SMB and rates of change of SMB of the Greenland Ice Sheet, calculated from ice sheet SMB models using meteorological observations and reanalyses as input, expressed as sea level equivalent (SLE). A negative SLE number for SMB indicates that accumulation exceeds runoff. A positive SLE for SMB anomaly indicates that accumulation has decreased, or runoff has increased, or both. Uncertainties are one standard deviation. Uncertainty in individual model results reflects temporal variability, that is one standard deviation of annual values; the uncertainty in the model average is one standard deviation of variation across models.

Notes:

(a) The approximate spatial resolution is stated and the model type denoted by PDD = positive degree day, EBM = energy balance model, RCM = regional climate model.

(b) Difference from the time-mean SMB of 1961–1990. This difference equals the sea level contribution from Greenland SMB changes if the ice sheet is assumed to have been near zero mass balance during 1961–1990 (Hanna et al., 2005; Sasgen et al., 2012).

All Greenland SMB simulations for the first half of the 20th century depend on reconstructions of meteorological variability over the ice sheet made using empirical relationships based on observations from coastal stations and estimates of accumulation from ice cores. Despite the similar input datasets in all cases, the various climate reconstruction and SMB methods used have led to a range of results (Fettweis et al., 2008; Wake et al., 2009; Hanna et al., 2011; Box, 2013; Box and Colgan, 2013; Box et al., 2013; Gregory et al., 2013b). For 1901–1990, Hanna et al. (2011) have a time-mean GMSL contribution of -0.3 mm yr^{-1} , while Box and Colgan (2013) have a weakly positive contribution and the others are about zero. In all cases, there is substantial variability associated with regional climate fluctuations, in particular the warm episode in the 1930s, during which glaciers retreated in southeastern Greenland (Bjork et al., 2012). Chylek et al. (2004) argued that this episode was associated with the NAO rather than with global climate change.

In Antarctica, accumulation (precipitation minus sublimation) approximates SMB since surface melting and runoff are negligible in the present climate (Section 4.4.2.1.1). There are uncertainties in model- and observation-based estimates of Antarctic SMB. Global climate models do not account for snow hydrology or for drifting snow processes which remove an estimated 7% of the accumulated snow (Lenaerts et al., 2012), and the ice sheet's steep coastal slopes are not well-captured by coarse-resolution models. Observation-based estimates rely on sparse accumulation measurements with very little coverage in high-accumulation areas. For the Antarctic ice sheet and ice shelves together, CMIP3 AOGCMs simulate SMB for 1979–2000 of $-7.1 \pm 1.5 \text{ mm yr}^{-1}$ SLE (Connolley and Bracegirdle, 2007; Uotila et al., 2007), the mean being about 10% larger in magnitude than observation-based estimates, for instance -6.3 mm yr^{-1} SLE from Vaughan et al. (1999). For the SMB of the grounded ice sheet alone, four global reanalysis models, with resolutions of 38–125 km (Bromwich et al., 2011), give $-5.2 \pm 0.5 \text{ mm yr}^{-1}$ SLE for 1979–2010, which compares well with an observational estimate of $-4.9 \pm 0.1 \text{ mm yr}^{-1}$ SLE for 1950–2000 (Arthern et al., 2006). Because of higher accumulation near the coast, the regional climate model RACMO2 gives the somewhat larger value of $-5.5 \pm 0.3 \text{ mm yr}^{-1}$ SLE for 1979–2000 (Lenaerts et al., 2012). This relatively good agreement, combined with the similarity of the geographical distribution of modelled and observed SMB, give *medium confidence* in the realism of the RCM SMB simulation.

Some global reanalyses have been shown to contain spurious trends in various quantities in the Southern Hemisphere related to changes in the observing systems, for example new satellite observations (Bromwich et al., 2007; 2011). In the RCMs and in global reanalyses that are not affected by spurious trends, no significant trend is present in accumulation since 1980 (Section 4.4.2.3). This agrees with observation-based studies (Monaghan et al., 2006; Anschütz et al., 2009) (Chapter 4) and implies that Antarctic SMB change has not contributed significantly to recent changes in the rate of GMSL rise. Likewise, CMIP3 historical

simulations do not exhibit any systematic trend in Antarctic precipitation during the late 20th century (Uotila et al., 2007). No observational assessments have been made of variability in SMB for the whole ice sheet for the earlier part of the 20th century, or of its longer term mean.

GCM and RCM projections consistently indicate significant Antarctic warming and concomitant increase in precipitation. We have *high confidence* in expecting a relationship between these quantities on physical grounds (Section 13.4.4.1) and from ice-core evidence (Van Ommen et al., 2004; Lemieux-Dudon et al., 2010; Stenni et al., 2011). The absence of a significant trend in Antarctic precipitation up to the present is not inconsistent with the expected relationship, because observed temperature trends over the majority of the continent are weak (Section 10.5.2.1) and trends in Antarctic precipitation simulated for recent decades are much smaller than interannual variability (van den Broeke et al., 2006; Uotila et al., 2007). Taking all these considerations together, we have *medium confidence* in model projections of future Antarctic SMB increase, implying a negative contribution to GMSL rise (see also Sections 13.4.4.1, 13.5.3 and 14.7.14).

Figure 13.5: Annual-mean surface mass balance (accumulation minus ablation) for the Greenland Ice Sheet, simulated by regional climate models for the period 1960–2010.

13.3.4 Contributions from Water Storage on Land

Changes in water storage on land in response to climate change and variability (i.e., water stored in rivers, lakes, wetlands, the vadose zone, aquifers, and snow pack at high latitudes and altitudes) and from direct human-induced effects (i.e., storage of water in reservoirs and groundwater pumping) have the potential to contribute to sea level change. Based on satellite observations of the northern hemisphere snowpack, Biancamaria et al. (2011) found no significant trend in the contribution of snow to sea level. Estimates of climate-related changes in land water storage over the past few decades rely on global hydrological models because corresponding observations are inadequate (Milly et al., 2010). In assessing the relation between terrestrial water storage and climate, Milly et al. (2003) and Ngo-Duc et al. (2005) found no long-term climatic trend in total water storage, but documented large interannual to decadal fluctuations, equivalent to several millimetres of sea level. Recent studies have shown that interannual variability in observed GMSL is correlated with ENSO indices (Nerem et al., 2010) and is inversely related to ENSO-driven changes of terrestrial water storage, especially in the tropics (Llovel et al., 2011). During El Niño events, sea level (and ocean mass) tends to be higher because ocean precipitation increases and land precipitation decreases in the tropics (Cazenave et al., 2012). The reverse happens during La Niña events, as seen during 2010–2011, when there was a decrease in GMSL due to a temporary increase in water storage on the land, especially in Australia, northern South America, and southeast Asia (Boening et al., 2012) (Section 13.3.5).

Direct human interventions on land water storage also induce sea level changes (Sahagian, 2000; Gornitz, 2001; Huntington, 2008; Lettenmaier and Milly, 2009). The largest contributions come from impoundment in reservoirs and groundwater withdrawal. Over the past half-century, storage in tens of thousands of reservoirs has offset some of the sea level rise that would otherwise have occurred. Chao et al. (2008) estimated that the nearly 30,000 reservoirs built during the 20th century resulted in nominal reservoir storage up to 2007 equivalent to ~23 mm of sea level fall (mostly since 1940), with a stabilization in recent years. Chao et al. further assumed that the reservoirs were 85% full, and by including seepage into groundwater as estimated from a model, they obtained a total of 30 mm of sea level fall (equivalent to a rate of sea level fall of 0.55 mm yr⁻¹ from 1950 to 2000). Their seepage estimate was argued to be unrealistically large, however, because it assumes aquifers are infinite and have no interfering boundary conditions (Lettenmaier and Milly, 2009; Konikow, 2013). Chao et al. (2008) argued that sedimentation of reservoirs does not reduce their sea level contribution, but their argument is disputed (Gregory et al., 2013b). Lettenmaier and Milly (2009) suggested a loss of capacity due to sedimentation at 1% yr⁻¹. Given the uncertainty about them, neither the seepage nor the effect of sedimentation is included in the budget (Section 13.3.6). Here the (negative) GMSL contribution from reservoir storage is estimated as 85% [70–100%] of the nominal capacity (with the lower limit coming from Pokhrel et al. (2012)).

Konikow (2011) estimated that human-induced groundwater depletion contributed 0.26 ± 0.07 mm yr⁻¹ to GMSL rise over 1971–2008 and 0.34 ± 0.07 mm yr⁻¹ over 1993–2008 (based mostly on observational methods), whereas Wada et al. (2012) estimated values of 0.42 ± 0.08 mm yr⁻¹ over 1971–2008 and $0.54 \pm$

0.09 mm yr⁻¹ over 1993–2008 (based on modelling of water fluxes). The average of these two series with the difference as a measure of the uncertainty is used in the sea level budget (Section 13.3.6). Pokhrel et al. (2012) estimated a larger groundwater depletion, but Konikow (2013) (disputed by Pokhrel et al. (2013)) argued that their underlying assumptions of defining depletion as equivalent to groundwater use, and allowing unlimited extraction to meet water demand, lead to substantial overestimates of depletion.

In summary, climate-related changes in water and snow storage on land do not show significant long-term trends for the recent decades. However, direct human interventions in land water storage (reservoir impoundment and groundwater depletion) have each contributed at least several tenths of mm yr⁻¹ of sea level change (Figure 13.4, Table 13.1). Reservoir impoundment exceeded groundwater depletion for the majority of the 20th century but groundwater depletion has increased and now exceeds current rates of impoundment, contributing to an increased rate of GMSL rise. The net contribution for the 20th century is estimated to be small.

13.3.5 Ocean Mass Observations from GRACE

As discussed in Chapter 3, it has been possible to directly estimate changes in ocean mass using satellite gravity data from GRACE since 2002 (Chambers et al., 2004; Chambers, 2006; Cazenave et al., 2009; Leuliette and Miller, 2009; Chambers et al., 2010; Llovel et al., 2010). These measurements represent the sum of total land-ice plus land-water components, and thus provide an independent assessment of these contributions. However, GRACE is also sensitive to mass redistribution associated with GIA and requires that this effect (on the order of –0.7 to –1.3 mm yr⁻¹ when averaged over the ocean domain) (Paulson et al., 2007; Peltier, 2009; Chambers et al., 2010; Tamisiea, 2011) be removed before estimating the ocean-mass component. Most recent estimates (Leuliette and Willis, 2011; von Schuckmann and Le Traon, 2011) report a global mean ocean-mass increase of 1.8 [1.4 to 2.2] mm yr⁻¹ over 2003–2012 after correcting for the GIA component. The associated error results from the low signal-to-noise ratio over the ocean domain and uncertainty in the model-based GIA correction (Quinn and Ponte, 2010).

Chapter 3 notes that, in terms of global averages, the sum of the contribution to GMSL due to change in global ocean mass (the barystatic contribution), measured by GRACE, and the contribution due to global ocean thermal expansion (the thermosteric contribution), measured by Argo, agrees within uncertainties with the GMSL change observed by satellite altimetry (Leuliette and Willis, 2011; von Schuckmann and Le Traon, 2011), although there is still a missing contribution from expansion in the deep ocean below 2000 m. These datasets have allowed an investigation of the cause of variability in sea level over the last few years (Figure 13.6). In particular, Boening et al. (2012) concluded that the decrease in GMSL over 2010–2011 followed by a rapid increase since 2011 was related to the 2011 La Niña event, whereby changes in land/ocean precipitation patterns caused a temporary increase in water storage on the land (and corresponding decrease in GMSL) during the La Niña event, especially in Australia, northern South America, and southeast Asia (Boening et al., 2012).

[INSERT FIGURE 13.6 HERE]

Figure 13.6: Global mean sea level from altimetry from 2005 to 2012 (blue line). Ocean mass changes are shown in green (as measured by GRACE) and thermosteric sea level changes (as measured by Argo) are shown in red. The black line shows the sum of the ocean mass and thermosteric contributions (updated from Boening et al. (2012)).

13.3.6 Budget of GMSL Rise

Drawing on Sections 13.3.1–13.3.5, the budget of GMSL rise (Table 13.1, Figure 13.7) is analysed using models and observations for the periods 1901–1990 (the 20th century, excluding the period after 1990 when ice-sheet contributions to GMSL rise have increased; Sections 4.4 and 13.3.3.1), since 1971 (when significantly more ocean data became available and systematic glacier reconstructions began), and since 1993 (when precise satellite sea level altimetry began). The 2005–2010 period when Argo and GRACE data are available is short and strongly affected by interannual climate variability, as discussed in the previous subsection (Section 13.3.5, Figure 13.6). Such variability is not externally forced and is therefore not expected to be reproduced in AOGCM historical experiments. For the contribution from land water storage (Figure 13.4c) we use the estimated effect of human intervention, neglecting climate-related variation, whose effect is unimportant on multidecadal timescales (Section 13.3.4). Contributions due to runoff from thawed

permafrost, change in atmospheric moisture content, and sedimentation in the ocean are not considered in the budget because they are negligible compared with observed GMSL rise and the uncertainties.

For 1993–2010, allowing for uncertainties, the observed GMSL rise is consistent with the sum of the observationally estimated contributions (Table 13.1, Figure 13.7e). The two largest terms are ocean thermal expansion (accounting for about 35% of the observed GMSL rise) and glacier mass loss (accounting for a further 25%, not including those in Greenland and Antarctica). Observations indicate an increased ice-sheet contribution over the last two decades (Sections 4.4.2.2, 4.4.2.3 and 13.3.3.1) (Shepherd et al., 2012). The closure of the observational budget since 1993, within uncertainties, represents a significant advance since the AR4 in physical understanding of the causes of past GMSL change, and provides an improved basis for critical evaluation of models of these contributions in order to assess their reliability for making projections.

The observational budget cannot be rigorously assessed for 1901–1990 or 1971–2010 because there is insufficient observational information to estimate ice-sheet contributions with *high confidence* before the 1990s, and ocean data sampling is too sparse to permit an estimate of global mean thermal expansion before the 1970s. However, a closed observational GMSL budget since the 1970s can be demonstrated with reasonable estimates of ice-sheet contributions (Church et al., 2011a; Moore et al., 2011) (Table 13.1, Figure 13.7). For 1971–2010, the observed contributions from thermal expansion and mass loss from glaciers (not including those in Antarctica) alone explain about 75% of the observed GMSL.

AOGCM-based estimates of the thermal expansion, which agree well with observations since 1971, observational estimates of the glacier contribution, and the estimated change in land water storage (Figure 13.4c), which is relatively small, can all be made from the start of the 20th century (Sections 13.3.1.2, 13.3.2.2 and 13.3.4, Table 13.1). Model estimates of Greenland Ice Sheet SMB changes give an uncertain but relatively small contribution during most of the 20th century, increasing since the early 1990s (Section 13.3.2.2). There could be a small constant contribution from the Antarctic Ice Sheet (Huybrechts et al., 2011; Gregory et al., 2013b) due to long-term adjustment to climate change in previous millennia. Any secular rate of sea level rise in the late Holocene was small (order of few tenths mm yr^{-1}) (Section 13.2.1.4), probably less than 0.2 mm yr^{-1} (see discussion in Gregory et al. (2013b)). Including these ice-sheet contributions (but omitting Antarctic SMB variations, for which no observationally based information for the ice sheet as a whole is available for the majority of the 20th century), GMSL rise during the 20th century can be accounted for within uncertainties, including the observation that the linear trend of GMSL rise during the last 50 years is little larger than for the 20th century, despite the increasing anthropogenic forcing (Gregory et al., 2013b). Model-based attribution of sea level change to radiative forcings is discussed in Section 10.4.3.

The sum of CMIP5 AOGCM thermal expansion (Section 13.3.1.2), glacier model results with CMIP5 AOGCM input (not including glaciers in Antarctica; Section 13.3.2.2; Marzeion et al. (2012a)) and anthropogenic intervention in land water storage (Section 13.3.4) accounts for about 65% of the observed rate of GMSL rise for 1901–1990, and 90% for 1971–2010 and 1993–2010 (Table 13.1; Figure 13.7). In all periods, the residual is small enough to be attributed to the ice sheets (Section 13.3.2.2).

The unusually warm conditions in the Arctic during the 1930s (Chylek et al., 2004), which are attributed to unforced climate variability (Delworth and Knutson, 2000) and are not therefore expected to be simulated by AOGCMs, *likely* produced a greater mass loss by glaciers in high northern latitudes (Section 13.3.2.2). The difference between the glacier mass loss calculated with the Marzeion et al. (2012a) model when it is forced with observed climate rather than AOGCM simulated climate (the purple and blue curves in Figure 13.4b) is an estimate of this effect.

If the glacier model results for observational input are used (Marzeion et al. (2012a), not including glaciers in Antarctica) and an illustrative value of 0.1 mm yr^{-1} is included for a long-term Antarctic contribution, the model mean is within 20% of the observed GMSL rise (Figure 13.7a,c, dashed line), and 10% since 1993 (Figure 13.7d, dashed line; Church et al. (2013)). When the observed ice-sheet contributions since 1992 are included as well, the sum is almost equivalent to the observed rise (dotted line in Figure 13.7). Both observations and models have a maximum rate of rise in the 1930–1950 period, a minimum rate in the 1960s, and a maximum rate over the last two decades (Figure 13.7b). This agreement provides evidence that the larger rate of rise since 1990, with a significant component of ocean thermal expansion (Figure 13.4d),

results from increased radiative forcing (both natural and anthropogenic) and increased ice-sheet discharge, rather than a natural oscillation (Church et al., 2013).

In summary, the evidence now available gives a clearer account of observed GMSL change than in previous IPCC assessments, in two respects. First, reasonable agreement can be demonstrated throughout the period since 1900 between GMSL rise as observed and as calculated from the sum of contributions. From 1993, all contributions can be estimated from observations; for earlier periods, a combination of models and observations is needed. Second, when both models and observations are available, they are consistent within uncertainties. These two advances give confidence in the 21st century sea level projections. The ice-sheet contributions have the potential to increase substantially due to rapid dynamical change (Sections 13.1.5.1, 13.4.3.2 and 13.4.4.2) but have been relatively small up to the present (Sections 4.4 and 13.3.2.2). Therefore, the closure of the sea level budget to date does not test the reliability of ice-sheet models in projecting future rapid dynamical change; we have only *medium confidence* in these models, on the basis of theoretical and empirical understanding of the relevant processes and observations of changes up to the present (13.4.3.2, 13.4.4.2).

[INSERT FIGURE 13.7 HERE]

Figure 13.7: Comparison of the observed global mean sea level rise with the sum of the modelled contributions from ocean thermal expansion, glaciers (excluding glaciers peripheral to the Antarctic ice sheet; from Marzeion et al. (2012a)) and changes in land-water storage. In panels (a)-(d): the grey lines are results for individual CMIP5 AOGCMs; the black line is the model mean plus a correction for the omission of volcanic forcing in the AOGCM control experiments (see Section 13.3.1.2); the adjusted model mean (dashed black line) is the sum of the corrected model mean thermal expansion, the change in land-water storage, the Marzeion et al. (2012a) glacier estimate using observed (rather than modelled) climate, and an illustrative long-term ice-sheet contribution (of 0.1 mm yr^{-1}); the adjusted model mean including the observed ice sheet contribution (dotted black line) begins in 1993 and includes the ice-sheet contributions (from Section 4.4), but excludes the glaciers peripheral to the both the Greenland Ice Sheet and the Antarctic Ice Sheet, to avoid double counting because the observational ice-sheet estimates include the peripheral glaciers; the estimates of global mean sea level are from Church and White (2011), Ray and Douglas (2011) and Jevrejeva et al. (2008), with the shading indicating the uncertainty estimates (two standard deviations); the satellite altimeter data since 1993 are shown in red. The modelled sea level is given (a) for the period 1900 to 2010, (b) the rates of sea level change for the same period, with the satellite altimeter data shown as a red dot for the rate, (c) for 1961 to 2010 and (d) for 1990 to 2010. Panel (e) compares the sum of the observed contributions (orange) and the observed sea level from the satellite altimeter data (red). (Figure and caption updated from Church et al. (2013))

[START BOX 13.1 HERE]

Box 13.1: The Global Energy Budget

The global energy balance is a fundamental aspect of the Earth's climate system. At the top of the atmosphere (TOA), the boundary of the climate system, the balance involves shortwave radiation received from the sun, shortwave radiation reflected and long-wave radiation emitted by the Earth (Section 1.2.2). The rate of storage of energy in the Earth system must be equal to the net downward radiative flux at the TOA.

The TOA fluxes (Section 2.3) have been measured by the Earth Radiation Budget Experiment (ERBE) satellites from 1985 to 1999 (Wong et al., 2006) and the Cloud and the Earth's Radiant Energy System (CERES) satellites from March 2000 to the present (Loeb et al., 2009). The TOA radiative flux measurements are highly precise, allowing identification of changes in the Earth's net energy budget from year to year within the ERBE and CERES missions (Kato, 2009; Stackhouse et al., 2010; Loeb et al., 2012), but the absolute calibration of the instruments is not sufficiently accurate to allow determination of the absolute TOA energy flux or to provide continuity across missions (Loeb et al., 2009).

The ocean has stored over 90% of the increase in energy in the climate system over recent decades (Box 3.1), resulting in ocean thermal expansion and hence sea level rise (Sections 3.7, 9.4, 13.4). Thus the energy and sea level budgets are linked and must be consistent (Church et al., 2011b). This Box focuses on the Earth's global energy budget since 1970 when better global observational data coverage is available. The radiative forcings (from Chapter 8), the global averaged surface temperatures (HadCRUT4) (Morice et al., 2012) and the rate of energy storage are relative to the time mean of 1860 to 1879. Otto et al. (2013) used an

energy imbalance over this reference period of $0.08 \pm 0.03 \text{ W m}^{-2}$, which is subtracted from the observed energy storage.

Since 1970, the effective radiative forcing (ERF) of the climate system has been positive as a result of increased greenhouse gas concentrations (well-mixed and short-lived greenhouse gases, tropospheric and stratospheric ozone and stratospheric water vapour) and a small increase in solar irradiance (Box 13.1, Figure 1a). This positive ERF has been partly compensated by changes in tropospheric aerosols which predominantly reflect sunlight and modify cloud properties and structure in ways that tend to reinforce the negative ERF, although black carbon produces positive forcing. Explosive volcanic eruptions (such as El Chichón in Mexico in 1982 and Mount Pinatubo in the Philippines in 1991) can inject sulphur dioxide into the stratosphere, giving rise to stratospheric aerosol, which persists for several years. This reflects some of the incoming solar radiation, and thus gives a further negative forcing. Changes in surface albedo from land-use change have also led to a greater reflection of shortwave radiation back to space and hence a negative forcing. Since 1970, the net ERF of the climate system (including black carbon on snow and combined contrails and contrail induced cirrus, not shown) has increased (Chapter 8) resulting in a cumulative total energy inflow over this period (Box 13.1, Figure 1a).

[INSERT BOX 13.1, FIGURE 1 HERE]

Box 13.1, Figure 1: The Earth's energy budget from 1970 through 2011. (a) The cumulative energy flux into the Earth system from changes in well-mixed and short-lived greenhouse gases, solar forcing, changes in tropospheric aerosol forcing, volcanic forcing and surface albedo, (relative to 1860–1879) are shown by the coloured lines and these are added to give the cumulative energy inflow (black; including black carbon on snow and combined contrails and contrail induced cirrus, not shown separately). (b) The cumulative total energy inflow from (a, black) is balanced by the sum of the warming of the Earth system (blue; energy absorbed in warming the ocean, the atmosphere and the land and in the melting of ice) and an increase in outgoing radiation inferred from changes in the global averaged surface temperature. The sum of these two terms is given for a climate feedback parameter α of 0.82, 1.23 and $2.47 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$, (corresponding to an equilibrium climate sensitivity of 4.5, 3.0 and 1.5°C). The energy budget would be closed for a particular value of α if that line coincided with the total energy inflow. For clarity, all uncertainties (shading) shown are for a likely range.

If the ERF were fixed, the climate system would eventually warm sufficiently that the radiative response would balance the ERF, and there would be zero net heat flux into the system. As the ERF is increasing, the ocean's large capacity to store heat means the climate system is not in equilibrium (Hansen et al., 2005), and continues to store energy (Box 3.1; Box 13.1, Figure 1b). This storage provides strong evidence of a changing climate. The majority of this additional heat is in the upper 700 m of the ocean but there is also warming in the deep and abyssal ocean (Box 3.1). The associated thermal expansion of the ocean has contributed about 40% of the observed sea level rise since 1970 (Section 13.4.2.2.6; Church et al., (2011b)). A small amount of additional heat has been used to warm the continents, warm and melt glacial and sea ice, and warm the atmosphere (Box 3.1).

As the climate system warms, energy is lost to space through increased outgoing radiation. This radiative response by the system is predominantly due to increased thermal grey-body radiation emitted by the atmosphere and surface, but is modified by climate feedbacks, such as changes in water vapour, surface albedo and clouds, which affect both outgoing longwave and reflected shortwave radiation. Following Murphy et al. (2009), Box 13.1, Figure 1b relates the cumulative total energy inflow to the Earth system to the change in energy storage and the cumulative outgoing radiation. Calculation of the latter is based on the observed globally averaged surface temperature change ΔT relative to a reference temperature for which the Earth system would be in radiative balance. This temperature change is multiplied by the climate feedback parameter α , which in turn is related to the equilibrium climate sensitivity. For equilibrium climate sensitivities of 4.5°C , 3.0°C to 1.5°C (Box 12.2) and an ERF for a doubled CO_2 concentration of $3.7 \pm 0.74 \text{ W m}^{-2}$ (Sections 8.1, 8.3), the corresponding estimates of the climate feedback parameter α are 0.82, 1.23 and $2.47 \text{ W m}^{-2} \text{ }^\circ\text{C}^{-1}$.

In addition to these forced variations in the Earth's energy budget, there is also internal variability on decadal time scales. Observations and models indicate that because of the comparatively small heat capacity of the atmosphere, a decade of steady or even decreasing surface temperature can occur in a warming world (Easterling and Wehner, 2009; Palmer et al., 2011). GCM simulations indicate that these periods are associated with a transfer of heat from the upper to the deeper ocean, of order 0.1 W m^{-2} (Katsman and van

Oldenborgh, 2011; Meehl et al., 2011), with a near steady (Meehl et al., 2011) or an increased radiation to space (Katsman and van Oldenborgh, 2011), again of order 0.1 W m^{-2} . While these natural fluctuations represent a large amount of heat, they are significantly smaller than the anthropogenic forcing of the Earth's energy budget (Huber and Knutti, 2012), particularly when looking at time scales of several decades or more (Santer et al., 2011).

These independent estimates of ERF, observed heat storage and surface warming combine to give an energy budget for the Earth that is consistent with the assessed range of climate sensitivity (2°C to 4.5°C ; Box 12.2) to within estimated uncertainties. Quantification of the terms in the Earth's energy budget and verification that these terms balance over recent decades provides strong evidence for our understanding of anthropogenic climate change. Changes in the Earth's energy storage are a powerful observation for the detection and attribution of climate change (Section 10.3) (Gleckler et al., 2012; Huber and Knutti, 2012).

[END BOX 13.1 HERE]

13.4 Projected Contributions to Global Mean Sea Level

13.4.1 Ocean Heat Uptake and Thermal Expansion

Over 90% of the net energy increase of the climate system on multiannual timescales is stored in the ocean (Box 3.1). GMSL rise due to thermal expansion is approximately proportional to the increase in ocean heat content. The constant of proportionality is $0.11 \pm 0.01 \text{ m per } 10^{24} \text{ J}$ in CMIP5 models (Kuhlbrodt and Gregory, 2012); it depends on the vertical and latitudinal distribution of warming in the ocean, because the expansion of sea water per degree of warming is greater at higher temperature and higher pressure (Russell et al., 2000; Hallberg et al., 2012; Körper et al., 2013; Perrette et al., 2013).

For the early decades of the 21st century, the upper ocean dominates the ocean heat uptake, and ocean heat content rises roughly linearly with global mean surface air temperature (SAT) change (Pardaens et al., 2011b; Körper et al., 2013). On multidecadal timescales under scenarios of steadily increasing radiative forcing, the rate of increase of ocean heat content is approximately proportional to the global mean SAT change from equilibrium (Gregory, 2000; Meehl et al., 2007; Rahmstorf, 2007a; Gregory and Forster, 2008; Katsman et al., 2008; Schwartz, 2012), with the constant of proportionality (in $\text{W m}^{-2} \text{ K}^{-1}$) being the ocean heat uptake efficiency κ .

The ocean heat uptake efficiency quantifies the effect of ocean heat uptake on moderating time-dependent climate change; neglecting the small fraction of heat stored elsewhere in the climate system, the surface warming can be approximated as $F/(\alpha+\kappa)$, where F is the radiative forcing and α is the climate feedback parameter (Raper et al., 2002), and hence the rate of ocean heat uptake is approximately $\kappa F/(\alpha+\kappa)$. In CMIP3 and CMIP5, the model spread in projections of surface warming is dominated by the spread in F and α , but the spread in κ accounts for a substantial part of the spread in projections of ocean heat uptake (Dufresne and Bony, 2008; Gregory and Forster, 2008; Knutti and Tomassini, 2008; Geoffroy et al., 2012; Sriver et al., 2012; Forster et al., 2013).

The spread in κ relates to differences among models in heat-transport processes within the ocean. The warming spreads downwards from the surface over time, and the greatest increases in projected ocean heat content occur where the warming penetrates most deeply, in the Southern Ocean and the North Atlantic (Figure 12.12; Section 12.4.7.1) (Kuhlbrodt and Gregory, 2012). Changes in convection and the large-scale vertical circulation are particularly important to heat uptake in the North Atlantic (Banks and Gregory, 2006; Rugenstein et al., 2013). Heat is also transported vertically by eddies, especially in the Southern Ocean, and by turbulent mixing. These processes are parameterised in models when they occur at unresolved scales. Observed ocean heat uptake has been used in conjunction with observed global SAT change to constrain the ocean effective thermal diffusivity representing all unresolved vertical transports in simple climate models and EMICs (Forest et al., 2008; Knutti and Tomassini, 2008; Marčelja, 2010; Sokolov et al., 2010). The simulated ocean vertical temperature profile and the depth of penetration of the warming in AOGCMs have also been evaluated by comparison with observations, and both bear a relationship to κ (Hallberg et al., 2012; Kuhlbrodt and Gregory, 2012). Such comparisons suggest that model projections might be biased towards overestimating ocean heat uptake and thermal expansion for a given surface warming (Sections

9.4.2.2, 10.8.3, and 13.3.1.2). The physical causes of this tendency are unclear. Although the simulated vertical temperature profile is affected by the model representation of vertical heat transport processes, Brierley et al. (2010) found only a small effect on κ from variation of model parameters that influence interior heat transport.

Because the ocean integrates the surface heat flux, thermal expansion projections following different scenarios do not significantly diverge for several decades. Scenarios assuming strong mitigation of greenhouse gas emissions begin to show a reduced rate of thermal expansion beyond about 2040; the amount by 2100 is about one-third less than in a non-mitigation scenario (Washington et al., 2009; Pardeens et al., 2011b; Körper et al., 2013), and half as much in RCP2.6 as in RCP8.5 (Yin, 2012a); Section 13.5.1). The integrating effect means that thermal expansion depends on the pathway of CO₂ emissions, not only on the cumulative total; reducing emissions earlier rather than later, for the same cumulative total, leads to a larger mitigation of sea level rise due to thermal expansion (Zickfeld et al., 2012; Bouttes et al., 2013). The integrating effect also means that annual time series of global ocean thermal expansion show less interannual variability than time series of global SAT. For the present assessment of GMSL rise, projections of ocean heat uptake and thermal expansion up to 2100 have been derived from the CMIP5 AOGCMs (Yin, 2012a). Methods are described in Section 13.5.1 and the Supplementary Material and the results for ocean heat uptake are shown in Figure 13.8, and for thermal expansion in Table 13.5 and Figures 13.10 and 13.11.

[INSERT FIGURE 13.8 HERE]

Figure 13.8: Heat uptake by the climate system during the 21st century relative to 1986–2005 projected by CMIP5 AOGCMs under RCP scenarios ($1 \text{ YJ} = 10^{24} \text{ J}$). The heat uptake is diagnosed by two different methods. The thick solid lines, and the coloured ranges for RCP2.6 and RCP8.5, are the time- and global integral of the net downward radiative flux perturbation at the top of the atmosphere, from the 21 AOGCMs used to make the global mean sea level projections (in some cases estimated from other scenarios, as described in the Supplementary Material). The broken solid lines, and the thin solid lines delimiting ranges for RCP2.6 and RCP8.5, are the global volume integral of ocean temperature change, in a smaller and different set of AOGCMs for each scenario. The difference between the two diagnoses is due partly to the different sets of models (which is a consequence of diagnostics available in the CMIP5 dataset), and partly to heat uptake in other parts of the simulated climate system than the ocean water. In both methods, climate drift in the pre-industrial control run has been subtracted.

Ocean heat uptake efficiency is not constant on timescales of many decades or in scenarios of stable or decreasing radiative forcing (Rahmstorf, 2007a; Schewe et al., 2011; Bouttes et al., 2013). A good representation of AOGCM behaviour is obtained by distinguishing a shallow layer, which is associated with surface temperature variations on decadal timescales, from a deep layer, which has the majority of the heat capacity (Hansen et al., 1985; Knutti et al., 2008; Held et al., 2010; Olivié et al., 2012; Schwartz, 2012; Bouttes et al., 2013; Geoffroy et al., 2013). Ocean heat uptake and thermal expansion take place not only while atmospheric GHG concentrations are rising, but continue for many centuries to millennia after stabilization of radiative forcing, at a rate which declines on a centennial time scale (Stouffer, 2004; Meehl et al., 2005; 2007; Solomon et al., 2009; Hansen et al., 2011; Meehl et al., 2012; Schwartz, 2012; Bouttes et al., 2013; Li et al., 2013; Zickfeld et al., 2013). This is because the timescale for warming the deep ocean is much longer than for the shallow ocean (Gregory, 2000; Held et al., 2010).

The rate and the stabilization timescale for thermal expansion depend on the GHG stabilization level. For the highest scenario (RCP8.5), GMSL rise due to thermal expansion can reach up to 2 m above the pre-industrial level by the year 2500 (Section 12.5.2, Figure 12.44, Figure 13.14a), and is still rising at that time. Changes in ocean circulation, particularly due to a reduction in deep water formation, can also have a large effect on global ocean heat uptake, and may relate non-linearly to global surface warming (Levermann et al., 2005; Fluckiger et al., 2006; Vellinga and Wood, 2008). As the rate of ocean heat uptake decreases, the surface warming approaches the level determined by the equilibrium climate sensitivity.

On a multi-millennial time scale, the range from Earth System Models of Intermediate complexity suggests that thermal expansion contributes between 0.20–0.63 m per °C of global mean temperature increase (Meehl et al., 2007; Zickfeld et al., 2013) (Section 12.5.2, Figure 13.14a). The median of the six models of 0.38 m °C⁻¹ is consistent with a uniform increase in ocean temperature from the presently observed temperature and salinity distribution (Levitus et al., 2009). Uncertainty arises due to the different spatial distribution of the warming in models and the dependence of the expansion on local temperature and salinity.

13.4.2 *Glaciers*

The 21st century sea level contribution from glaciers presented in the AR4 assessment ranged from 0.06 to 0.15 m SLE by 2100 across a range of scenarios (Meehl et al., 2007). The Randolph Glacier Inventory (RGI) (Arendt et al., 2012) has improved projections of glacier contribution to sea level rise by providing the first globally complete accounting of glacier location, area, and area-elevation distribution (hypsometry). Several analyses of scenario-dependent SMB glacier projections (referred to here as “process-based” models) have been produced using the RGI, including Marzeion et al. (2012a), Giesen and Oerlemans (2013) and Radić et al. (2013). The Marzeion, and Radić approaches each used different suites of CMIP5 AOGCM models to calculate SMB terms from RCP forcings, and the model by Slangen and van de Wal (2011) was used to calculate SMB terms from RCP forcings (Supplementary Material 13.SM.1). Giesen and Oerlemans (2013) used CRU forcing but calculated SMB from three different combinations of variations in modelled temperature, precipitation, and atmospheric transmissivity. Only their results for varying temperature are shown here. Machguth et al. (2013) is also included in Table 13.3, but this projection represents changes in Greenland peripheral glaciers only, and is not included in the global glacier summaries. While these details differ among the models, all share a generally common time-evolving structure, with SMB initially determined by model-generated climate forcing applied to a subset of global glaciers, the ensuing volume change converted to area change via volume-area scaling, and this result upscaled to a new global distribution and hypsometry to create initial conditions for the subsequent time step. These methods are described further in Section 13.5.1 and in the Supplementary Material. Related results are shown in Table 13.5 and Figures 13.10 and 13.11.

While the peripheral glaciers surrounding the ice sheets are included with the ice sheets in assessment of present-day losses, future projections should ideally assess the peripheral glaciers separately, since these are too small and dynamically responsive to be modeled adequately with coarse-grid, non-dynamic ice-sheet SMB models. The peripheral glaciers surrounding both Greenland and Antarctica are thus included in the process-based models described above, but for summation with the ice sheet projections, the Antarctic peripheral glaciers are excluded, and included instead with the Antarctic ice sheet projection models. Projected losses from both ice-sheet peripheral glaciers are listed separately in Table 13.3

Several glacier loss projections derived from model types other than process-based models have been published since 2007; their projections range from 0.08 to 0.39 m SLE by 2100 (Table 13.3). These used methods of projecting future losses from glaciers developed in response to the absence of a global compilation of glacier observations after 2005 and the absence of a globally complete glacier inventory to provide geographic boundary conditions for conventional modeling. These methods include extrapolation from observed rates (Meier et al., 2007), semi-empirical methods applied to sea level change components (Jevrejeva et al., 2012b), kinematic (or “limit seeking”) projections (Pfeffer et al., 2008), and power-law scaling estimates based on re-establishing equilibrium accumulation-area ratios (AARs) from initial non-equilibrium AARs (Bahr et al., 2009). Strengths of these approaches include the fact that observations used to calibrate extrapolation and semi-empirical projection partially account for future dynamically forced losses, that semi-empirical methods use modelled future forcings as guidance for projections, and that AAR equilibration has strong physical and theoretical underpinnings and gives generalized but robust projections. These strengths partially offset the weaknesses of these models, which include, in the case of extrapolation and semi-empirical projection, an assumption of statistical stationarity that may not be valid, while the AAR equilibration approach gives only a final steady state value, so that rates or cumulative losses at any intermediate time must be estimated by area-response time scaling. However, these alternate methods are valuable because of their construction on fundamental and robust principles together with their use of the limited available information to produce projections that, while imprecise, are transparent, and require less detailed input information or knowledge of details of complex processes in comparison to conventional “process-based” models.

Published results from process-based models are shown in Table 13.3. Glacier contributions at 2100, expressed as SLE, range between 0.04 and 0.11 m for SRES A1B, 0.07 and 0.17 m for RCP2.6, between 0.07 and 0.20 m for RCP4.5, between 0.07 and 0.20 m for RCP6.0, and between 0.12 and 0.26 m for RCP8.5.

The projections derived from alternative models are also shown in Table 13.3; the mean and range of these models listed here is 0.24 [0.08–0.39] m SLE, consistent with the process-based models. Results from the process-based models, plotted as time series and grouped by forcing scenario, are shown in Figure 13.9. See Table 13.3 for specific start/end dates for each projection.

Table 13.3: 21st century sea level rise projections for global glaciers, from process-based surface mass balance models, and from alternate model strategies. Dates for beginning and end of model period are as shown; mean and 5%/95% confidence sea level equivalents are shown in meters. Process-based models all use variations on AOGCM mass balance forcing applied to inventoried glacier hypsometries on a subset of global glaciers and upscaling by power-law techniques to the global total. Calving and rapid dynamic response is not included in any models except for Jevrejeva et al. (2012b), where calving losses are present to a limited degree in input data, and NRC (2012), where calving is explicitly included in future losses. Other model details are discussed in the text.

[INSERT FIGURE 13.9 HERE]

Figure 13.9: Time series plots for process-based model projections of sea level contributions from global glaciers (in mm), including peripheral glaciers surrounding the Greenland Ice Sheet but excluding the glaciers surrounding the Antarctic Ice Sheet. Projections are grouped by forcing scenario as indicated on the plots. Results are plotted for a common time interval of 2011 to 2099. Colors correspond to particular model analyses: red = Marzeion et al. (2012a); blue = Slangen and van de Wal (2011); green = Radić et al. (2013); black = Giesen and Oerlemans (2013). Individual AOGCM model projections are plotted for each analysis, so the ranges of the curves at 2099 are different than those listed in Table 13.3, where 5–95% confidence limits are shown. In the panel showing results for RCP6.0 and A1B forcings, only Geisen and Oerlemans (black lines) use the A1B forcing.

Unresolved uncertainties in the projection of glacier contributions to sea level rise include the potential for near-term dynamic response from marine-terminating glaciers and interception of terrestrial runoff. Of the 734,400 km² of global glacier area exclusive of the Greenland and Antarctic ice sheets, 287,300 km² (38%) is now known to drain through marine-terminating outlets (Gardner et al., 2013). While the long-term potential for dynamic discharge from glaciers (as opposed to ice sheets) is limited by their small total volume, dynamic losses may be an important component of total sea level rise on the decade-to-century scale. In Alaska, Columbia Glacier lost 7.65 Gt yr⁻¹ between 1996 and 2007, with 94% of that loss coming from rapid tidewater retreat (Rasmussen et al., 2011); the loss from this single 1000 km² glacier is 1.3% of the global cryospheric component of sea level rise during 1993–2010 (Table 13.1) and 0.7% of total sea level rise. The observations required to estimate the potential for similar dynamic response from other glacier regions are unknown at this time, but the dynamic contribution could be large on the century time scale. If the basin-wide thinning rate observed at Columbia Glacier over the past 25 years (ca. 5 m yr⁻¹) were to occur over the area of global glaciers draining through marine outlets (280,500 km²) during the next 89 years (2011–2100), the sea level contribution would be approximately 30 cm SLE, compatible with Jeverajeva et al.'s (2012b) projected loss of 26 cm SLE from glaciers. While this is a rough calculation and an upper bound, since drainage through marine outlets does not guarantee tidewater instability, it indicates that the potential for a significant sea level response to dynamic retreat of glaciers cannot be rejected *a priori*.

Completion of the global inventory has allowed large improvements in assessment and modelling, but further uncertainties related to the inventory remain to be resolved, including those arising from the size cutoff decided for the inventory (Bahr and Radić, 2012). Another source of uncertainty is interception of glacier runoff by land hydrology. Despite rapidly growing knowledge of changes in terrestrial water storage, especially through increased reliability of GRACE observations, glacier mass loss rates are still generally assumed to flow directly to the ocean, with no delay or interception by surface or aquifer storage. While this is very unlikely to apply to discharge from glaciers located near coasts (e.g., Canadian Arctic, Patagonia, Alaska, ice-sheet peripheries), runoff from regions within interiors (e.g., Alps, High Mountain Asia) may be significantly depleted before reaching the ocean. Whether terrestrial interception has any significant effect on the net glacier contribution to sea level rise is undetermined at this time.

13.4.3 Greenland Ice Sheet

13.4.3.1 Surface Mass Balance Change

Greenland SMB is positive in the present climate but shows a decreasing trend (Section 13.3.3.2), which implies an increasing contribution to GMSL rise. Like the AR4, all recent studies have indicated that the future sea level contribution from Greenland SMB change will be increasingly positive because the increase in ablation (mostly runoff) outweighs that in accumulation (mostly snowfall), and that scenarios of greater radiative forcing lead to a larger sea level contribution. Precipitation is projected to increase at about 5% per °C of annual-mean warming over Greenland, but the increase in snowfall is smaller because the fraction of rain increases as temperature rises (Gregory and Huybrechts, 2006; Fettweis et al., 2013).

We compare post-AR4 studies of Greenland SMB change using time-dependent simulations of the 21st century by CMIP3 AOGCMs for scenario SRES A1B and CMIP5 AOGCMs for scenario RCP4.5 (Table 13.4). The time-integral of the Greenland SMB anomaly with respect to a reference period is interpreted as a contribution to GMSL rise, on the assumption that the ice sheet was in approximate mass balance during the reference period (see discussion in Section 13.1.5.1 and 13.3.3.2); this assumption can be avoided only if

ice-sheet outflow is also modelled. Making this assumption, the Greenland SMB contribution lies in the range 0.00–0.13 m for these two scenarios.

The spread in the magnitude and patterns of Greenland climate change projected by the AOGCMs causes a large part of the spread in the projected contribution to GMSL rise (Table 13.4). Yoshimori and Abe-Ouchi (2012) found that the inter-model spread in global mean SAT change accounts for about 60% of the spread in the change of projected Greenland ablation. Two important contributions to the remaining spread are the weakening of the AMOC, which affects the magnitude of warming over Greenland, and the SAT of Greenland in the model control climate, which affects the sensitivity of melting to warming (Yoshimori and Abe-Ouchi, 2012; Fettweis et al., 2013).

Ablation is computed using either a surface energy balance model (EBM), which may be stand-alone or part of a regional climate model, or from surface air temperature using an empirical temperature-index method, mostly commonly the positive-degree-day (PDD) method, in which melting is proportional to the time-integral of temperature above freezing point. Meltwater production increases faster than linearly with temperature increase because of reduced albedo due to refreezing of meltwater in the snowpack and expansion of the area of bare ice (van Angelen et al., 2012; Fettweis et al., 2013; Franco et al., 2013). The simulation of this positive albedo feedback on mass loss depends sensitively on the model snow-albedo parameterisation (Rae et al., 2012). Goelzer et al. (2013) projected 14–31% more runoff during the 21st century when using an EBM than when using a PDD method, mainly because of the omission of the albedo feedback in the latter. However, other studies using temperature-index methods (Graversen et al., 2011; Yoshimori and Abe-Ouchi, 2012) have ranges extending to higher values than those from EBMs, indicating that this is not the only difference between these classes of methods (Table 13.4).

SMB simulations are also particularly sensitive to the treatment of meltwater refreezing (Bougamont et al., 2007; Rae et al., 2012). The pore space in the present-day percolation zone could accommodate 1–5 mm SLE of refrozen meltwater over the next several decades (Harper et al., 2012), and the importance of meltwater refreezing will become greater as melting becomes prevalent in areas where it has previously been rare. On the other hand, refreezing will be restricted, and runoff consequently increased, by the expansion of the area of bare ice (Fettweis et al., 2013).

Another source of model spread is the representation of topography, which is lower when represented at coarser resolution. This allows precipitation to spread further inland because of reduced topographic barriers (Bengtsson et al., 2011), and enhances ablation because there is more area at lower, warmer altitudes (Bengtsson et al., 2011; Seddik et al., 2012). Most of the models in Table 13.4 use a fixed Greenland topography, and thus cannot simulate the positive feedback on ablation that can be expected as the ice-sheet surface becomes lower. Dynamical models are required to simulate this effect (Section 13.4.3.2).

For the present assessment of GMSL rise, changes in Greenland ice sheet SMB up to 2100 have been computed from global mean SAT change projections derived from the CMIP5 AOGCMs, following methods described in Section 13.5.1 and the Supplementary Material. The distribution of results, shown in Table 13.5 and Figures 13.10 and 13.11, covers the ranges obtained using the methods of Fettweis et al. (2013), Gregory and Huybrechts (2006) and Yoshimori and Abe-Ouchi (2012).

Table 13.4: Contribution to sea level rise from change in the surface mass balance of the Greenland ice sheet during the 21st century. Where given, ranges are 5–95% estimated from the published results and indicate the uncertainty due to the climate change modelling by AOGCMs, except where noted otherwise.

Notes:

(a) The spatial resolution is stated and the SMB method denoted by TI = temperature index, PDD = positive degree day, EBM = energy balance model.

(b) The amount of sea level rise is the time-integral of the SMB anomaly from the period or date labelled ‘starting from’ to the one labelled ‘up to’. Unless otherwise indicated, the SMB anomaly is calculated relative to the mean SMB for the ‘starting from’ period, and the rate of sea level rise is the SMB anomaly in the ‘up to’ period.

(c) These results are estimated from global mean SAT change, using formulae fitted to results from a Greenland SMB model.

(d) The SMB anomaly is relative to the late 19th century.

(e) This experiment used time-slices, with boundary conditions from the ECHAM5 GCM, rather than a simulation of the complete century; thus, results are not available for the amount.

(f) Fettweis et al. (2008) and Franco et al. (2011) use a hybrid approach: they derive a regression relationship from simulations of the recent past using an RCM, incorporating an EBM, between annual anomalies in Greenland climate and in Greenland SMB, then apply this relationship to project future SMB from projected future climate anomalies. The method assumes that a relationship derived from past variability will also hold for future forced climate change.

(g) Range including uncertainty in choice of emission scenario (B1, A1B or A2), SMB modelling and ice sheet dynamical modelling, as well as uncertainty in climate modelling.

(h) Results are given for the HadRM3P, HIRHAM5 and MAR RCMs driven with the same boundary conditions from the ECHAM5/MPI-OM AOGCM.

(i) Results are given for two ice sheet models (Elmer/Ice, SICOPOLIS) using the same AOGCM climate boundary conditions. The resolution given is for SICPOLIS; Elmer/Ice has variable resolution.

(j) Results calculated from CMIP5 AOGCMs by the same method as used in the paper.

(k) These results were obtained from the model of Van Angelen et al. (2012) using boundary conditions from the HadGEM2-ES AOGCM and are shown by Fettweis et al. (2013).

(l) With respect to 1992–2011 as a reference period, during which there is a significant simulated trend in SMB (Section 13.3.3.2), the amount is 0.07 m and the rate 1.4 mm yr⁻¹.

On multi-centennial to millennial time scales, feedbacks between regional climate and the ice sheet become increasingly relevant, especially under strong climate change scenarios, thus requiring coupled climate ice-sheet models to capture potential feedbacks beyond the year 2100. These models apply a reduced spatial resolution in order to be computationally efficient enough to evaluate longer time scales and to combine the different climatic components. Consistent with regional climate models for the 21st century, they project an increasingly negative mass balance for the Greenland Ice Sheet for all warming scenarios which is mainly due to a decreasing SMB (Ridley et al., 2005; Winguth et al., 2005; Driesschaert et al., 2007; Mikolajewicz et al., 2007a; Swingedouw et al., 2008; Vizcaíno et al., 2008; Vizcaíno et al., 2010; Huybrechts et al., 2011; Goelzer et al., 2013). The main feedbacks between climate and the ice sheet arise from changes in ice elevation, atmospheric and ocean circulation, and sea-ice distribution.

Comparing the different feedbacks, *high confidence* can be assigned to the models’ ability to capture the feedback between SMB and surface elevation. As a consequence, a nonlinear increase in ice loss from Greenland with increasing regional radiative forcing is found across different scenarios (Driesschaert et al., 2007). This nonlinearity arises from the increase in both the length of the ablation season and the daily amount of melting. This feedback is also the main reason for the threshold behaviour of the Greenland Ice Sheet on multi-millennial time scales (Section 13.4.3.3).

Medium-to-low confidence is assigned to the models' representation of the atmospheric and ocean circulation and sea-ice changes. On multi-centennial time scales, Swingedouw et al. (2008) find enhanced ice loss from Greenland in a coupled simulation (compared to the uncoupled version) in which ice topography and melt-water flux influence the ocean and atmospheric circulation as well as sea-ice distribution. Vizcaíno et al. (2010) found reduced ice loss due to the coupling, mainly caused by the effect of topographic changes on the surface temperature, but less pronounced in amplitude compared with Swingedouw et al. (2008). Both the atmospheric circulation and the ocean currents, especially in coastal areas, are poorly resolved by these models. It is therefore *likely* that the time scales associated with ocean transport processes are distorted and there is *low confidence* that these feedbacks, while existent, can be quantified accurately by the applied models.

The AMOC exerts a strong influence on regional climate around the Greenland Ice Sheet and consequently its SMB. Most CMIP5 models show a reduction of the AMOC under future warming during the 21st century and beyond (Section 12.4.7.2). While coupled climate-ice sheet models show some influence of melt water from Greenland on the AMOC, the uncertainty between models with respect to the AMOC response to warming is significantly larger than the difference between simulations with or without this feedback within one model.

In the coupled climate-ice sheet model applied by Mikolajewicz et al. (2007a) and Vizcaíno et al. (2008), the AMOC shows a strongly non-linear response to global warming. A weak AMOC reduction is found for 1%-per-year-CO₂-increase scenarios up to 560 and 840 ppm, and a near-complete cessation of the AMOC for 1120 ppm. As a consequence, after 600 years of integration, the sea level contribution for the 1120 ppm scenario is similar to that of the 560 ppm scenario, but doubles for the medium scenario which stabilizes at 840 ppm. In the most recent model version (Vizcaíno et al., 2010), the AMOC shows a strong weakening of the AMOC in all scenarios (~60% reduction in 560 ppm scenario; ~80% for 1120 ppm). The total sea level contribution from Greenland, including the effect of the AMOC weakening, is ~1 m (corresponding to an average rate of 1.7 mm yr⁻¹) for 560 ppm CO₂ and ~3 m (5 mm yr⁻¹) for 1120 ppm CO₂.

Even though the AMOC weakening in the model by (Huybrechts et al., 2011) is less pronounced (10–25%), the ice loss through melting is significantly weaker in this model. During the first 1000 years of integration, the Greenland Ice Sheet contributes 0.36 m (corresponding to an average rate of 0.36 mm yr⁻¹) for 560 ppm CO₂ and 2.59 m (2.59 mm yr⁻¹) for 1120 ppm CO₂. In (Huybrechts et al., 2011), the respective increases in global mean SAT are 2.4°C (2 × CO₂) and 6.3°C (4 × CO₂) after 1000 years with respect to pre-industrial. This relatively weak warming response to GHG forcing compared to CMIP5 models and the climate model used in Vizcaíno et al. (2010) explains the relatively low sea level response.

Using the same model as Huybrechts et al. (2011), albeit with a slightly higher polar warming, Goelzer et al. (2012) computed temperatures and sea level under the SRES scenarios B1, A1B and A2, with subsequent GHG stabilization after the year 2100. As in Huybrechts et al. (2011), the ice-sheet evolution is dominated by the SMB. They find sea level contributions of 1.4, 2.6 and 4.2 m in the year 3000 for the scenarios B1, A1B and B2, which correspond to mean rates of sea level rise of 1.4 mm yr⁻¹, 2.6 mm yr⁻¹, and 4.2 mm yr⁻¹, respectively.

In summary, coupled climate-ice sheet models consistently show an increasingly negative mass balance of the Greenland Ice Sheet mainly due to a decreasing SMB under warming scenarios on centennial time scales beyond 2100. On multi-millennial time scales, these models show a threshold temperature beyond which the melting of the Greenland Ice Sheet self-amplifies and the ice volume is reduced to less than 30% of its present volume (Section 13.4.3.3).

13.4.3.2 Dynamical Change

Observations suggest three main mechanisms by which climate change can affect the dynamics of ice flow in Greenland (Sections 4.4.3 and 4.4.4): by directly affecting ice loss (outflow) through the calving of ice bergs and marine melt from marine-terminating outlet glaciers; by altering basal sliding through the interaction of surface melt water with the glacier bed; and indirectly through the interaction between SMB and ice flow. We assess the consequences of each of the processes.

Section 4.4.3.2 presents the observational basis on which concerns about increased ice loss by calving and marine melt are based. In particular, recent increases in loss are thought to be linked to the migration of subtropical water masses around the coast of Greenland (Holland et al., 2008) and its occupation of coastal fjords (Straneo et al., 2010; Christoffersen et al., 2011). Output from 19 AOGCMs under scenario A1B showed warming of 1.7°C to 2.0°C around Greenland over the course of the 21st century (Yin et al., 2011), suggesting that the trend towards increased outflow triggered by warming coastal waters will continue.

Although projections of outflow are at a fairly early stage, literature now exists to make an assessment. Flow-line modelling has successfully simulated the observed retreat and associated acceleration of the main outlet glaciers of the Greenland ice sheet (Helheim and Petermann Glaciers (Nick et al., 2009; Nick et al., 2012); Jakobshavn Isbræ (Viel and Nick, 2011)). The same model has been used to project mass loss from these glaciers (Nick et al., 2013), as well as Kangerdlugssuaq Glacier, using ocean and atmosphere forcing based on scenarios A1B and RCP8.5. At 2100, total projected SLR spans 8–13 mm for A1B and 11–17 mm for RCP8.5. These figures generalise to 40–63 mm and 57–85 mm, respectively, for the whole ice sheet based on a simple scaling between modelled and total ice-sheet area (a factor ~5). Price et al. (2011) modelled the century-scale response of the ice sheet to the observed recent retreat of three outlet glaciers (Jakobshavn Isbræ, and Helheim and Kangerdlugssuaq Glaciers). At 2100, the projected SLR associated with the three modelled outlet glaciers is 0.6–1.4 mm, which equates to SLR of 4–8 mm after scaling (by a factor of ~6) to all outlet glaciers based on observed mass loss (van den Broeke et al., 2009). Total projected SLR then varies between 10 and 45 mm at 2100 if successive retreats are specified with a notional repeat interval between 50 and 10 years.

Goelzer et al. (2013) implemented the Nick et al. (2013) retreat chronology within a 5-km resolution ice-sheet model along with their own generalization for including unsampled outlet glaciers. Associated SLR at 2100 is projected to vary between 8 and 18 mm. Graverson et al. (2011) attempted to capture the effect of increased outflow by enhancing basal sliding and generated SLR of 9–24 mm at 2100.

Two estimates of the effect of dynamical change on Greenland's contribution to SLR by 2100 have been made on the basis of physical intuition. Pfeffer et al. (2008) developed a low scenario by assuming a first-decade doubling of outlet glacier velocity throughout the ice sheet that equates to 93 mm SLR, while a high scenario that assumes an order of magnitude increase on the same time scale contributes 467 mm. Katsman et al. (2011) used a similar methodology to obtain an estimate of 100 mm SLR.

Based primarily on Nick et al. (2013), we assess the upper limit of the *likely* 5–95% model range of this dynamical effect to be 85 mm for RCP8.5 and 63 mm for all other RCP scenarios. We have *medium confidence* in this as an upper limit because it is compatible with Katsman et al. (2011), the low scenario of Pfeffer et al. (2008), and Price et al. (2011) in the probable event of a sub-decadal recurrence interval. Although the *likely* upper limit is less than the high scenario of Pfeffer et al. (2008), process modelling gives no support to the order of magnitude increase in flow on which this scenario is based. It is higher than the contributions found by Goelzer et al. (2013) and Graverson et al. (2011) for which there are two potential explanations. First, the generalization used to extrapolate from the modelled sample to all outlet glaciers differs. Nick et al. (2013) used a scaling similar to the independently derived value of Price et al. (2011), while the implied scaling used by Goelzer et al. (2013) is substantially lower. Second, Goelzer et al. (2013) suggested that surface ice melt and calving compete to remove marginal ice (see below) implying that overall mass loss may be over predicted by the flow-line model of Nick et al. (2013). At present, these studies cannot be reconciled and we therefore use the more inclusive range.

The lower limit of the *likely* 5–95% range is assessed as 20 mm for RCP8.5 and 14 mm for all other RCP scenarios. This reflects the individual outlet glacier projections of Nick et al. (2013) but uses a lower generalization more similar to that found by Goelzer et al. (2013). This assessment of the lower limit is compatible with Price et al. (2011) and Graverson et al. (2011).

Section 4.4.3.2 assesses understanding of the link between abundant summer meltwater, lubrication of the ice-sheet base and enhanced ice flow. While this mechanism appears important in modulating present-day ice flow, it is not supported as the cause of recent mass loss. Goelzer et al. (2013) incorporated a parameterisation of this effect based on field observations, which results in less than a millimetre SLR by 2100 in their projections. Bindschadler et al. (2013) and Nowicki et al. (2013) reported a suite of

experiments assessing this effect in an eight-model ensemble, but their parameterization appears overly simplistic and may well exaggerate the importance of the effect. These projections do not incorporate the effect on ice flow of the latent heat released by increased future quantities of melt water within the ice sheet (Phillips et al., 2010; 2013), for which no projections are currently available. Basal lubrication is therefore assessed as making an insignificant contribution to the likely range of SLR over the next century and is omitted in the remainder of the assessment. We have *medium confidence* in projections of this effect primarily because recent improvements in process-based understanding show that it has little contribution to mass loss (Section 4.4.3.2); the potential of latent-heat effects in the future limits a higher level of confidence.

Finally, we assess the level of interaction between SMB change and ice flow. In AR4, this effect is assessed as $0 \pm 10\%$ (likely range) of SMB, based on Huybrechts and de Wolde (1999) and Gregory and Huybrechts (2006). This assessment included both the positive feedback between SMB and the height of the ice sheet, and a countering negative feedback involving ice flow and depletion effects. The latter effect is partly included in our assessment of the direct impacts of climate change on ice flow, and we therefore limit our assessment to SMB-height feedback. Few studies explicitly determine this effect, but Goelzer et al. (2013) reported that it amounts to 5–15% of SMB over the course of the 21st century, which we extend slightly (0–15%) to reflect possible interaction with mass loss by calving (Goelzer et al., 2013).

Goelzer et al. (2013) and Gillet-Chaulet et al. (2012) suggested that SMB and ice dynamics cannot be assessed separately because of the strong interaction between ice loss and climate due to, for instance, calving and SMB. The current assessment has by necessity separated these effects because the type of coupled ice sheet—climate models needed to make a full assessment do not yet exist. These interactions may well combine to reduce SLR in comparison to the assessed range because of the mass-depletion effect of retreating outlet glaciers. Another source of uncertainty is the bedrock topography of Greenland, although recent improvements in data coverage (Bamber et al., 2013) suggest that the majority of the ice sheet rests on bedrock above sea level and the number of deep bedrock troughs penetrating into the interior of Greenland is limited, thus limiting the potential for marine ice-sheet instability (see Box 13.2).

Although not strictly comparable because they contain a different balance of ice-dynamical effects, the assessment is consistent with Bindschadler et al. (2013) and Nowicki et al. (2013) who reported an extensive model inter-comparison exercise in which standardised experiments are combined to represent the impact of climate change under RCP8.5 on the Greenland Ice Sheet. The resultant projection included contributions from lubrication, marine melt and SMB-coupling and generated a mean SLR at 2100 of 162 mm over five models, or 53 mm if an outlier with anomalously high response is removed (including SMB results in SLR at 2100 of 223 and 114 mm for five- and four-model means, respectively). This comparison lends further weight to our confidence.

In summary, dynamic change within the Greenland Ice Sheet is *likely (medium confidence)* to lead to SLR during the next century with a range of 20–85 mm for RCP8.5, and 14–63 mm for all other scenarios. The latter are assumed to have uniform SLR in the absence of literature allowing these scenarios to be assessed individually, although dependency on scenario is expected to exist. In addition, mass loss associated with SMB-height feedback is *likely* to contribute a further 0–15% of SMB (in itself scenario dependent). This equates to, for example, 0 to 11 mm based on the central estimate of RCP8.5 in Table 13.5. The peripheral glaciers of Greenland are not included here but are in the assessment of global glaciers' contribution to SLR (Section 13.4.2). All the available literature suggests that this dynamical contribution to sea level rise will continue well beyond 2100.

13.4.3.3 Possible Irreversibility of Greenland Ice Loss and Associated Temperature Threshold

A number of model results agree in showing that the Greenland Ice Sheet, like other climatic subsystems (Lenton et al., 2008; Levermann et al., 2012) (see Section 12.5.5), exhibits a strongly nonlinear and potentially irreversible response to surface warming. The mechanism of this threshold behaviour is the SMB-height feedback (Section 13.4.3.2); that is, as the surface is lowered due to ice loss, the associated warming of the near surface increases ablation, leading to further ice loss. This feedback is small but not negligible in the 21st century (Section 13.4.3.2) and becomes important for projections for the 22nd century (Goelzer et

al. 2013). This nonlinear behaviour may be accelerated by a reduced surface albedo caused by surface melting which tends to further decrease the surface mass balance (Box et al., 2012) (Section 13.4.3.1).

While the ice-sheet mean SMB is positive, in a steady state it must be balanced by ice outflow, so the ice sheet must extend to the coast. In a warmer climate, the mean SMB is reduced (Section 13.4.3.1) and the steady-state ice sheet will have a lower surface and volume. Models show a threshold in surface warming beyond which self-amplifying feedbacks result in a partial or near complete ice loss on Greenland (Greve, 2000; Driesschaert et al., 2007; Charbit et al., 2008; Ridley et al., 2010; Robinson et al., 2012). If a temperature above this threshold is maintained over a multi-millennial time period, the majority of the Greenland Ice Sheet will be lost by changes in SMB on a millennial to multi-millennial time scale (equivalent to a sea level rise of about 7 m, Table 4.1). During the Middle Pliocene warm intervals, when global mean temperature was 2°C–3.5°C higher than pre-industrial, ice-sheet models suggest near-complete deglaciation of Greenland.

A simplifying assumption is that the threshold is the warming required with the current ice-sheet topography to reduce the mean SMB to zero, on the argument that the ice sheet must then retreat from the coast. Using this criterion, Gregory and Huybrechts (2006) estimated that the SMB threshold occurs for a global mean surface temperature increase of 3.1 [1.9 to 4.6]°C (5–95% confidence interval, 4.5 [3.0 to 6.0]°C for Greenland surface temperature) above pre-industrial (assumed to be a steady state). More recent studies have found thresholds below or in the lower part of this range. In a coupled ice sheet-climate model of intermediate complexity, (Huybrechts et al., 2011) found this threshold at 2.5°C of annual average Greenland SAT. Comparing three regional climate models, (Rae et al., 2012) found a strong dependence of the threshold on the model formulation of the SMB. Based on the model's performance against observations and the physical detail of its surface scheme, MAR is considered the most realistic model, and yields a threshold value 2.8 [2.1–3.4] °C for changes in Greenland annual average temperature compared to preindustrial. Using MAR driven with output from various CMIP5 AOGCMs, Fettweis et al. (2013) evaluated the threshold as ~3°C in global mean surface temperature above 1980–1999 (hence about 3.5°C relative to pre-industrial), and found that it is not exceeded in the 21st century under the RCP4.5 scenario but is reached around 2070 under the RCP8.5 scenario.

Some of the uncertainty in the threshold results from the value assumed for the steady-state ice-sheet SMB (see Table 13.2), and whether this is assumed to be pre-industrial or a more recent period. For 400 Gt yr⁻¹ (Fettweis et al., 2013), the parametrisation of Greenland ice-sheet SMB used for present assessment of 21st century changes (Section 13.4.3.1, Supplementary Material) gives a global warming threshold of 3.0 [2.1–4.1]°C with respect to 1860–1879 (the reference period used in Box 13.1); for 225 Gt yr⁻¹ (Gregory and Huybrechts, 2006, following Church et al., 2001), the threshold is 2.1 [1.5–3.0]°C.

While a negative SMB is a sufficient condition for passing the threshold, it will overestimate the value of the threshold quantitatively, because the SMB-height feedback (even without passing the threshold) means that the steady-state SMB is reduced by more than is calculated assuming fixed topography. The actual SMB change will depend on the dynamical response of the ice sheet that determines its topography. Constraining simulations with a dynamic ice sheet model to changes during the last interglacial, Robinson et al. (2012) estimated the threshold as 1.6 [0.9–2.8]°C (5–95% confidence interval) global averaged temperature above pre-industrial. In these simulations they find that the threshold is passed when southeastern Greenland has a negative SMB. The near-complete ice loss then occurs through ice flow and SMB.

The complete loss of the ice sheet is not inevitable because it has a long timescale (tens of millennia near the threshold and a millennium or more for temperatures a few degrees above the threshold). If the surrounding temperatures decline before the ice sheet is eliminated, the ice sheet might regrow. In the light of future GHG emissions, the time scale of ice loss is competing with the time scale of temperature decline after a reduction of GHG emissions (Allen et al., 2009; Solomon et al., 2009; Zickfeld et al., 2009). The outcome therefore depends on both the CO₂ concentration and on how long it is sustained. Charbit et al. (2008) found that loss of the ice sheet is inevitable for cumulative emissions above about 3000 GtC, but a partial loss followed by regrowth occurs for cumulative emissions less than 2500 GtC. Ridley et al. (2010) identified three steady states of the ice sheet. If the CO₂ concentration is returned to pre-industrial when more than 20–40% of the ice sheet has been lost, it will regrow only to 80% of its original volume due to a local climate feedback in one region; if 50% or more, it regrows to 20–40% of the original. Similar states with ice volume

around 20, 60–80 and 100% of the initial ice volume are also found in other models (Langen et al., 2012; Robinson et al., 2012). If all the ice is lost, temperatures must decline to below a critical threshold for regrowth of the ice sheet (Robinson et al., 2012; Solgaard and Langen, 2012).

On the evidence of paleo data and modelling (Section 5.6.2.4, 13.2.1), it is *likely* that during the LIG, when global mean temperature never exceeded 2°C pre-industrial, the Greenland Ice Sheet contributed no more than 3 m to GMSL. This could indicate that the threshold for near-complete deglaciation had not been passed, or that it was not greatly exceeded so that the rate of mass loss was low; however, the forcing responsible for the LIG warming was orbital rather than from CO₂ (van de Berg et al., 2011), so it is not a direct analogue and the applicable threshold may be different. Studies with fixed-topography ice-sheets indicate a threshold of 2°C or above of global warming with respect to pre-industrial for near-complete loss of the Greenland ice-sheet, while the one study presently available with a dynamical ice-sheet suggests that the threshold could be as low as about 1°C (Robinson et al. 2012). Recent studies with fixed-topography ice-sheets indicate that the threshold is less than about 4°C. With currently available information, we do not have sufficient confidence to assign a *likely* range for the threshold. If the threshold is exceeded temporarily, an irreversible loss of part or most of the Greenland Ice Sheet could result, depending on for how long and by how much the threshold is exceeded.

13.4.4 Antarctic Ice Sheet

13.4.4.1 Surface Mass Balance Change

Since the ice loss from Antarctic due to surface melt and runoff is about 1% of the of the total mass gain from snowfall, most ice loss occurs through solid ice discharge into the ocean. In the 21st century, ablation is projected to remain small on the Antarctic ice sheet because low surface temperatures inhibit surface melting, except near the coast and on the Antarctic Peninsula, and meltwater and rain continue to freeze in the snowpack (Ligtenberg et al., 2013). Projections of Antarctic SMB changes over the 21st century thus indicate a negative contribution to sea level because of the projected widespread increase in snowfall associated with warming air temperatures (Krinner et al., 2007; Uotila et al., 2007; Bracegirdle et al., 2008). Several studies (Krinner et al., 2007; Uotila et al., 2007; Bengtsson et al., 2011) have shown that the precipitation increase is directly linked to atmospheric warming via the increased moisture holding capacity of warmer air, and is therefore larger for scenarios of greater warming. The relationship is exponential, resulting in an increase of SMB as a function of Antarctic SAT change evaluated in various recent studies with high-resolution (~60 km) models as 3.7% °C⁻¹ (Bengtsson et al., 2011), 4.8% °C⁻¹ (Ligtenberg et al., 2013) and ~7% °C⁻¹ (Krinner et al., 2007). These agree well with the sensitivity of $5.1 \pm 1.5\% \text{ °C}^{-1}$ (one standard deviation) of CMIP3 AOGCMs (Gregory and Huybrechts, 2006).

The effect of atmospheric circulation changes on continental-mean SMB is an order of magnitude smaller than the effect of warming, but circulation changes can have a large influence on regional changes in accumulation, particularly near the ice-sheet margins (Uotila et al., 2007) where increased accumulation may induce additional ice flow across the grounding line (Huybrechts and De Wolde, 1999; Gregory and Huybrechts, 2006; Winkelmann et al., 2012). Simulated SMB is strongly and non-linearly influenced by ocean surface temperature and sea ice conditions (Swingedouw et al., 2008). This dependence means that the biases in the model-control climate may distort the SMB sensitivity to climate change, suggesting that more accurate predictions may be obtained from regional models by using boundary conditions constructed by combining observed present-day climate with projected climate change (Krinner et al., 2008). There is a tendency for higher resolution models to simulate a stronger future precipitation increase because of better representation of coastal and orographic precipitation processes (Gentson et al., 2009).

For the present assessment of GMSL rise, changes in Antarctic ice sheet SMB up to 2100 have been computed from global mean SAT change projections derived from the CMIP5 AOGCMs, using the range of sensitivities of precipitation increase to atmospheric warming summarized above, and the ratio of Antarctic to global warming evaluated from CMIP3 AOGCMs by Gregory and Huybrechts (2006) (see also Section 13.5.1 and Supplementary Material). The results are shown in Table 13.5 and Figures 13.10 and 13.11. The projected change in ice outflow is affected by the SMB because of the influence of topography on ice dynamics (Section 13.4.4.2 and Supplementary Material). Ozone recovery, through its influence on atmospheric circulation at high southern latitudes (Section 10.3.3.5), may offset some effects of greenhouse

gas increase in the 21st century, but Antarctic precipitation is nonetheless projected to increase (Polvani et al., 2011). Bintanja et al. (2013) suggested that Antarctic warming and precipitation increase may be suppressed in the future by expansion of Antarctic sea ice, promoted by freshening of the surface ocean, caused by basal melting of ice shelves, and they conduct an AOGCM sensitivity test of this hypothesis. We consider these possibilities in Section 13.5.3.

Beyond the year 2100, regional climate simulations run at high spatial resolution (5–55 km) but without climate-ice sheet feedbacks included show a net ice gain until the year 2200 (Ligtenberg et al., 2013). During the 22nd century, the ice gain is equivalent to an average rate of sea level fall of 1.2 mm yr⁻¹ for the A1B scenario and 0.46 mm yr⁻¹ the E1 scenario.

For multi-centennial to multi-millennial projections, feedbacks between the ice sheet and regional climate need to be accounted for. This is currently done using ice-sheet models coupled to climate models of intermediate complexity, which have a significantly lower spatial resolution in the atmospheric component than regional climate models used to assess future SMB within the 21st century. These coarser resolution models capture the increase in snowfall under future warming, but the regional distribution is represented less accurately. Accordingly, there is *low confidence* in their ability to model spatial melting and accumulation patterns accurately. In contrast, *medium confidence* can be assigned to the models' projection of total accumulation on Antarctica, since it is controlled by the large-scale moisture transport toward the continent.

In idealized scenarios of 1% increase of CO₂ yr⁻¹ up to 560 ppm with subsequent stabilization, Vizcaíno et al. (2010) and Huybrechts et al. (2011) found an initial increase of ice volume due to additional snowfall during the first 600 years of integration. In both models, the changes in SMB dominate the mass changes during and beyond the first 100 years. After 600 years of integration, Vizcaíno et al. (2010) found a mass gain corresponding to a sea level fall of 0.15 m (–0.25 mm yr⁻¹ on average). For the same experiment and the same period, Huybrechts et al. (2011) found a similar sea level fall of 0.08 m (–0.13 mm yr⁻¹ on average).

In a similar experiment but allowing GHG concentrations to reach 1120 ppm CO₂ before being stabilized, both models show a net positive sea level contribution after 600 years of integration. Huybrechts et al. (2011) found a weak sea level contribution during the first 500 years of integration followed by a stronger and relatively constant long-term average rate of ~2 mm yr⁻¹ after 1000 years of integration up to a total contribution of ~4 m SLE after 3000 years of integration. While they found some grounding line retreat due to basal ice-shelf melt, the multi-centennial evolution of the ice sheet is dominated by changes in SMB while the solid-ice discharge after an initial increase shows a significant decrease during the scenario.

For the same scenario, Vizcaíno et al. (2010) found that the initial mass gain is followed by a weak mass loss. After 250 years of integration, the contribution is stronger and relatively constant at a rate of about 3 mm yr⁻¹, corresponding to a net contribution of 1.2 m to global mean sea level rise after 600 years.

The same model as in Huybrechts et al. (2011), although with a slightly stronger polar amplification, was applied to the three SRES scenarios used in the AR4 (B1, A1B, A2) with stabilization in the year 2100 (Goelzer et al., 2012). For the lowest scenario (B1), they found practically no net Antarctic contribution to sea level in the year 3000. Under the medium scenario (A1B), the ice sheet contributes 0.26 m, and under the highest scenario (A2), it contributes 0.94 m SLE in the year 3000.

These simulations include a negative feedback on the regional climate by ice-sheet melt through which summer temperatures can be significantly reduced over Antarctica (Swingedouw et al., 2008). However, due to the coarse resolution and the high polar amplification, there is *low confidence* in the model's representation of oceanic circulation changes around Antarctica.

In both models (Vizcaíno et al., 2010; Huybrechts et al., 2011), the ice sheets are not equilibrated with the surrounding climate after the integration period under the 1120 ppm CO₂ forcing. Though GHG concentrations were stabilized after 120 years of integration, the Antarctic Ice Sheet continues to contribute to sea level rise at a relatively constant rate for another 480 years in Vizcaíno et al. (2010) and 2880 years in Huybrechts et al. (2011). This is consistent with a positive sea level contribution from Antarctica during past warmer climates (Sections 13.2.1, 13.5.2).

In summary, both coupled ice sheet-climate models consistently show that for high-emission scenarios, the surface melt increases and leads to an ice loss on multi-centennial time scales. The long time period over which the Antarctic Ice Sheet continues to lose mass indicates a potential role of the feedback between climate and ice sheet. Consistent with regional climate models for the 21st and 22nd centuries, both coarse-resolution coupled models show a positive SMB change for most of the first 100 years of climate change. Due to the inertia in the climate system, regional temperatures continue to rise after that. Together with enhanced solid ice discharge, this results in mass loss of AIS. The corresponding decline in surface elevation increases the surface temperature and leads to additional ice loss.

13.4.4.2 Dynamical Change

The Antarctic Ice Sheet represents the largest potential source of future SLR; the West Antarctic Ice Sheet (WAIS) alone has the potential to raise sea level by ~4.3 m (Fretwell et al., 2013). The rate at which this reservoir will be depleted and cause sea level to rise, however, is not easily quantifiable. In this section, we focus on dynamical changes (i.e., those related to the flow of the ice sheet) which affect SLR by altering the flux of ice across the grounding line (or outflow) that separates ice resting on bedrock (some of which does not currently displace ocean water) from floating ice shelves (which already displace ocean water and have only a negligible effect on sea level) (Jenkins and Holland, 2007).

Issues associated with the inability of models to reproduce recently observed changes in the dynamics of the Antarctic Ice Sheet prevented the AR4 from fully quantifying the effect of these changes on future sea level. Since the AR4, progress has been made in understanding the observations (Sections 4.4.3 and 4.4.4), and projections are becoming available. It must be stressed, however, that this field has yet to reach the same level of development that exists for modelling many other components of the Earth system. There is an underlying concern that observations presage the onset of large-scale grounding line retreat in what is termed the Marine Ice Sheet Instability (MISI; Box 13.2), and much of the research assessed here attempts to understand the applicability of this theoretical concept to projected SLR from Antarctica.

There are three distinct processes that could link climate change to dynamical change and potentially trigger increased outflow directly through the increased potential for melt ponds to form on the upper surface of ice shelves, which may destabilize them, or by increases in submarine melt experienced by ice shelves as a consequence of oceanic warming, which leads to their thinning, and indirectly by coupling between SMB and ice flow. Section 4.4.3.2 presents the observational basis on which understanding of these processes is based, while their potential future importance is assessed here. Literature on two mechanisms directly linked to climate change will be assessed first, followed by their relation to outflow change and lastly SMB coupling.

There is strong evidence that regional warming and increased melt water ponding in the Antarctic Peninsula led to the collapse of ice shelves along the length of Antarctic Peninsula (Cook and Vaughan, 2010), most notably the Larsen B ice shelf (MacAyeal et al., 2003). Substantial local warming (~5-7 °C) would, however, be required before the main Antarctic ice shelves (the Ross and Filchner-Ronne ice shelves) would become threatened (Joughin and Alley, 2011). An assessment of the AR4 AOGCM ensemble under scenario A1B yielded an Antarctic continental-average warming rate of $0.034 \pm 0.01^\circ\text{C yr}^{-1}$ (Bracegirdle et al., 2008), suggesting that the required level of warming may not be approached by the end of the century. Using an intermediate complexity model with scenario A2, Fyke et al. (2010) found that melt starts to reach significant levels over these ice shelves around 2100 to 2300. Barrand et al. (2013) made a process-based assessment of the effect of ice-shelf collapse on outflow from the Antarctic Peninsula, which yields a range of SLR at 2100 between 10 and 20 mm, with a bounding maximum of 40 mm.

There is good evidence linking the focus of current Antarctic mass loss in the Amundsen Sea sector of WAIS (containing Pine Island and Thwaites Glaciers) (Shepherd and Wingham, 2007; Rignot et al., 2008; Pritchard et al., 2009) to the presence of relatively warm Circumpolar Deep Water on the continental shelf (Thoma et al., 2008; Jenkins et al., 2010). However, it is not possible to determine whether this upwelling was related directly or indirectly to a rise in global mean temperature. Yin et al. (2011) assessed output from 19 AOGCMs under scenario A1B to determine how subsurface temperatures are projected to evolve around the West and East Antarctic ice sheets. They showed decadal-mean warming of 0.4°C – 0.7°C and 0.4°C –

0.9°C around West and East Antarctica, respectively (25th to 75th percentiles of ensemble) by the end of the 21st century. More detailed regional modelling using scenario A1B illustrates the potential for warm water to invade the ocean cavity underlying the Filchner-Ronne ice shelf in the second half of the 21st century, with an associated 20-fold increase in melt (Hellmer et al., 2012). Based on the limited literature, there is *medium confidence* that oceanic processes may potentially trigger further dynamical change particularly in the latter part of the 21st century, while there is also *medium confidence* that atmospheric change will not affect dynamics outside of the Antarctic Peninsula.

Several process-based projections of the future evolution of Pine Island Glacier have now been made, and some of the issues that this modelling faced (such as the need for sub-kilometre resolution to ensure consistent results; Cornford et al. (2013), Durand et al. (2009)) are being resolved (Pattyn et al., 2013). In experiments using an idealised increase in marine melt, Joughin et al. (2010) demonstrated only limited (~25 km) retreat of the grounding line before a new equilibrium position was established. Gladstone et al. (2012) used a flow-line model forced with ocean-model output (Hellmer et al., 2012) to identify two modes of retreat: one similar to that identified by Joughin et al. (2010), and a second characterized by complete collapse from 2150 onwards. More sophisticated ice-flow modelling (albeit with idealized forcing) suggests grounding line retreat of ~100 km in 50 years (Cornford et al., 2013). These studies support the theoretical finding of Gudmundsson et al. (2012) that grounding line retreat, if triggered, does not inevitably lead to MISI but may halt if local buttressing from ice rises or channel sidewalls is sufficient. Parizek et al. (2013) used a flow-line model to study Thwaites Glacier and found that grounding line retreat is only possible under extreme ocean forcing. It is also thought that considerably less back pressure is exerted by Thwaites' ice shelf in comparison to Pine Island's (Rignot, 2001; 2008), which may make it less sensitive to forcing by submarine melt (Schoof, 2007b; Goldberg et al., 2012). Based on this literature, there is *high confidence* that the retreat of Pine Island Glacier (if it occurs) can be characterised by a SLR measured in centimetres by 2100, although there is *low confidence* in the models' ability to determine the probability or timing of any such retreat. There is also *moderate confidence* (in the light of the very limited literature) that Thwaites Glacier is probably less prone to undergo ocean-driven grounding line retreat than its neighbour in the 21st century. No process-based modelling is available on which to base projections of EAIS glaciers currently losing mass, such as Totten and Cook Glaciers.

Bindschadler et al. (2013) reported a model inter-comparison exercise on the impact of climate change under RCP8.5 on the Antarctic Ice Sheet. The resultant projection includes contributions from increased marine melt in the Amundsen Sea and Amery sectors, and generated a mean SLR at 2100 of ~100 mm over four models (with overall SLR of 81 mm when SMB change was included). There is, however, *low confidence* in the projection because of the unproven ability of many of the contributing models to simulate grounding line motion. Bindschadler et al. (2013) also reported idealized experiments in which ice-shelf melt is increased by 2, 20 and 200 m yr⁻¹. The resulting five-model mean SLR of 69, 693 and 3477 mm by 2100, respectively, can only be considered as a general indication because of the shortcomings of the contributing models (e.g., two do not include ice shelves) which may be offset by the use of a multi-model mean. While grounding line migration in the 20 m yr⁻¹ experiment is extensive in some models and consistent with what might be expected under MISI (Nowicki et al., 2013), the 200 m yr⁻¹ experiment is unrealistic, even if used as a proxy for the improbable atmosphere-driven collapse of the major ice shelves, and is not considered further.

We now assess two alternatives to process-based modelling that exist in the literature: the development of plausible high-end projections based on physical intuition (Pfeffer et al., 2008; Katsman et al., 2011) and the use of a probabilistic framework for extrapolating current observations of the ice sheet's mass budget (Little et al., 2013a; 2013b). Pfeffer et al. (2008) postulated a possible but extreme scenario of 615 mm SLR based on vastly accelerated outflow in the Amundsen Sea sector and East Antarctica, whereas a more plausible scenario involving reduced acceleration in the Amundsen Sea sector yields 136 mm. Katsman et al. (2011) used similar assumptions in a "modest" scenario that generates SLR of 70–150 mm, and a "severe" scenario that attempts to capture the consequences of the collapse of the WAIS through the MISI and has a SLR contribution of 490 mm. The NRC (2012) extrapolated mass-budget observations of the ice sheet to generate a projection of 157–323 mm (including future SMB change), with an additional 77–462 mm accounting for 21st-century increases in outflow (summing as 234 to 785 mm).

Little et al. (2013a) applied a range of linear growth rates to present-day SMB and outflow observations of Antarctic sectors (Rignot et al., 2008; Shuman et al., 2011; Zwally and Giovinetto, 2011), which are then

weighted using a continental-scale observational synthesis (Shepherd et al., 2012) (consistent with the assessment of Chapter 4). In the case of Pine Island Glacier, growth rates are based on the process-based modelling of Joughin et al. (2010). Within this framework, SLR at 2100 has a 5–95% range of –20 to 185 mm for dynamical change only, and –86 to 133 mm when SMB change is included (based on Uotila et al. (2007)). Projections for the Antarctic Peninsula are consistent with the process-based modelling of Barrand et al. (2013). Further, Little et al. (2013a) found that the upper (95%) limit of the projected range can only approach 400 mm under scenarios expected for MISI (such as the immediate collapse of Pine Island and Thwaites Glaciers or all marine-based sectors experiencing the same rates of mass loss as Pine Island Glacier).

Our assessment of the *likely* (17 to 83%) range of SLR by 2100 is based around Little et al. (2013a). Their weighted 5–95% range of –20 to 185 mm is consistent with the lower scenarios of Katsman et al. (2011) (70–150 mm) and Pfeffer et al. (2008) (136 mm), and with the RCP8.5 projection and low-melt experiment of Bindschadler et al. (2013) (~100–69 mm, respectively). The base projection of the NRC (2012) (157–323 mm including future SMB change), however, is less compatible. This moderate level of consistency across a range of techniques suggests *medium confidence* in this assessment. We assess this as the *likely* (as opposed to *very likely*) range because it is based primarily on perturbations of the ice-sheet's present-day state of mass imbalance and does not include the potentially large increases in outflow that may be associated with the MISI discussed below.

The probability of extensive grounding line retreat being both triggered and continuing to the extent that it contributes to significant SLR in the 21st century is very poorly constrained, as the results of a recent expert elicitation indicate (Bamber and Aspinall, 2013). We have *medium confidence*, however, that this probability lies outside of the *likely* range of SLR (i.e., with probability less than 17%). Five arguments support this assessment. First, the partial loss of Pine Island Glacier is included by Little et al. (2013a) in their range and the full loss of the ice stream (if it were to occur) is thought to raise sea level by centimetres only (consistent with the use of the Little et al. (2013a) 9–95% range as the assessed *likely* 17–83% range). Second, the current grounding line position of the neighbouring Thwaites Glacier appears to be more stable than that of Pine Island Glacier (Parizek et al., 2013) so that its potentially large contribution to SLR by 2100 is assessed to have a significantly lower probability. Third, there is a low probability that atmospheric warming in the 21st century will lead to extensive grounding line retreat outside of the Antarctic Peninsula because summer air temperatures will not rise to the level where significant surface melt and ponding occur. Fourth, while this retreat may be triggered by oceanic warming during the 21st century (in particular, under the Filchner-Ronne ice shelf), current literature suggests that this may occur late in the century (Hellmer et al., 2012), reducing the time over which enhanced outflow could affect end-of-century SLR. Finally, there are theoretical grounds to believe that grounding line retreat may stabilise (Gudmundsson et al., 2012) so that MISI (and associated high SLR) is not inevitable.

We next assess the magnitude of potential SLR at 2100 in the event that MISI affects the Antarctic Ice Sheet. Bindschadler et al. (2013), Katsman et al. (2011), the NRC (2012), and Pfeffer et al. (2008) presented contrasting approaches that can be used to make this assessment, which are upper-end estimates of 693, 490, 785 and 615 mm, respectively. Together this literature suggests with *medium confidence* that this contribution would be several tenths of a metre. The literature does not offer a means of assessing the probability of this contribution, however, other than our assessment (above) that it lies above the *likely* range (i.e., less than 17% probability).

Literature investigating the relation between the SLR generated by dynamical change and emission scenario does not currently exist. There is also a lack of literature on the relation between emission scenario and the intrusions of warm water into ice-shelf cavities thought to be important in triggering observed mass loss (Jacobs et al., 2011) and potentially important in the future (Hellmer et al., 2012). It is therefore premature to attach a scenario-dependence to projections of dynamical change, even though such a dependency is expected to exist.

Likely increases in snowfall over the next century (Section 13.4.4.1) will affect the amount of ice lost by outflow across the grounding line because of local changes in ice thickness and stress regime (Huybrechts and De Wolde, 1999). This effect was incorporated in AR4 projections for 2100 as a compensatory mass loss amounting to 0–10% of the SMB mass gain (Gregory and Huybrechts, 2006). Winkelmann et al. (2012) re-

evaluated the effect and reported a range of 15–35% for the next century (30–65% after 500 years). The two studies are difficult to compare because of differences in model physics and experimental design so that the use of their joint range (0–35%) is an appropriate assessment of the *likely* range of this effect. This range is supported by Barrand et al. (2013) who quantified the effect for the Antarctic Peninsula as ~15% of SMB. Moreover, because this contribution relies on similar physics to the grounding line migration discussed above, it is appropriate to assume that their uncertainties are correlated. Winkelmann et al. (2012) showed that the fractional size of this compensatory effect is independent of scenario. Accounting for this effect equates to SLR of 0–32 mm by 2100 based on the SMB range over all emission-scenario projections in Section 13.5.1.1.

Beyond the 21st century, only projections with coarse-resolution ice sheet-climate models are available (Vizcaíno et al., 2010; Huybrechts et al., 2011). *Confidence* in the ability of these two models to capture both change in the oceanic circulation around Antarctica and the response of the ice sheet to these changes, especially a potential grounding line retreat, is *low*. The model applied by Vizcaíno et al. (2010) is lacking a dynamic representation of ice shelves. Since dynamic ice discharge from Antarctica occurs predominately through ice shelves, it is *likely* that the projections using this model considerably underestimate the Antarctic contribution.

In summary, it is *likely* that dynamical change within the Antarctic ice sheet will lead to SLR during the next century with a range of –20 to 185 mm. SLR beyond the *likely* range is poorly constrained and considerably larger increases are possible, which will probably be associated with the MISI (Box 13.2). Although the likelihood of such SLR cannot yet be assessed more precisely than falling above the *likely* range, literature suggests (with *medium confidence*) that its potential magnitude is several tenths of a metre. We are unable to assess SLR as a function of emission scenario, although a dependency of SLR on scenario is expected to exist. In addition, coupling between SMB and dynamical change is *likely* to make a further contribution to SLR of 0–35% of the SMB. All the available literature suggests that this dynamical contribution to sea level rise will continue well beyond 2100.

13.4.4.3 Possible Irreversibility of Ice Loss from West Antarctica

Due to relatively weak snowfall on Antarctica and the slow ice motion in its interior, it can be expected that the West Antarctic Ice Sheet (WAIS) would take at least several thousand years to regrow if it was eliminated by dynamic ice discharge. Consequently any significant ice loss from West Antarctica that occurs within the next century will be irreversible on a multi-centennial to millennial time scale. We discuss here the possibility of abrupt dynamic ice loss from West Antarctica (see Section 12.5.5 for definition of abrupt).

Information on the ice- and bed-topography of WAIS suggest that it has about 3.3 m of equivalent global sea level grounded on areas with downward sloping bedrock (Bamber et al., 2009). As detailed in Box 13.2, large areas of WAIS may therefore be subject to potential ice loss via the marine ice-sheet instability (MISI). As it is the case for other potential instabilities within the climate system (Section 12.5.5), there are four lines of evidence to assess the likelihood of a potential occurrence: theoretical understanding, present-day observations, numerical simulations, and paleo-records.

The MISI is based on a number of studies which indicated the theoretical existence of the instability (Weertman, 1961; Schoof, 2007b) (see also Box 13.2). The most fundamental derivation, i.e. starting from a first-principle ice-equation, states that in one-dimensional ice flow the grounding line between grounded ice sheet and floating ice shelf cannot be stable on a landward sloping bed. The limitation of the one-dimensional case disregards likely stabilizing effects of the ice shelves (Dupont and Alley, 2005). While it is clear that ice shelves that are laterally constrained by embayments inhibit ice flow into the ocean, the effect has not been quantified against the MISI. The same is true for other potentially stabilizing effects such as sedimentation near the grounding line (Alley et al., 2007) or the influence of large-scale bedrock roughness (i.e. topographic pinning points) on ice flow. While these stabilizing effects need to be further investigated and quantified against the destabilizing effect of the MISI, no studies are available that would allow dismissing the MISI on theoretical grounds.

Although direct observations of ice dynamics are available, they are neither detailed enough nor cover a sufficiently long period to allow the monitoring of the temporal evolution of an MISI. Most Antarctic ice

loss that has been detected during the satellite period has come from WAIS (Rignot et al., 2008; Pritchard et al., 2012). Some studies have found an acceleration of ice loss (Rignot et al., 2011) as well as enhanced basal ice-shelf melting (Pritchard et al., 2012), but the short period of observations does not allow one to either dismiss or confirm that these changes are associated with destabilization of WAIS.

Paleo records suggest that WAIS may have deglaciated several times during warm periods of the last 5 million years, but they contain no information on rates (Naish et al., 2009). While coarse-resolution models are in principle capable of modelling the MISI, there is *medium confidence* in their ability to simulate the correct response time to external perturbations on decadal to centennial time scales (Pattyn et al., 2013). One of these models (Pollard and DeConto, 2009) reproduced paleo-records of deglaciation with a forced ice-sheet model at 40 km resolution and parameterized ice flow across the grounding line according to Schoof (2007b). These simulations showed a sea level rise of about 7 m over time spans of 1000–7000 years with approximately equal contributions from West and East Antarctica. However, no available model results or paleo records have indicated the possibility of self-accelerated ice discharge from these regions.

In summary, based on ice-dynamics theory, numerical simulations, and paleo records, it is *likely* that abrupt and irreversible ice loss from WAIS is possible. However, theoretical considerations, current observations, numerical models, and paleo records currently do not allow a quantification of the perturbation that is necessary to destabilize the ice sheet.

Box 13.2: History of the Marine Ice Sheet Instability Hypothesis

Marine ice sheets rest on bedrock that is submerged below sea level (often by 2–3 km). The most well-researched marine ice sheet is the West Antarctic Ice Sheet (WAIS) where approximately 75% of the ice sheet's area currently rests on bedrock below sea level. The East Antarctic Ice Sheet (EAIS), however, also has appreciable areas grounded below sea level (~35%), in particular around the Totten and Cook Glaciers.

These ice sheets are fringed by floating ice shelves, which are fed by flow from grounded ice across a grounding line (GL). The GL is free to migrate both seawards and landwards as a consequence of the local balance between the weight of ice and displaced ocean water. Depending on a number of factors, which include ice-shelf extent and geometry, ice outflow to the ocean generally (but not always) increases with ice thickness at the GL. Accordingly, when the ice sheet rests on a bed that deepens towards the ice-sheet interior (see Box 13.2, Figure 1a), the ice outflow to the ocean will generally increase as the GL retreats. It is this feature that gives rise to the marine ice sheet instability (MISI), which states that a GL cannot remain stable on a landward-deepening slope. Even if snow accumulation and outflow were initially in balance (Box 13.2, Figure 1b), natural fluctuations in climate cause the GL to fluctuate slightly (Box 13.2, Figure 1c). In the case of a retreat, the new GL position is then associated with deeper bedrock and thicker ice, so that outflow increases (Box 13.2, Figure 1d). This increased outflow leads to further, self-sustaining retreat until a region of shallower, seaward-sloping bedrock is reached. Stable configurations can therefore only exist where the GL rests on slopes that deepen towards the ocean. A change in climate can therefore potentially force a large-scale retreat of the GL from one bedrock ridge to another further inland.

The MISI has a long history based on theoretical discussions that were started by Weertman (1974) and Mercer (1978), and has seen many refinements over the subsequent years. The advent of satellite-based observations has given fresh impetus to this debate, in particular work on the GL retreat and associated thinning of Pine Island (PIG), Thwaites (TG) and Smith Glaciers (all part of WAIS), which are collectively responsible for most of Antarctica's present mass loss (Rignot et al., 2008). These observations highlighted the need to develop a better understanding of the MISI to make more accurate projections of the ice sheet's future contribution to sea level rise.

Early studies of the MISI were not based on a formal derivation from the basic laws of mechanics thought to control ice-sheet flow and the robustness of their results was therefore difficult to assess. An open question was the expected impact of changes at the GL on the ice-sheet flow (Hindmarsh, 1993). Recently, however, a more complete analysis from first principles has been developed that suggests that the fundamental relation between thickness and flux at the GL exists and has a power ~ 5 (i.e., that a 10% increase in thickness leads

to a 60% increase in flux) (Schoof, 2007a, 2011). This analysis, however, does not include ice shelves that occupy laterally constrained embayments, which is often the case (for instance at PIG). In such situations, drag from ice-shelf sidewalls may suppress the positive feedback between increasing ice thickness and ice flux at the GL (Dupont and Alley, 2005; Goldberg et al., 2009; Gudmundsson et al., 2012). Other factors that could suppress the instability include a sea level fall adjacent to the GL resulting from the isostatic and gravitational effects of ice loss (Gomez et al., 2010a).

Two processes that could trigger GL retreat are particularly relevant to contemporary polar climate change. The first is the presence of warmer ocean water under ice shelves, which leads to enhanced submarine ice-shelf melt (Jacobs et al., 2011). The second is the presence of melt water ponds on the surface of the ice shelf, which can cause stress concentrations allowing fractures to penetrate the full ice-shelf thickness. This process appears to have been a primary factor in the collapse of the Larsen B Ice Shelf (LBIS) over the course of two months in 2002 (MacAyeal et al., 2003). The collapse of the LBIS provided a natural demonstration of the linkage between the structural integrity of an ice shelf and the flow of grounded ice draining into it. Following the breakup of LBIS, the speeds of the glaciers feeding the collapsed portion of the shelf increased two-to-eightfold, while the flow of glaciers draining into a surviving sector was unaltered (Rignot et al., 2004; Scambos et al., 2004; Rott et al., 2011). This indicates that a mechanical link does indeed exist between shelf and sheet, and has important implications for the future evolution of the far more significant PIG and TG systems of the WAIS.

The recent strides made in placing MISI on a sound analytical footing are, however, limited to the analysis of steady states. Numerical modelling is needed to simulate the GL retreat rates that are required to make accurate SLR projections. There are major challenges in designing models whose results are not controlled by the details of their numerical design. Problems arise at the GL because, in addition to flotation, basal traction is dramatically reduced as the ice loses contact with the underlying bedrock (Pattyn et al., 2006). This is a topic of active research, and a combination of more complete modelling of the GL stress regime (Favier et al., 2012) and the use of high-resolution (sub kilometre) models (Durand et al., 2009; Cornford et al., 2013) shows promise towards resolving these problems. Much progress has also been made by using model inter-comparison as a means of understanding these effects (Pattyn et al., 2013).

[START FAQ 13.2 HERE]

FAQ 13.2: Will the Greenland and Antarctic Ice Sheets Contribute to Sea Level Change Over the Rest of the Century?

The Greenland, West and East Antarctic ice sheets are the largest reservoirs of freshwater on the planet. As such, they have contributed to sea level change over geological and recent times. They gain mass through accumulation (snowfall) and lose it by surface ablation (mostly ice melt) and outflow at their marine boundaries, either to a floating ice shelf, or directly to the ocean through iceberg calving. Increases in accumulation cause global mean sea level to fall, while increases in surface ablation and outflow cause it to rise. Fluctuations in these mass fluxes depend on a range of processes, both within the ice sheet and without, in the atmosphere and oceans. Over the course of this century, however, sources of mass loss appear set to exceed sources of mass gain, so that a continuing positive contribution to global sea level can be expected. This FAQ summarises current research on the topic and provides indicative magnitudes for the various end-of-century sea level contributions from the full assessment, which are reported as the 17 to 83% probability range across all emission scenarios.

Over millennia, the slow horizontal flow of an ice sheet carries mass from areas of net accumulation (generally, in the high-elevation interior) to areas of net loss (generally, the low-elevation periphery and the

coastal perimeter). At present, Greenland loses roughly half of its accumulated ice by surface ablation, and half by calving. Antarctica, on the other hand, loses virtually all its accumulation by calving and submarine melt from its fringing ice shelves. Ice shelves are floating, so their loss has only a negligible direct effect on sea level, although they can affect sea level indirectly by altering the mass budget of their parent ice sheet (see below).

In East Antarctica, some studies using satellite radar altimetry suggest that snowfall has increased, but recent atmospheric modelling and satellite measurements of changes in gravity find no significant increase. This apparent disagreement may be because relatively small long-term trends are masked by the strong inter-annual variability of snowfall. Projections suggest a substantial increase in 21st century Antarctic snowfall, mainly because a warmer atmosphere would be able to carry more moisture into polar regions. Regional changes in atmospheric circulation probably play a secondary role. For the whole of the Antarctic Ice Sheet, this process is projected to contribute between 0 and 70 mm to sea level fall.

Currently, air temperatures around Antarctica are too cold for substantial surface ablation. Field and satellite-based observations, however, indicate enhanced outflow—manifested as ice surface lowering—in a few localised coastal regions. These areas (Pine Island and Thwaites Glaciers in West Antarctica, and Totten and Cook Glaciers in East Antarctica) all lie within kilometre-deep bedrock troughs towards the edge of Antarctica's continental shelf. The increase in outflow is thought to have been triggered by regional changes in ocean circulation, bringing warmer water in contact with floating ice shelves.

On the more northerly Antarctic Peninsula, there is a well-documented record of ice-shelf collapse, which appears to be related to the increased surface melting caused by atmospheric warming over recent decades. The subsequent thinning of glaciers draining into these ice shelves has had a positive—but minor—effect on sea level, as will any further such events on the Peninsula. Regional projections of 21st century atmospheric temperature change suggest that this process will probably not affect the stability of the large ice shelves of both the West and East Antarctica, although these ice shelves may be threatened by future oceanic change (see below).

Estimates of the contribution of the Antarctic ice sheets to sea level over the last few decades vary widely, but great strides have recently been made in reconciling the observations. There are strong indications that enhanced outflow (primarily in West Antarctica) currently outweighs any increase in snow accumulation (mainly in East Antarctica), implying a tendency towards sea level rise. Before reliable projections of outflow over the 21st century can be made with greater confidence, models that simulate ice flow need to be improved; especially of any changes in the grounding line that separates floating ice from that resting on bedrock and of interactions between ice shelves and the ocean. The concept of “marine ice-sheet instability” is based on the idea that the outflow from an ice sheet resting on bedrock below sea level increases if ice at the grounding line is thicker and, therefore, faster flowing. On bedrock that slopes downward towards the ice-sheet interior, this creates a vicious cycle of increased outflow, causing ice at the grounding line to thin and go afloat. The grounding line then retreats down slope into thicker ice that, in turn, drives further increases in outflow. This feedback could potentially result in the rapid loss of parts of the ice sheet, as grounding lines retreat along troughs and basins that deepen towards the ice sheet's interior. Future climate forcing could trigger such an unstable collapse, which may then continue independently of climate. This potential collapse might unfold over centuries for individual bedrock troughs in West Antarctica and sectors of East Antarctica. Much research is focused on understanding how important this theoretical concept is for those ice sheets. Sea level could rise if the effects of marine instability become important, but there is not enough evidence at present to unambiguously identify the precursor of such an unstable retreat. Change in outflow is projected to contribute between –20 (i.e., fall) and 140 mm to sea level rise, although the uncertain impact of marine ice-sheet instability could increase this figure by several tenths of a metre. Overall, increased snowfall seems set to only partially offset sea level rise caused by increased outflow. In Greenland, mass loss through more surface ablation and outflow dominates a possible recent trend towards increased accumulation in the interior. Estimated mass loss due to surface ablation has doubled since the early 1990s. This trend is expected to continue over the next century as more of the ice sheet experiences surface ablation for longer periods. Indeed, projections for the 21st century suggest that increasing mass loss will dominate over weakly increasing accumulation. The refreezing of melt water within the snow pack high up on the ice sheet offers an important (though perhaps temporary) dampening effect on the relation between atmospheric warming and mass loss.

While the observed response of outlet glaciers is both complex and highly variable, iceberg calving from many of Greenland's major outlet glaciers has increased substantially over the last decade, and constitutes an appreciable additional mass loss. This seems to be related to the intrusion of warm water into the coastal seas around Greenland, but it is not clear whether this phenomenon is related to inter-decadal variability, such as the North Atlantic Oscillation, or a longer term trend associated with greenhouse-gas induced warming. Projecting its effect on 21st century outflow is therefore difficult, but it does highlight the apparent sensitivity of outflow to ocean warming. The effects of more surface melt water on the lubrication of the ice sheet's bed, and the ability of warmer ice to deform more easily, may lead to greater rates of flow, but the link to recent increases in outflow is unclear. Change in the net difference between surface ablation and accumulation is projected to contribute between 10 and 160 mm to sea level rise, while increased outflow is projected to contribute a further 10 to 70 mm.

The Greenland Ice Sheet has contributed to a rise in global mean sea level over the last few decades, and this trend is expected to increase during this century. Unlike Antarctica, Greenland has no known large-scale instabilities that might generate an abrupt increase in sea level rise over the 21st century. A threshold may exist, however, so that continued shrinkage might become irreversible over multi-centennial timescales, even if the climate were to return to a pre-industrial state over centennial time scales. While mass loss through the calving of icebergs may increase in future decades, this process will eventually end when the ice margin retreats onto bedrock above sea level where the bulk of the ice sheet resides.

FAQ 13.2, Figure 1: Illustrative synthesis of projected changes in SMB and outflow by 2100 for (a) Greenland and (b) Antarctic ice sheets. Colours shown on the maps refer to projected SMB change between 1990–2009 and 2079–2098 using the RACMO2 regional climate model under scenarios A1B (Antarctic) and RCP4.5 (Greenland) AOGCMs. For Greenland, average equilibrium line altitudes during both these time periods are shown in purple and green, respectively. Ice perimeter and grounding lines are shown as black lines, as are ice sheet sectors. For Greenland, results of flow-line modelling for four major outlet glaciers are shown as inserts, while for Antarctica the coloured rings reflect projected change in outflow on the basis of a statistical extrapolation of observed trends. The outer and inner radius of each ring indicate the 17th and 83rd percentiles, respectively (scale in upper right); red refers to mass loss (sea level rise) while blue refers to mass gain (sea level fall). Finally, total sea level contribution is shown for each ice sheet (insert located above maps) with light grey referring to SMB (model experiment used to generate the SMB map is shown as a dashed line) and dark grey to outflow. All projections refer to the 17–83% probability range across all scenarios. Data provided by F. M. Nick, C. M. Little, J. H. van Angelen, S. R. M. Ligtenberg, J. T. M. Lenaerts and M. R. van den Broeke.

13.4.5 Anthropogenic Intervention in Water Storage on Land

The potential future effects that human activities have on changing water storage on land, thus affecting sea level, have been little studied in the published peer-reviewed scientific literature. For depletion of groundwater arising from extraction (for agriculture and other uses), we consider two possibilities. The first assumes that this contribution to GMSL rise continues throughout the 21st century at the rate of 0.40 ± 0.11 mm yr⁻¹ (mean \pm SD) assessed for 2001–2008 by Konikow (2011), amounting to 38 [21–55, 90% confidence] mm by 2081–2100 relative to 1986–2005. The second uses results from land-surface hydrology models (Wada et al., 2012) with input from climate and socioeconomic projections for SRES scenarios, yielding 70 [51–90] mm for the same time interval. Because of the improved treatment of groundwater recharge by Wada et al. (2012), this is less than Rahmstorf et al. (2012a) obtained by assuming that the groundwater extraction estimates of Wada et al. (2010) can be scaled up in the future with global population. These two possibilities indicate a range of about 20–90 mm for the contribution of groundwater depletion to GMSL rise.

For the rate of impoundment of water in reservoirs, we evaluate two possibilities. The first assumes it will continue throughout the 21st century (e.g., (Lempérière, 2006) at the average rate of -0.2 ± 0.05 mm yr⁻¹ SLE (mean \pm SD) estimated for 1971–2010 using data updated from Chao et al. (2008), giving a negative contribution to GMSL rise of -19 [-11 to -27 , 90% confidence] mm by 2081–2100 relative to 1986–2005. The second assumes it will be zero after 2010 (i.e., no further net impoundment), as shown for the 1990s and

2000s by Lettenmaier and Milly (2009) (see Section 13.3.4 for discussion). A zero contribution implies a balance between further construction of reservoir capacity and reduction of storage volume by sedimentation, each of which could plausibly have a rate of about $1\% \text{ yr}^{-1}$ of existing capacity (Lempérière, 2006; Lettenmaier and Milly, 2009). These two possibilities together indicate a range of about 0–30 mm of GMSL fall for the contribution of reservoir impoundment.

Our assessment thus leads to a range of –10 to +90 mm for the net contribution to GMSL rise from anthropogenic intervention in land water storage by 2081–2100 relative to 1986–2005. This range includes the range of 0–40 mm assumed by Katsman et al. (2008). Because of the limited information available, we do not have sufficient confidence to give ranges for individual RCP scenarios.

13.5 Projections of Global Mean Sea Level Rise

Process-based projections for GMSL rise during the 21st century, given in Section 13.5.1, are the sum of contributions derived from models that were evaluated by comparison with observations in Section 13.3 and used to project the contributions in Section 13.4. Projections of GMSL rise by semi-empirical models (SEMs) are given in Section 13.5.2. We compare these two and other approaches in Section 13.5.3 and assess the level of confidence that we can place in each approach. Longer term projections are discussed in 13.5.4.

13.5.1 Process-Based Projections for the 21st Century

The process-based projections of GMSL rise for each RCP scenario are based on results from 21 CMIP5 AOGCMs from which projections of surface air temperature (SAT) change and thermal expansion are available (see Section 13.4.1). Where CMIP5 results were not available for a particular AOGCM and scenario, they were estimated (Good et al., 2011; 2013) (Section 12.4.1.2; Supplementary Material). The projections of thermal expansion do not include an adjustment for the omission of volcanic forcing in AOGCM spin-up (Section 13.3.4.2), since this is uncertain and relatively small (about 10 mm during the 21st century). Changes in glacier and ice-sheet SMB are calculated from the global mean SAT projections using parameterisations derived from the results of process-based models of these components (Sections 13.4.2, 13.4.3.1, 13.4.4.1 and Supplementary Material). According to the assessment in Section 12.4.1.2, global mean SAT change is *likely* to lie within the 5–95% range of the projections of CMIP5 models. Following this assessment, the 5–95% range of model results for each of the GMSL rise contributions that is projected on the basis of CMIP5 results is interpreted as the *likely* range.

Possible ice-sheet dynamical changes by 2100 are assessed from the published literature (Sections 13.4.3.2 and 13.4.4.2), which as yet provides only a partial basis for making projections related to particular scenarios; therefore they are treated as independent of scenario, except that a higher rate of change is used for Greenland ice-sheet outflow under RCP8.5. Projections of changes in land-water storage due to human intervention are also treated as independent of emissions scenario, because we do not have sufficient information to give ranges for individual scenarios. The scenario-independent treatment does not imply that the contributions concerned will not depend on the scenario followed, only that the current state of knowledge does not permit a quantitative assessment of the dependence. For each of these contributions (Greenland and Antarctic ice-sheet dynamics, land water storage), our assessment of the literature provides a 5–95% range by 2100. For consistency with the treatment of the CMIP5-derived results, we interpret this range as the *likely* range. We assume that each of these contributions begins from its present-day rate and that the rate increases linearly in time, in order to interpolate from the present day to 2100 (see Supplementary Material for details).

The *likely* range of GMSL rise given for each RCP combines the uncertainty in global climate change, represented by the CMIP5 ensemble (Section 12.4.1.2), with the uncertainties in modelling the contributions to GMSL. The part of the uncertainty related to the magnitude of global climate change is correlated among all the scenario-dependent contributions, while the methodological uncertainties are treated as independent (see also Supplementary Material).

The sum of the projected contributions gives the *likely* range for future GMSL rise. The median projections for GMSL in all scenarios lie within a range of 0.05 m until the middle of the century (Figure 13.11),

because the divergence of the climate projections has a delayed effect owing to the time-integrating characteristic of sea level. By the late 21st century (over an interval of 95 years, between the 20-year mean of 2081–2100 and the 20-year mean of 1986–2005), they have a spread of about 0.2 m, with RCP2.6 giving the least amount of rise (0.40 [0.26–0.54] m) (*likely* range) and RCP8.5 giving the most (0.62 [0.45–0.81] m). RCP4.5 and RCP6.0 are very similar at the end of the century (0.47 [0.32–0.62] m and 0.47 [0.33–0.62] m respectively), but RCP4.5 has a greater rate of rise earlier in the century than RCP6.0 (Figure 13.10 and Table 13.5). At 2100, the *likely* ranges are 0.43 [0.28–0.60] m (RCP2.6), 0.52 [0.35–0.70] m (RCP4.5), 0.54 [0.37–0.72] m (RCP6.0), and 0.73 [0.53–0.97] m (RCP8.5).

In all scenarios, the rate of rise at the start of the RCP projections (2007–2013) is about 3.7 mm yr⁻¹, slightly above the observational range of 3.2 [2.8–3.6] mm yr⁻¹ for 1993–2010, because the modelled contributions for recent years, although consistent with observations for 1993–2010 (Section 13.3), are all in the upper part of the observational ranges, perhaps related to the simulated rate of climatic warming being greater than has been observed (Box 9.2). In the projections, the rate of rise initially increases. In RCP2.6 it becomes roughly constant (central projection 4.5 mm yr⁻¹) before the middle of the century, and subsequently declines slightly. The rate of rise becomes roughly constant in RCP4.5 and RCP6.0 by the end of the century, whereas acceleration continues throughout the century in RCP8.5, reaching 11 [7–15] mm yr⁻¹ in 2081–2100.

In all scenarios, thermal expansion is the largest contribution, accounting for about 30–55% of the projections. Glaciers are the next largest. By 2100, 15–55% of the present glacier volume is projected to be eliminated under RCP2.6, and 35–85% under RCP8.5. SMB change on the Greenland ice sheet makes a positive contribution, whereas SMB change in Antarctica gives a negative contribution (Sections 13.3.3.2 and 13.4.4.1). The positive contribution due to rapid dynamical changes that result in increased ice outflow from both ice sheets together has a *likely* range of 0.03–0.20 m in RCP8.5 and 0.03–0.19 m in the other RCPs. There is a relatively small positive contribution from human intervention in land-water storage, predominantly due to increasing extraction of groundwater.

[INSERT FIGURE 13.10 HERE]

Figure 13.10: Projections from process-based models with likely ranges and median values for global-mean sea level rise and its contributions in 2081–2100 relative to 1986–2005 for the four RCP scenarios and scenario SRES A1B used in the AR4. The contributions from ice sheets include the contributions from ice-sheet rapid dynamical change, which are also shown separately. The contributions from ice-sheet rapid dynamics and anthropogenic land water storage are treated as having uniform probability distributions, and as independent of scenario (except that a higher rate of change is used for Greenland ice-sheet outflow under RCP8.5). This treatment does not imply that the contributions concerned will not depend on the scenario followed, only that the current state of knowledge does not permit a quantitative assessment of the dependence. See discussion in Sections 13.5.1 and 13.5.3 and Supplementary Material for methods. Only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause GMSL to rise substantially above the likely range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise.

[INSERT FIGURE 13.11 HERE]

Figure 13.11: Projections from process-based models of (a) GMSL rise relative to 1986–2005 and (b) the rate of GMSL rise and its contributions as a function of time for the four RCP scenarios and scenario SRES A1B. The lines show the median projections. For GMSL rise and the thermal expansion contribution, the likely range is shown as a shaded band. The contributions from ice sheets include the contributions from ice-sheet rapid dynamical change, which are also shown separately. The time series for GMSL rise plotted in (a) are tabulated in Annex II (Table AII.7.7), and the time series of GMSL rise and all its contributions are available in the Supplementary Material. The rates in (b) are calculated as linear trends in overlapping 5-year periods. Only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause GMSL to rise substantially above the likely range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise.

Table 13.5: Median values and likely ranges for projections of global-mean sea level rise and its contributions in metres in 2081–2100 relative to 1986–2005 for the four RCP scenarios and SRES A1B, GMSL rise in 2046–2065 and 2100, and rates of GMSL rise in mm yr⁻¹ in 2081–2100. See Section 13.5.1 concerning how the likely range is defined. Because some of the uncertainties in modelling the contributions are treated as uncorrelated, the sum of the lower bound of contributions does not equal the lower bound of the sum, and similarly for the upper bound (see Supplementary Material). Because of imprecision from rounding, the sum of the medians of contributions may not

exactly equal the median of the sum. The net contribution (SMB + dynamics) for each ice sheet, and the contribution from rapid dynamical change in both ice sheets together, are shown as additional lines below the sum; they are not contributions in addition to those given above the sum. The contributions from ice-sheet rapid dynamical change and anthropogenic land water storage are treated as having uniform probability distributions, uncorrelated with the magnitude of global climate change (except for the interaction between Antarctic ice-sheet SMB and outflow), and as independent of scenario (except that a higher rate of change is used for Greenland ice-sheet outflow under RCP8.5). This treatment does not imply that the contributions concerned will not depend on the scenario followed, only that the current state of knowledge does not permit a quantitative assessment of the dependence. Regional sea level change is expected in general to differ from the global mean (see Section 13.6).

	SRES A1B	RCP2.6	RCP4.5	RCP6.0	RCP8.5
Thermal Expansion	0.21 [0.16 to 0.26]	0.14 [0.10 to 0.18]	0.19 [0.14 to 0.23]	0.19 [0.15 to 0.24]	0.27 [0.21 to 0.33]

Land Water Storage	0.04 [-0.01 to 0.08]	0.04 [-0.01 to 0.08]	0.04 [-0.01 to 0.08]	0.04 [-0.01 to 0.08]	0.04 [-0.01 to 0.08]
Sea Level Rise in 2081–2100	0.52 [0.36 to 0.69]	0.40 [0.26 to 0.54]	0.47 [0.32 to 0.62]	0.47 [0.33 to 0.62]	0.62 [0.45 to 0.81]
Greenland Ice Sheet	0.09 [0.05 to 0.15]	0.06 [0.04 to 0.10]	0.08 [0.04 to 0.13]	0.08 [0.04 to 0.13]	0.12 [0.07 to 0.21]
Antarctic Ice Sheet	0.04 [-0.05 to 0.13]	0.05 [-0.03 to 0.14]	0.05 [-0.04 to 0.13]	0.05 [-0.04 to 0.13]	0.04 [-0.06 to 0.12]
Ice-Sheet Rapid Dynamics	0.10 [0.03 to 0.19]	0.10 [0.03 to 0.19]	0.10 [0.03 to 0.19]	0.10 [0.03 to 0.19]	0.12 [0.03 to 0.20]
Rate of Sea Level Rise	8.0 [5.0 to 11.1]	4.3 [2.0 to 6.6]	6.0 [3.5 to 8.5]	7.3 [4.6 to 10.0]	11.1 [7.4 to 15.5]
Sea Level Rise in 2046–2065	0.26 [0.19 to 0.34]	0.24 [0.17 to 0.31]	0.26 [0.19 to 0.33]	0.25 [0.18 to 0.32]	0.29 [0.22 to 0.37]
Sea Level Rise in 2100	0.60 [0.41 to 0.79]	0.43 [0.28 to 0.60]	0.52 [0.35 to 0.70]	0.54 [0.37 to 0.72]	0.73 [0.53 to 0.97]

Only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause GMSL to rise substantially above the *likely* range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise.

Notes:

- (a) Excluding glaciers on Antarctica but including glaciers peripheral to the Greenland ice sheet.
- (b) Including the height-SMB feedback.
- (c) Including the interaction between SMB change and outflow.

13.5.2 Semi-Empirical Projections for the 21st Century

The development of semi-empirical models (SEMs) was motivated by two problems. First, process-based modelling was incomplete in the AR4 because of the unavailability of ice-sheet dynamical models which could be used to simulate the observed recent accelerations in ice flow and make projections with confidence (Meehl et al., 2007) (Sections 13.1.5.1, 13.3.3.2, 13.4.3.2, 13.4.4.2). Second, in all previous IPCC assessments, observed GMSL rise during the 20th century could not be completely accounted for by the contributions to GMSL from thermal expansion, glaciers and ice sheets. For example, the AR4 assessed the mean observational rate for 1961–2003 as $1.8 \pm 0.5 \text{ mm yr}^{-1}$, and the sum of contributions as $1.1 \pm 0.5 \text{ mm yr}^{-1}$ (Bindoff et al., 2007; Hegerl et al., 2007). With the central estimates, only about 60% of observed sea level rise was thus explained, and the potential implication was that projections using process-based models which reproduce only those known contributions would underestimate future sea level rise (Rahmstorf,

2007a; Jevrejeva et al., 2009; Grinsted et al., 2010). SEMs do not aim to solve the two problems that motivated their development, but instead provide an alternative approach for projecting GMSL.

The semi-empirical approach regards a change in sea level as an integrated response of the entire climate system, reflecting changes in the dynamics and thermodynamics of the atmosphere, ocean and cryosphere; it does not explicitly attribute sea level rise to its individual physical components. SEMs use simple physically motivated relationships, with various analytical formulations and parameters determined from observational time series, to predict GMSL for the 21st century (Figure 13.12 and Table 13.6) and beyond, from either global mean surface air temperature (SAT) (Rahmstorf, 2007a; Horton et al., 2008; Vermeer and Rahmstorf, 2009; Grinsted et al., 2010; Rahmstorf et al., 2012a) or radiative forcing (Jevrejeva et al., 2009; 2010, 2012a).

[INSERT FIGURE 13.12 HERE]

Figure 13.12: Range (5–95%) for projections of global-mean sea level rise (m) in 2081–2100 relative to 1986–2005 by semi-empirical models for (a) RCP2.6, (b) RCP4.5, (c) RCP6.0, and (d) RCP8.5. Blue bars are results from the models using RCP temperature projections, red bars are using RCP radiative forcing. The numbers on the horizontal axis refer to the literature source of the projection and the sea level reconstruction used for calibration (for studies using RCP temperature projections) or reconstruction of radiative forcing (for studies using RCP radiative forcing). (1) Rahmstorf et al. (2012a), with Kemp et al. (2011); (2) Schaeffer et al. (2012); (3) Rahmstorf et al. (2012a), with Church and White (2006); (4) Rahmstorf et al. (2012a), with Church and White (2011); (5) Rahmstorf et al. (2012a), with Jevrejeva et al. (2008); (6) Grinsted et al. (2010), with Moberg et al. (2005); (7) Jevrejeva et al. (2012a), with Goosse et al. (2005); (8) Jevrejeva et al. (2012a), with Crowley et al. (2003); (9) Jevrejeva et al. (2012a) with Tett et al. (2007). Also shown for comparison is the median (thick black line) and *likely* range (horizontal gray bar) (as defined in Section 13.5.1) from the process-based projections (Table 13.5), which are assessed as having *medium confidence*, in contrast to SEMs, which are assessed as having *low confidence* (Section 13.5.3).

SEMs are designed to reproduce the observed sea level record over their period of calibration, as this provides them with model parameters needed to make projections (Rahmstorf, 2007a; Jevrejeva et al., 2009; Vermeer and Rahmstorf, 2009; Grinsted et al., 2010). A test of the predictive skill of the models requires simulating a part of the observed record that has not been used for calibration. For instance, Rahmstorf (2007b) calibrated for 1880–1940 and predicted 1940–2000, obtaining results within 0.02 m of observed. Jevrejeva et al. (2012b) calibrated up to 1950 and predicted 0.03 m (about 25%) less than observed for 1950–2009, and 3.8 mm yr⁻¹ for 1993–2010, which is about 20% more than observed.

The GMSL estimates used for calibrating the SEMs are based on the existing sparse network of long tide-gauge records, and are thus uncertain, especially before the late 19th century; these uncertainties are reflected in the observational estimates of the rate of GMSL rise (Sections 3.7 and 13.2.2). Consequently, the projections may be sensitive to the statistical treatment of the temporal variability in the instrumental record of sea level change (Holgate et al., 2007; Rahmstorf, 2007b; Schmith et al., 2007). Rahmstorf et al. (2012a) reported that GMSL projections for the RCP4.5 scenario for 2100 (Table 13.6) varied by ±0.04 m when the embedding dimension used for temporal smoothing during the calibration was varied within a range of 0–25 years.

Furthermore, there is some sensitivity to the choice of datasets used for calibration. For instance, when calibrated up to 1960 and used to predict 1961–2003, the model of Bittermann et al. (2013) overestimates the GMSL dataset of Jevrejeva et al. (2008) by 75%, but makes an accurate estimate for the Church and White (2011) dataset, although these two datasets have similar rates of sea level rise in the predicted period. The central projections of Rahmstorf et al. (2012a) for 2100 under RCP4.5 (Table 13.6) for calibration with the GMSL dataset of Church and White (2006) are about 0.2 m more than for calibration with the Church and White (2011) dataset, although the two Church and White (2006, 2011) datasets differ at all times by less than one standard deviation. The ranges of the projections by Grinsted et al. (2010) and Jevrejeva et al. (2010, 2012a, 2012b) allow for the uncertainty in the GMSL reconstructions through the use of an uncertainty covariance matrix in determining the model parameters. Grinsted et al. (2010) also investigated the sensitivity to the temperature dataset used as predictor, and Jevrejeva et al. (2010) investigated the sensitivity to radiative forcing as predictor (Table 13.6). In the latter case, three datasets gave median projections under RCP4.5 for 2100 within a range of about ±0.20 m.

SEM projections will be biased unless contributions to past GMSL rise which are correlated with but not physically related to contemporary changes in the predictor variable (either global mean SAT change or radiative forcing) are subtracted from the observational sea level record before the calibration (Vermeer and Rahmstorf, 2009; Jevrejeva et al., 2012b; Rahmstorf et al., 2012a; Orlić and Pasarić, 2013). These include groundwater depletion due to anthropogenic intervention and storage of water by dams (Section 13.3.4), ongoing adjustment of the Greenland and Antarctic ice sheets to climate change in previous centuries and millennia (Section 13.3.6), and the effects of internally generated regional climate variability on glaciers (Marzeion et al., 2012a; Church et al., 2013) (Sections 13.3.2.2 and 13.3.6) and ice sheets (Section 13.3.3.2). For instance, Jevrejeva et al. (2012b) found that their median projections for 2100 were reduced by 0.02–0.10 m by excluding some such contributions.

Making projections with a SEM assumes that sea level change in the future will have the same relationship as it has had in the past to radiative forcing or global mean temperature change. The appropriate choice for the formulation of the SEM may depend on the nature of the climate forcing and the timescale, and potentially non-linear physical processes may not scale in the future in ways which can be calibrated from the past (von Storch et al., 2008; Vermeer and Rahmstorf, 2009; Rahmstorf et al., 2012a; Orlić and Pasarić, 2013). Two such effects that could lead to overestimated or underestimated projections by SEMs have been discussed in the literature.

First, AOGCMs indicate that the ocean heat uptake efficiency tends to decline as warming continues and heat penetrates more deeply (Gregory and Forster, 2008). A linear scaling of the rate of global ocean heat uptake with global SAT determined from the past, as proposed by Rahmstorf (2007a), will thus overestimate future time-integrated heat content change and the consequent global ocean thermal expansion on a century timescale (Orlić and Pasarić, 2013). Rahmstorf (2007a) found that the linear scaling overestimated by 0.12 m (about 30%) the thermal expansion simulated by a climate model with a 3D ocean from 1990 to 2100 under scenario SRES A1FI. Furthermore, the Rahmstorf (2007a) model is inadequate for simulating sea level variations of the last millennium (von Storch et al., 2008), which arise predominantly from episodic volcanic forcing, rather than the sustained forcing on multidecadal timescales for which it was intended. In both applications, the AOGCM behaviour is more accurately reproduced by taking into account the vertical profile of warming, at least by distinguishing the upper (mixed layer) and lower (thermocline) layers (Vermeer and Rahmstorf, 2009; Held et al., 2010) (Section 13.4.1), or by introducing a relaxation timescale for sea level rise (Jevrejeva et al., 2012b).

Second, the sensitivity of glaciers to warming will tend to decrease as the area most prone to ablation and the remaining volume decrease, partly counteracted by lowering of the surface due to thinning (Huss et al., 2012) (Section 13.4.2). On the other hand, glaciers at high latitudes which currently have negligible surface melting will begin to ablate as the climate becomes warmer, tending to give an increase in sensitivity (Rahmstorf et al., 2012a) (Section 13.4.2). Estimating the balance of these two effects will require detailed modelling of glacier SMB. The absence of a multidecadal acceleration in the rate of glacier mass loss in observations of the 20th and simulations of the 21st centuries (Section 4.3.3) (Radic and Hock, 2010; Marzeion et al., 2012a), despite rising global temperatures, suggests that the reduction in sensitivity may dominate (Gregory et al., 2013b).

Table 13.6: Global-mean sea level rise (m) projected by semi-empirical models and compared with the IPCC AR4 and AR5 projections. In each case the results have a probability distribution, whose 5-, 50- and 95-percentiles are shown in the columns as indicated. The AR5 5–95% process-based model range is interpreted as a likely range (medium confidence) (Section 13.5.1).

Notes:

- (a) Extrapolated to 2100 using the projected rates of sea level rise for 2090–2099 in Table 10.7 of Meehl et al. (2007).
- (b) Including scaled-up ice-sheet discharge given in Table 10.7 of Meehl et al. (2007) and extrapolated to 2100 as an illustration of the possible magnitude of this effect.
- (c) Uncertainty range not given.
- (d) The mean value and the range are shown for semi-empirical model projections based on results from 11 GCMs.

13.5.3 Confidence in Likely Ranges and Bounds

The AR4 (Meehl et al., 2007) presented process-model-based projections of GMSL rise for the end of the 21st century, but did not provide a best estimate or *likely* range principally because scientific understanding at the time was not sufficient to allow an assessment of the possibility of future rapid changes in ice-sheet dynamics (on timescales of a few decades, Section 4.4.5). Future rapid changes in ice-sheet outflow were consequently not included in the ranges given by the AR4. For the SRES A1B scenario, the AR4 range was 0.21–0.48 m, and for the highest emissions scenario, A1FI, it was 0.26–0.59 m. The AR4 also noted that if ice-sheet outflow increased linearly with global mean surface air temperature, the AR4 maximum projections would be raised by 0.1–0.2 m. The AR4 was unable to exclude larger values or to assess their likelihood.

Since the publication of the AR4, upper bounds of up to 2.4 m for GMSL rise by 2100 have been estimated by other approaches, namely semi-empirical models (SEMs, Section 13.5.2), evidence from past climates (Section 13.2.1), and physical constraints on ice-sheet dynamics (Sections 13.4.3.2 and 13.4.4.2). The broad range of values reflects the different methodologies for obtaining the upper bound, involving different constraining factors and sources of evidence. In particular, the upper bound is strongly affected by the choice of probability level, which in some approaches is unknown because the probability of the underlying assumptions is not quantified (Little et al., 2013b).

The confidence that can be placed in projections of GMSL rise and its upper bound by the various approaches must be considered. Confidence arises from the nature, quantity, quality and consistency of the evidence.

The first approach is based on process-based projections, which use the results from several models for each contribution (Sections 13.4 and 13.5.1, Table 13.5). There is medium evidence in support of this approach, arising from our understanding of the modelled physical processes, the consistency of the models with wider physical understanding of those processes as elements of the climate system (e.g., Box 13.1), the consistency of modelled and observed contributions (Sections 13.3.1–13.3.5), the consistency of observed and modelled GMSL (Section 13.3.6), and the consistency of process-based projections based on the CMIP5 ensemble of AOGCMs, which have a range of 50–60% of the ensemble mean under a given scenario (Table 13.5). Considering this evidence, we have *medium confidence* in the process-based projections.

The second approach uses SEMs (Section 13.5.2, Table 13.6), which make projections by calibrating a physically motivated relationship between GMSL and some other parameter of the climate system in the past and applying it to the future, without quantifying the contributory physical processes. If we had no physical understanding of the causes of sea level rise, the semi-empirical approach to projections would be the only possible one, but extrapolation beyond the range of calibration implies uncertainty that is difficult to quantify, due to the assumption that sea level change in the future will have the same relationship as it has had in the past to radiative forcing or global mean temperature change (Section 13.5.2). As a result, there is low agreement and no consensus in the scientific community about the reliability of SEM projections, despite their successful calibration and evaluation against the observed 20th century sea level record.

For a given RCP, some semi-empirical models project a range that overlaps the process-based *likely* range while others project a median and 95-percentile that are about twice as large as the process-based models. In nearly every case, the semi-empirical model 95-percentile is above the process-based *likely* range (Figure 13.12). Two physical explanations have been suggested for the higher projections. First, the contribution from accelerated calving of tidewater glaciers may be substantial, and included in SEMs but not process-based models (Jevrejeva et al., 2012b); however, this could account for only 0.1–0.2 m of additional GMSL rise. Second, SEMs may allow for rapid ice-sheet dynamical change (Section 4.4.4) in response to future climate change (Grinsted et al., 2010; Little et al., 2013a). In order for large ice-sheet dynamical changes to be predictable by SEMs, two conditions must be met. First, these changes must have contributed substantially to sea level rise during the period of calibration. This is *very unlikely* to be the case, because it is *very likely* that dynamical changes have contributed only a small part of the observed sea level rise during the 20th century, rising to about 15% during 1993–2010 (Section 13.3.6). Second, the changes must have a link to global surface temperature or radiative forcing. Current understanding of recent dynamical changes in Greenland and Antarctica is that they have been triggered by local changes in ocean temperature (Holland et al., 2008; Thoma et al., 2008; Jacobs et al., 2011), but a link has not been demonstrated between these changes and global climate change or its drivers. Consequently there is great uncertainty regarding whether recent ice-sheet dynamical changes indicate a long-term trend or instead arise from internal variability (Bamber and Aspinall, 2013). Hence there is no evidence that ice-sheet dynamical change is the explanation for the higher GMSL rise projections of SEMs, implying that either there is some other contribution which is presently unidentified or underestimated by process-based models, or that the projections of SEMs are overestimates (cf. Section 13.5.2). Because of the limited or medium evidence supporting SEMs, and the low agreement about their reliability, we have *low confidence* in their projections.

The third approach uses paleo-records of sea level change that show that rapid GMSL rise has occurred during glacial terminations, at rates that averaged about 10 mm yr⁻¹ over centuries, with at least one instance (Meltwater Pulse 1A) that exceeded 40 mm yr⁻¹ (Section 5.6.3), but this rise was primarily from much larger ice-sheet sources that no longer exist. Contributions from these vanished ice sheets could have continued even after sea level and climate had reached interglacial states, if the Greenland and Antarctic ice sheets contracted during the termination to smaller sizes than at present. During past interglacial periods, only the Greenland and Antarctic ice sheets were present. For the time interval during the LIG in which GMSL was above present, there is *high confidence* that the maximum 1000-year average rate of GMSL rise during these periods exceeded 2 m kyr⁻¹ but did not exceed 7 m kyr⁻¹ (Kopp et al., 2013) (Sections 5.6.2, 13.2.1.3). Because climate variations during interglacial periods had different forcings from anthropogenic climate

change, they give only a limited basis for predictions of the future, and we do not consider that they provide upper bounds for GMSL rise during the 21st century.

The fourth approach is concerned particularly with the contribution from ice-sheet dynamical change, for which it considers kinematic limits. Pfeffer et al. (2008) argued that scenarios of GMSL rise exceeding 2 m by 2100 are physically untenable, ruling out, for example, the heuristic argument of Hansen et al. (2007) giving 5 m by 2100. Pfeffer et al. (2008) constructed scenarios of 0.8 m and 2.0 m, and Katsman et al. (2011) of 1.15 m, for GMSL rise by 2100, including ice-sheet rapid dynamical acceleration. Although these authors considered their scenarios to be physically possible, they are unable to quantify their likelihood, because the probability of the assumptions on which they depend cannot be estimated from observations of the response of the Greenland and Antarctic ice sheets to climate change or variability on century timescales. These scenarios involve contributions of ~0.5 m from Antarctica. This is much greater than any process-based projections of dynamical ice-sheet change (Section 13.4.4.2), and would require either a sustained high increase in outflow in all marine-based sectors or the localised collapse of the ice sheet in the Amundsen Sea sector (Little et al., 2013a).

In summary, we have greater confidence in the process-based projections than in the other approaches, and our assessment is that GMSL rise during the 21st century for each RCP scenario is *likely (medium confidence)* to lie within the 5–95% range given by the process-based projections (Section 13.5.1 and Table 13.5; see Section 13.5.4 for following centuries), which are consistent with the *likely* ranges projected for global-mean surface air temperature change (Section 12.4.1.2). We are not able to assess a *very likely* range on the same basis, because there is no assessment available of the *very likely* range for global-mean SAT change, and because we cannot robustly quantify the probability of ice-sheet dynamical changes which would give rise to greater values.

Under the RCP8.5 scenario, which has the highest radiative forcing, the *likely* range reaches 0.95 m by 2100 relative to 1986–2005. Observations do not show an increase in Antarctic precipitation, which is projected by models and makes a negative contribution to the projected GMSL rise (Table 13.5). The recovery of Antarctic stratospheric ozone concentration and increased basal melting of Antarctic ice-shelves have both been suggested as giving rise to mechanisms whereby the Antarctic warming and precipitation increase might be suppressed with respect to CMIP5 projections (Section 13.4.4.1). If the Antarctic precipitation increase is omitted from the process-based projections, the *likely* range for RCP8.5 at 2100 reaches 1.03 m (assuming uncorrelated errors). Higher values for 2100 are given in the scientific literature on the basis of various approaches: 1.15 m (Katsman et al., 2011), 1.21 m (Schaeffer et al., 2012) (for RCP4.5), 1.40 m (National Research Council, 2012), 1.65 m (Jevrejeva et al., 2012b) (for RCP8.5), 1.79 m (Vermeer and Rahmstorf, 2009) (for SRES A1FI), 1.90 m (Rahmstorf et al., 2012a) (with proxy calibration, for RCP8.5), 2.0 m (Pfeffer et al., 2008), 2.25 m (Srifer et al., 2012), and 2.4 m (Nicholls et al., 2011). Considering this inconsistent evidence, we conclude that the probability of specific levels above the likely range cannot be reliably evaluated.

Only the collapse of marine-based sectors of the Antarctic Ice Sheet could cause GMSL rise substantially above the *likely* range during the 21st century. Expert estimates of contributions from this source have a wide spread (Bamber and Aspinall, 2013), indicating a lack of consensus on the probability for such a collapse. The potential additional contribution to GMSL rise also cannot be precisely quantified, but there is *medium confidence* that, if a collapse were initiated, it would not exceed several tenths of a metre during the 21st century (Section 13.4.4.2).

The time-mean rate of GMSL rise during the 21st century is *very likely* to exceed the rate of 2.0 [1.7–2.3] mm yr⁻¹ observed during 1971–2010, because the process-based GMSL projections indicate a significantly greater rate even under the RCP2.6 scenario, which has the lowest radiative forcing. It has been asserted that the acceleration of GMSL rise implied by the IPCC AR4 projections is inconsistent with the observed magnitude of acceleration during the 20th century (Boretti, 2011, 2012b, 2012a; Boretti and Watson, 2012; Boretti, 2012c; Boretti, 2013b, 2013a; Boretti, 2013c; Parker, 2013a; Parker, 2013b, 2013c). Refuting this argument, Hunter and Brown (2013) show that the acceleration projected in the AR4 is consistent with observations since 1990s. Present understanding of the contributions to GMSL rise (Section 13.3) gives an explanation of the rate of 20th century GMSL rise and confidence in the process-based projections, which indicate a greater rate of rise in the 21st century because of increasing forcing.

The improved agreement of process-based models with observations and physical understanding represents progress since the AR4, in which there was insufficient confidence to give *likely* ranges for 21st century GMSL rise, as we have done here. For scenario SRES A1B, which was assessed in the AR4, the *likely* range on the basis of science assessed in the AR5 is 0.60 [0.41–0.79] m by 2100 relative to 1986–2005, and 0.57 [0.40–0.75] m by 2090–2099 relative to 1990. Compared with the AR4 projection of 0.21–0.48 m for the same scenario and period, the largest increase is from the inclusion of rapid changes in Greenland and Antarctic ice-sheet outflow, for which the combined *likely* range is 0.03–0.21 m by 2091–2100 (assuming uncorrelated uncertainties). These terms were omitted in the AR4 because a basis to make projections was not available in published literature at that time. The contribution from thermal expansion is similar to the AR4 projection and has smaller uncertainty. The contribution from glaciers is larger than in the AR4 primarily because of the greater estimate of the present glacier volume in new inventories (although the glacier area estimate is similar, Table 4.1), and the Greenland SMB contribution is larger because of recent improvement in models of relevant surface processes. Further progress on modelling each of the contributions is still needed in order to attain high confidence in GMSL projections, in particular concerning the probability distribution of GMSL above the *likely* ranges.

13.5.4 Long-Term Scenarios

Less information is available on climate change beyond the year 2100 than there is up to the year 2100. However, the ocean and ice sheets will continue to respond to changes in external forcing on multi-centennial to multi-millennial time scales. For the period up to the year 2500, available physical model projections discussed in Sections 13.4.1–4 are combined into an assessment of future sea level rise. Paleo simulations are combined with paleodata to estimate the sea level commitment on a multi-millennial time scale beyond 2500 for different levels of sustained increases in global mean temperature.

The RCPs, as applied in Chapter 12 and Sections 13.4 and 13.5.1, are defined up to the year 2100. Their extension up to the year 2300 is used to project long-term climate change (Section 12.3.1.3) (Meinshausen et al., 2011), but they are not directly derived from integrated assessment models. In simulations that are reported here up to the year 2500, the radiative forcing has generally been kept constant at the 2300 level except for RCP2.6, in which the forcing continues to decline at the 2300 rate. Some model simulations of ice sheets and ocean warming assessed here have used scenarios different from the RCP scenarios. Because of the limited number of available simulations, sea level projections beyond the year 2100 have thus been grouped into three categories according to their GHG concentration in the 22nd century: *low scenarios* in which atmospheric GHG concentrations peak and decline and do not exceed values that are equivalent to 500 ppm CO₂, *medium scenarios* with concentrations between 500 and 700 ppm CO₂-equivalent, and *high scenarios* above 700 ppm. As a consequence, the model spread shown in Figure 13.13 and Table 13.8 combines different scenarios and is not merely due to different model physics. The low scenarios include RCP2.6, SRES B1 and scenarios with 0.5 and 2% yr⁻¹ increases in CO₂ followed by no emissions after 450 ppm has been reached and the commitment scenarios, CC, in Goelzer et al. 2013 which stabilizes CO₂ at present-day levels. In a number of the low scenarios, the global mean temperature peaks during the 21st century and declines thereafter. These peak-and-decline scenarios include RCP2.6 as well as all scenarios with no GHG emissions after a specified year. Even in these scenarios sea level continues to rise up to the year 2500 in accordance with the multi-millennial sea level commitment of about 2 m °C⁻¹ as discussed in Section 13.5.4.3. The medium scenarios include RCP4.5 as well as scenarios with 1% yr⁻¹ increase in CO₂ up to 560 ppm and SRES-B1 and SRES-A1B. The high scenarios include RCP6.0 and RCP8.5 as well as 1120 ppm scenarios and SRES A2. Also included are scenarios with 0.5 and 2% increase in CO₂ and a SRES A2 scenario with zero emissions after 1200 and 1120 ppm have been reached, respectively.

13.5.4.1 Multi-Centennial Projections

The multi-centennial sea level contributions from ocean expansion and the cryospheric components are discussed in Sections 13.4.1–13.4.4. A synthesis of these contributions is provided in Table 13.8 and Figure 13.13 for the end of each century until the year 2500. Thermal expansion contributions (dark blue bars, Figure 13.13) were obtained from coarse-resolution coupled climate models (Vizcaíno et al., 2008; Solomon et al., 2009; Gillett et al., 2011; Schewe et al., 2011; Zickfeld et al., 2013). For comparison, the full model spread of the CMIP5 models which were integrated beyond 2100 is provided in Table 13.7 and as light blue

bars in Figure 13.13. Even though the models used for the long-term projections (Table 13.8) are less complex compared to the CMIP5 models, their model spread for the different periods and scenarios encompasses the CMIP5 spread, which provides *medium confidence* in the application of the less complex models beyond 2300.

Contributions from the Greenland and Antarctic ice sheets were obtained with climate models of comparable complexity coupled to ice-sheet models (Vizcaíno et al., 2010; Huybrechts et al., 2011; Goelzer et al., 2012). Glacier projections were obtained by application of the method by Marzeion et al. (2012a) to the CMIP5 model output for scenarios and models that were integrated up to the year 2300. For 2400 and 2500, the same model spread as for 2300 is shown. This is probably underestimating the glacier's sea level contribution beyond 2300.

[INSERT FIGURE 13.13 HERE]

Figure 13.13: Sea level projections beyond the year 2100 are grouped into three categories according to the concentration of GHG concentration (in CO₂-equivalent) in the year 2100 (upper panel: >700 ppm; middle panel: 500–700 ppm; lower panel: <500 ppm). Colored bars show the full model spread. Horizontal lines provide the specific model simulations. The different contributions are given from left to right as thermal expansion, glaciers, Greenland Ice Sheet, Antarctic Ice Sheet and the total contribution. The range provided for the total sea level change represents the maximum possible spread that can be obtained from the four different contributions. Light red shaded bars exhibit the likely range for the 21st century total sea level projection from Figure 13.10 with the median as the horizontal line. Light blue bars provide the model spread of the thermal expansion of the CMIP5 simulations as used for the 21st century projections (Section 13.5.1), with the median indicated by the horizontal bar.

The ranges of sea level contributions provided in Figure 13.13 and Table 13.8 only represent the model spread and cannot be interpreted as uncertainty ranges. An uncertainty assessment cannot be provided beyond the year 2100 because of the small number of available simulations, the fact that different scenarios were combined within one scenario group, and the overall *low confidence* in the ability of the coarse-resolution ice-sheet models to capture the dynamic ice discharge from Greenland and Antarctica, as discussed below. The range for the total sea level change was obtained by taking the sum of contributions that result in the lowest and the highest sea level rise and thereby covers the largest possible model spread.

It should be noted that the models used here for the period beyond 2100 are different from the models used for the 21st century (Sections 13.4.1, 13.4.3, 13.4.4, and 13.5.1) except for the glacier models (Section 13.4.2). Generally, the model spread for the total sea level contribution in 2100 is slightly lower than the likely range provided in Section 13.5.1 (light red bars in Figure 13.13). This is due to the ice-sheets models, particularly of the Antarctic Ice Sheet, since coarse-resolution model results for thermal expansion are similar to the CMIP5 projections (light blue vertical lines in Figure 13.10, Table 13.7.) and the glacier contribution is the same.

Projections beyond 2100 show positive contributions to sea level from thermal expansion, glaciers and changes in Greenland Ice Sheet SMB. Due to enhanced accumulation under warming, the Antarctic Ice Sheet SMB change makes a negative contribution to sea level in scenarios below 700 ppm CO₂-equivalent. These results were obtained with fully coupled climate-ice sheet models which need to apply a relatively low spatial resolution. In light of the discussion in Section 13.3.3.2 and the assessment of the 21st century changes in Section 13.4.4.1, there is *low confidence* in this result. For scenarios above 700 ppm CO₂-equivalent, Antarctic SMB change is contributing positively to GMSL.

As discussed in Sections 13.4.3.2 and 13.4.4.2, there is *medium confidence* in the ability of coupled ice sheet-climate models to project sea level contributions from dynamic ice-sheet changes in Greenland and Antarctica for the 21st century. In Greenland, dynamic mass loss is limited by topographically defined outlets regions. Furthermore, solid-ice discharge induced from interaction with the ocean is self-limiting because retreat of the ice sheet results in less contact with the ocean and less mass loss by iceberg calving (Pfeffer et al., 2008; Graversen et al., 2011; Price et al., 2011). By contrast, the bedrock topography of Antarctica is such that parts of the retreating ice sheet will remain in contact with the ocean. In particular, due to topography that is sloping landward, especially in West Antarctica, enhanced rates of mass loss are expected as the ice retreats.

While the model used by Huybrechts et al. (2011) is in principle capable of capturing grounding line motion of marine ice sheets (see Box 13.2), *low confidence* is assigned to the model's ability to capture the associated time scale and the perturbation required to initiate a retreat (Pattyn et al., 2013). The model used by Vizcaino et al. (2010) does not represent ice-shelf dynamics and is thus lacking a fundamental process that can trigger the instability. As stated by the authors, *low confidence* is thus also assigned to the model's ability to project future solid-ice discharge from Antarctica. It is thus *likely* that the values depicted in Figure 13.13 systematically underestimate Antarctica's future contribution. As detailed in Section 13.5.4.3, simulations of the last five million years (Pollard and DeConto, 2009) indicate that on multi-millennial time scales, the Antarctic Ice Sheet loses mass for elevated temperatures, in contrast to the projections until the year 2500 for the low and medium scenarios.

The model spread of total sea level change in 2300 ranges from 0.41 to 0.85 m for the low scenario (Table 13.8). Using a SEM, Schaeffer et al. (2012) obtained a significantly larger 90% confidence range of 1.3–3.3 m for the RCP2.6 scenario. The RCP4.5 scenario, for which they obtained a range of 2.3–5.5 m, is categorized here as a medium scenario, and is also significantly higher than the range of 0.27–1.51 m computed by the process-based models. Using a different semi-empirical approach, Jevrejeva et al. (2012a) obtained a 90% confidence range of 0.13–1.74 m for RCP2.6 in the year 2500, which encloses the model spread of 0.50–1.02 m for the low scenario from the process-based models. For the medium and high scenarios, however, they obtained ranges of 0.72–4.3 m and 1.0–11.5 m, respectively, which are significantly higher than the corresponding process-based model spread of 0.18–2.32 m and 1.51–6.63 m (Table 13.8). Since projections of land water storage are not available beyond the year 2100 these were not included here.

The higher estimates from the SEMs than the process-based models used here for the long-term projections are consistent with the relation between the two modeling approaches for the 21st century (Figure 13.12). Section 13.5.3 concluded that the limited or medium evidence supporting SEMs, and the low agreement about their reliability, provides *low confidence* in their projections for the 21st century. We note here that the confidence in the ability of SEMs is further reduced with the length of the extrapolation period and the deviation of the future forcing from the forcing of the learning period (Schaeffer et al., 2012), thus decreasing confidence over the long time frames considered here.

For increasing global mean SAT, sea level is *virtually certain* to continue to rise beyond the year 2500 as shown by available process-based model simulations of thermal expansion and ice sheets that were computed beyond 2500 (Rahmstorf and Ganopolski, 1999; Ridley et al., 2005; Winguth et al., 2005; Driesschaert et al., 2007; Mikolajewicz et al., 2007b; Swingedouw et al., 2008; Vizcaino et al., 2008; Solomon et al., 2009; Vizcaino et al., 2010; Gillett et al., 2011; Goelzer et al., 2011; Huybrechts et al., 2011; Schewe et al., 2011).

13.5.4.2 Multi-Millennial Projections

Here sea level commitment in response to a global mean temperature increase on a multi-millennial time scale is assessed. Figure 13.14 shows the sea level rise after several millennia of constant global mean temperature increase above pre-industrial. The thermal expansion of the ocean was taken from 1000-year integrations with six coupled climate models as used in the AR4 (models Bern2D, CGoldstein, CLIMBER-2, MIT, MoBidiC and UCL in Figure 10.34 in Meehl et al. (2007)). These yield a rate of sea level change in the range of 0.20–0.63 m °C⁻¹ (Figure 13.14a). For reference, a spatially uniform increase of ocean temperature yields a global mean sea level rise of 0.38 m °C⁻¹ when added to observed data (Levitus et al., 2009) (black dots in Figure 13.14a). Uncertainty arises due to the different spatial distribution of the warming in models and the dependence of the expansion on local temperature and salinity. The contribution for glaciers was obtained with the models from Mazeion et al. (2012a) and Radic and Hock (2011) by integration with fixed boundary conditions corresponding to different global mean SAT levels for 3000 years.

[INSERT FIGURE 13.14 HERE]

Figure 13.14: Left column: multi-millennial sea level commitment per degree of warming as obtained from physical model simulations of (a) ocean warming, (b) mountain glaciers, (c) the Greenland and (d) the Antarctic ice sheet. (e) The corresponding total sea level commitment, compared to paleo-estimates from past warm periods (PI = pre-industrial, LIG = last interglacial period, M11 = Marine Isotope Stage 11, Plio = Mid-Pliocene). Temperatures are relative to pre-industrial. Dashed lines provide linear approximations in (d) & (e) constant slopes of 1.2, 1.8 and 2.3 m

$^{\circ}\text{C}^{-1}$. Shading as well as the vertical line represents the uncertainty range as detailed in the text. Right column: 2000-year-sea level commitment. The difference in total sea level commitment (j) compared to the fully equilibrated situation (e) arises from the Greenland Ice Sheet which equilibrates on tens of thousands of years. After 2000 years one finds a non-linear dependence on the temperature increase (h) consistent with coupled climate-ice-sheet simulations by Huybrechts et al. (2011) (black dot). The total sea level commitment after 2000 years is quasi-linear with a slope of $2.3 \text{ m } ^{\circ}\text{C}^{-1}$.

As detailed in Sections 13.4.3.2 and 13.4.4.2, there is *low confidence* in the ability of ice-sheet models to capture the temporal response to changes in external forcing on a decadal to centennial time scale. On multi-centennial to multi-millennial time scales, however, these models can be validated against paleo-sea level records. The contributions from the Greenland Ice Sheet were computed with a dynamic ice-sheet model coupled to an energy-moisture balance model for the SMB (Robinson et al., 2012). The model's parameters were constrained by comparison with SMB estimates and topographic data for the present day and with estimated summit-elevation changes from ice-core records for the Last Interglacial period (LIG), in order to ensure that the coupled model ensemble has a realistic sensitivity to climatic change. The parameter spread leads to a spread in ice-sheet responses (dark green lines in Figure 13.14c). The contribution to sea level commitment from the Greenland Ice Sheet is relatively weak (on average $0.18 \text{ m } ^{\circ}\text{C}^{-1}$ up to 1°C and $0.34 \text{ m } ^{\circ}\text{C}^{-1}$ between 2°C and 4°C) apart from the abrupt threshold of ice loss between 0.8°C and 2.2°C above pre-industrial (90% confidence interval in the particular model calculations reported here) (Figure 13.14c). This represents a change from a fully ice-covered Greenland to an essentially ice-free state, reducing the ice sheet to around 10% of present-day volume and raising sea level by over 6 m (Ridley et al., 2005; Ridley et al., 2010). The threshold temperature is lower than estimates obtained from the assumption that the threshold coincides with a negative total SMB of the Greenland Ice Sheet (see Section 13.4.3.2 for a more complete discussion).

The Antarctic Ice Sheet contribution comes from a simulation of the last 5 million years (Pollard and DeConto, 2009), which is in good agreement with regional paleo-records (Naish et al., 2009). The sensitivity of the ice sheet was extracted from this model simulation by correlating the ice volume with the global mean temperature which forces the simulation. The standard deviation of the resulting scatter is used as a measure of uncertainty (Figure 13.14d). Uncertainty arises from uncertainty in the forcing data, the ice-physics representation, and from the time-dependent nature of the simulation. For example, the existence of hysteresis behavior on the sub-continental scale can lead to different contributions for the same temperature increase. The Antarctic Ice Sheet shows a relatively constant commitment of $1.2 \text{ m } ^{\circ}\text{C}^{-1}$. Paleorecords indicate that a potential hysteresis behaviour of East-Antarctica requires a temperature increase above 4°C and is thereby out of the scope discussed here (Foster and Rohling, 2013).

In order to compare the model results with past sea level anomalies for the temperature range up to 4°C , we focus on the three previous periods of warmer climates and higher sea levels than pre-industrial that were assessed in Sections 5.6.1, 5.6.2, and 13.2.1: the middle Pliocene, MIS 11, and the LIG (Figure 13.14e). In each case, there is reasonable agreement between the model result of a long-term sea level response for a given temperature with the information from the paleo record.

The ability of the physical models to reproduce paleo-sea level records on a multi-millennial time scale provides confidence in applying them to millennial time frame. After 2000 years, the sea level contribution will be largely independent of the exact warming path during the first century. As can be seen from Figure 10.34 of AR4, the oceanic heat content will be largely equilibrated after 2000 years; the same is true for the glacier component. The situation for Antarctica is slightly more complicated, but as can be inferred from Pollard and DeConto (2009), much of the retreat of the West Antarctic Ice Sheet will have already occurred by 2000 years, especially if the warming occurs on a decadal to centennial time scale. The opposite and smaller trend in East Antarctic ice volume due to increased snowfall in a warmer environment will also have largely equilibrated (Uotila et al., 2007; Winkelmann et al., 2012).

The most significant difference arises from the contribution of the Greenland Ice Sheet. Consistent with previous estimates (Huybrechts et al., 2011; Goelzer et al., 2012), the rate of the sea level contribution from Greenland increases with temperature. The transient simulations for an instantaneous temperature increase show a quasi-quadratic dependence of the sea level contribution on this temperature increase after 2000 years (Figure 13.14h) (Robinson et al. 2012). The results are quantitatively consistent with previous estimates on a millennial time scale (Huybrechts et al., 2011; Goelzer et al., 2012) The sea level contribution

of the Greenland Ice Sheet after 2000 years of integration at 560 ppm was plotted against the average Greenland temperature divided by the standard polar amplification of 1.5 between global mean and Greenland mean temperature increase (Gregory & Huybrechts, 2006, black dot in Figure 13.14h). Taken together, these results imply that a sea level rise of 1–3 m °C⁻¹ is expected if the warming is sustained for several millennia (*low confidence*) (Figure 13.14e, 13.14j).

Table 13.7: Median and model spread of the thermal expansion of CMIP5 comprehensive climate models. RCP2.6 belongs to the low scenarios as shown in Figure 13.13 and Table 13.8; RCP4.5 is a ‘medium scenario’ and RCP8.5 a ‘high scenario’. The model spread in Table 13.8 encloses the CMIP5 model spread for all scenarios. Sea level contributions are provided in meters.

Scenario	Mean 2191–2200			Mean 2291–2300		
	# of Models	Median	Model Spread	# of Models	Median	Model Spread
RCP2.6	3	0.19 m	0.15–0.22 m	3	0.21 m	0.15–0.25 m
RCP4.5	7	0.39 m	0.30–0.47 m	6	0.54 m	0.38–0.66 m
RCP8.5	2	0.85m	0.80–0.90 m	2	1.34 m	1.26–1.41 m

Table 13.8: Model spread of sea level contribution and total sea level change for low, medium and high scenarios as defined in the text and shown in Figure 13.13. As detailed in the text confidence of the ice-sheet models’ ability to project dynamic ice-discharge from Greenland and Antarctica is low which is likely to result in a systematic underestimation of the ice-sheet contributions. The unit of all sea level contributions is m.

Contribution	Scenario	2100	2200	2300	2400	2500
Thermal Expansion	low	0.07–0.31 m	0.08–0.41 m	0.08–0.47 m	0.09–0.52 m	0.09–0.57 m
Glaciers	low	0.15–0.18 m	0.19–0.23 m	0.22–0.26 m	0.22–0.26 m ^b	0.22–0.26 m ^b
Greenland Ice Sheet	low	0.05 m ^a	0.10 m ^a	0.15 m ^a	0.21 m ^a	0.26 m ^a

Antarctic Ice Sheet	medium	–0.07 to –0.01 m	–0.17 to –0.02 m	–0.25 to –0.03 m	–0.36 to –0.02 m	–0.45 to –0.01 m
Total	medium	0.19–0.66 m	0.26–1.09 m	0.27–1.51 m	0.21–1.90 m	0.18–2.32 m
Thermal Expansion	high	0.08–0.55 m	0.23–1.20 m	0.29–1.81 m	0.33–2.32 m	0.37–2.77 m
Glaciers	high	0.17–0.19 m	0.25–0.32 m	0.30–0.40 m	0.30–0.40 m ^b	0.30–0.40 m ^b
Greenland Ice Sheet	high	0.02–0.09 m	0.13–0.50 m	0.31–1.19 m	0.51–1.94 m	0.73–2.57 m
Antarctic Ice Sheet	high	–0.07 to –0.00	–0.04 to 0.01 m	0.02–0.19 m	0.06–0.51 m	0.11–0.88 m
Total	high	0.21–0.83	0.58–2.03 m	0.92–3.59 m	1.20–5.17 m	1.51–6.63 m

Notes:

(a) The value is based on one simulation only.

(b) Due to lack of available simulations the same interval used as for the year 2300.

13.6 Regional Sea Level Changes

Regional sea level changes may differ substantially from a global average, showing complex spatial patterns which result from ocean dynamical processes, movements of the sea floor, and changes in gravity due to water mass-redistribution (land ice and other terrestrial water storage) in the climate system. The regional distribution is associated with natural or anthropogenic climate modes rather than factors causing changes in the global average value, and include such processes as a dynamical redistribution of water masses and a change of water-mass properties caused by changes in winds and air pressure, air-sea heat and freshwater fluxes, and ocean currents. Since the characteristic time scales of all involved processes are different, their relative contribution to net regional sea level variability or change will depend fundamentally on the time scale considered.

13.6.1 Regional Sea Level Changes, Climate Modes and Forced Sea Level Response

As discussed in Chapter 3, most of the regional sea level changes observed during the recent altimetry era or reconstructed during past decades from tide gauges appear to be steric (Levitus et al., 2005; Lombard et al., 2005b; Lombard et al., 2005a; Ishii and Kimoto, 2009; Levitus et al., 2009; Stammer et al., 2013). Moreover, steric changes observed during the altimetry era appear to be primarily thermosteric in nature, although halosteric effects, which can reduce or enhance thermosteric changes, are also important in some regions (e.g., Atlantic Ocean, Bay of Bengal). Ocean models and ocean reanalysis-based results (Carton et al., 2005; Wunsch and Heimbach, 2007; Stammer et al., 2011) as well as ocean circulation models without data assimilation (Lombard et al., 2009) confirm these results.

Observations and ocean reanalysis (Stammer et al., 2011; 2013) also agree in showing that steric spatial patterns over the last half of the 20th century fluctuate in space and time as part of modes of the coupled ocean-atmosphere system such as ENSO, the NAO, and the PDO (Levitus et al., 2005; Lombard et al., 2005a; Di Lorenzo et al., 2010; Lozier et al., 2010; Zhang and Church, 2012). In these cases, regional sea level variability is associated with changing wind fields and resulting changes in the ocean circulation (Kohl and Stammer, 2008). For example, the large rates of sea level rise in the western tropical Pacific and of sea level fall in the eastern Pacific over the period 1993–2010 correspond to an increase in the strength of the trade winds in the central and eastern tropical Pacific over the same period (Timmermann et al., 2010; Merrifield and Maltrud, 2011; Nidheesh et al., 2012). The long-term sea level trend from 1958 to 2001 in the tropical Pacific can also be explained as the ocean's dynamical response to variations in the wind forcing (Qiu and Chen, 2006; Timmermann et al., 2010).

Spatial variations in trends in regional sea level may also be specific to a particular sea or ocean basin. For example, a sea level rise of $5.4 \pm 0.3 \text{ mm yr}^{-1}$ in the Japan Sea from 1993 to 2001 is nearly two times the GMSL trend, with more than 80% of this rise being thermosteric (Kang et al., 2005). Han et al. (2010) found that regional changes of sea level in the Indian Ocean that have emerged since the 1960s are driven by changing surface winds associated with a combined enhancement of Hadley and Walker cells.

13.6.2 CMIP5 GCM Projections on Decadal to Centennial Time Scales

CMIP5 projections of regional sea level provide information primarily about dynamic sea level changes resulting from increased heat uptake and changes in the wind forcing. On decadal time scales, the CMIP5 model ensemble identifies strong interannual variability (up to 8 cm, RMS) associated with ENSO and dynamics of the equatorial current system in the tropical Pacific and Indian Oceans (Figure 13.15a). Similar variability in the amplitude of sea level change but due to other climate modes is also apparent in the North Atlantic Current and in parts of the Southern Ocean.

[INSERT FIGURE 13.15 HERE]

Figure 13.15: (a) RMS interannual dynamic sea level variability (mm) in a CMIP5 multi-model ensemble (21 models), built from the historically forced experiments during the period 1951–2005; (b) Changes in the ensemble average interannual dynamic sea level variability (std. dev.; in mm) evaluated over the period 2081–2100 relative to the reference period 1986–2005. The projection data (2081–2100) are from the CMIP5 RCP4.5 experiment.

Toward the end of the 21st century, the CMIP5 results indicate that it is possible that the interannual to decadal variability of dynamic sea level can weaken in some parts of the world ocean, e.g., the western low-latitude Pacific and parts of the Indian Ocean, whereas it could be amplified in other parts, e.g., the North Pacific, the eastern tropical Pacific, the eastern subtropical Atlantic, and the Arctic (Figure 13.15b).

Longer-than-decadal-time-scale regional sea level changes can increasingly be expected to result from long-term changes in the wind field, changes in the regional and global ocean heat and freshwater content and the associated dynamical adjustment (with associated redistribution of ocean properties), and (to a lesser extent) from atmospheric pressure. The CMIP5 projections of steric sea level changes toward the end of the 21st century reveal a clear regional pattern in dynamical sea level change (Figure 13.16), in which the Southern Ocean shows a net decline relative to the global mean, while the remaining global ocean displays complex ridge-and-trough structures superimposed on a generally rising sea level (Yin, 2012b). For example, in the North Atlantic, the largest sea level rise is along and north of the North Atlantic Current, but less so further

to the south in the center of the warmer subtropical gyre. A similar dipole pattern was observed in CMIP3 results there due to a weakening of the AMOC which leads to a local steric sea level rise east of North America, resulting in more water on the shelf and directly impacting northeastern North America (Levermann et al., 2005; Landerer et al., 2007; Yin et al., 2010). A similar pattern can be observed in the North Pacific, but here and in other parts of the world ocean (e.g., Southern Ocean), regional sea level patterns are largely the result of changes in wind forcing, associated changes in the circulation, and an associated redistribution of heat and freshwater. Some regional changes can also be expected to result from modifications in the expansion coefficient due to changes in the ocean's regional heat content (Kuhlbrodt and Gregory, 2012).

The CMIP5 ensemble indicates that regions showing an enhanced sea level toward the end of the 21st century coincide with those showing the largest uncertainty (Figure 13.16b). While this also appeared in the earlier CMIP3 SRES A1B results, the CMIP5 results by comparison, show a general reduction in the ensemble spread, especially in high latitudes. On a global average, this reduction is from 5.7 cm to 2.1 cm, rms.

[INSERT FIGURE 13.16 HERE]

Figure 13.16: (a) Ensemble mean projection of the time-averaged dynamic and steric sea level changes for the period 2081–2100 relative to the reference period 1986–2005, computed from 21 CMIP5 climate models (in m), using the RCP4.5 experiment. The figure includes the globally averaged steric sea level increase of 0.18 ± 0.05 m. (b) RMS spread (deviation) of the individual model result around the ensemble mean (m).

The contribution of changes of global ocean heat storage to regional steric sea level anomalies is *virtually certain* to increase with time as the climate-warming signal increasingly penetrates into the deep ocean (Pardaens et al., 2011a). For the last three decades of the 21st century, the AR4 climate model ensemble mean shows a significant heat storage increase (Yin et al., 2010), about half of which is stored in the ocean below 700 m depth. Recent detection of ongoing changes in the ocean salinity structure (Durack and Wijffels, 2010) (Section 3.3.2) may also contribute to future regional steric sea level changes. Halosteric effects can dominate in some regions, especially in regions of high-latitude water mass formation where long-term heat and freshwater changes are expected to occur (e.g., in the subpolar North Atlantic, the Arctic, the Southern Ocean) (Yin et al., 2010; Pardaens et al., 2011a). Because of an anticipated increase in atmospheric moisture transport from low to high latitudes (Pardaens et al., 2003), halosteric anomalies are positive in the Arctic Ocean and dominate regional sea level anomalies there (Yin et al., 2010). It is *likely* that future thermosteric changes will dominate the steric variations in the Southern Ocean, and strong compensation between thermosteric and halosteric change will characterise the Atlantic (Pardaens et al., 2011a).

13.6.3 Response to Atmospheric Pressure Changes

Regional sea level also adjusts to regional changes in atmospheric sea level pressure relative to its instantaneous mean over the ocean. Over time scales longer than a few days, the adjustment is nearly isostatic. Sea level pressure is projected to increase over the subtropics and mid-latitudes (depressing sea level) and decrease over high latitudes (raising sea level), especially over the Arctic (order several millibars by the end of the 21st century associated with a poleward expansion of the Hadley Circulation and a poleward shift of the storm tracks of several degrees latitude (Held and Soden, 2006). These changes may therefore contribute positively to the sea level rise in the Arctic in the range of up to 1.5 cm and about 2.5 cm for RCP4.5 and RCP8.5, respectively (Yin et al., 2010) (Figure 13.17). In contrast, air pressure changes oppose sea level rise in mid- and low latitudes albeit with small amplitudes. Air pressure may also influence regional sea level elsewhere, as demonstrated by sea level changes in the Mediterranean in the second half of the 20th century (Tsimplis et al., 2005).

[INSERT FIGURE 13.17 HERE]

Figure 13.17: Projected ensemble mean sea level change (m) due to changes in atmospheric pressure loading over the period from 1986–2005 to 2081–2100 for (a) RCP4.5 and (b) RCP8.5 (contour interval is 0.01 m). Standard deviation of the model ensemble due to the atmospheric pressure loading for (c) RCP4.5 and (d) RCP8.5 (contour interval is 0.005 m).

13.6.4 Response to Freshwater Forcing

Enhanced freshwater fluxes derived from an increase in ice-sheet meltwater at high latitudes results in a regional pattern of sea level rise originating from adjustments in ocean dynamics and in the solid earth. Neither effect is included in CMIP5 models, although the latter adjustment is computed off line here.

13.6.4.1 Dynamic Ocean Response to Cryospheric Freshwater Forcing

The addition of freshwater from glaciers and ice sheets to the ocean leads to an instantaneous increase in global mean sea level, but because it is communicated around the ocean basins via a dynamical adjustment, it is not instantaneously globally uniform (Kawase, 1987; Cane, 1989). For the addition of mass, the barotropic adjustment of the ocean takes place in a few days (Gower, 2010; Lorbacher et al., 2012). The addition of freshwater to the ocean from melting of the Greenland Ice Sheet results in an additional basin-wide steric response of the North Atlantic within months and is communicated to the global ocean via boundary waves, equatorial Kelvin waves, and westward propagating baroclinic Rossby waves on decadal time scales (Stammer, 2008). A similar response but with a different pattern can be observed from Antarctic meltwater input. In both cases, an associated complete baroclinic adjustment of the global ocean might take as long as several centuries. The adjustment of the ocean to high-latitude meltwater input also involves atmospheric teleconnections; such a response to Greenland meltwater pulses could lead to sea level changes in the Pacific within months (Stammer et al., 2011). On longer-than-decadal time scales, the freshwater input to the North Atlantic raises sea level in the Arctic Ocean and leads to an anomalous southward Bering Strait throughflow, transporting colder, fresher water from the Arctic Ocean into the North Pacific (Hu et al., 2010) and causing North Pacific cooling (Okumura et al., 2009). Meltwater forcing in the subpolar North Atlantic also causes changes of the AMOC (Section 12.4.7.2), which in turn causes dynamic changes of sea level in the North Atlantic, particularly in its northwestern region (Lorbacher et al., 2010). The combination of this dynamic sea level rise and the global mean sea level rise makes the northeastern North American coast vulnerable to some of the fastest and largest sea level rises during this century (Yin et al., 2009).

13.6.4.2 Earth and Gravitational Response to Contemporary Surface Water Mass Redistribution

Deformational, rotational, and gravitational responses to mass redistribution between the cryosphere, the land, and the oceans produce distinctive regional departures from GMSL, referred to as sea level fingerprints (Mitrovica et al., 2001; Mitrovica et al., 2009; Gomez et al., 2010b; Riva et al., 2010) (Section 13.1, FAQ 13.1). Many existing studies of these effects have not defined a specific rate of ice-sheet mass loss (Mitrovica et al., 2001) or are based on end-member scenarios of ice retreat, such as from the West Antarctic Ice Sheet (Bamber et al., 2009; Mitrovica et al., 2009; Gomez et al., 2010b) and marine-based parts of the East Antarctic Ice Sheet (Gomez et al., 2010b). Bamber and Riva (2010) calculated the sea level fingerprint of all contemporary land-ice melt and each of its major components. Spada et al. (2013) examined the regional sea level pattern from future ice melt based on the A1B scenario.

As can be seen from Figure 13.18, a characteristic of the sea level fingerprints is that regions adjacent to the source of the mass loss are subject to relative sea level fall of about an order of magnitude greater than the equivalent GMSL rise from these mass contributions, whereas in the far field the sea level rise is larger (up to about 30%) than the global average rise (Mitrovica et al., 2001; Mitrovica et al., 2009; Gomez et al., 2010b). Gomez et al. (2010b) and Mitrovica et al. (2011) showed that differences in the maximum predicted rise (relative to the global mean) between published results is due to the accuracy with which water expulsion from the deglaciated marine basins is calculated. These changes are in addition to the ongoing response to past changes (e.g., glacial isostatic adjustment in response to the last deglaciation). Mitrovica et al. (2001) suggested that the lower rates of sea level change inferred from tide gauge records at European sites relative to the global average were consistent with 20th century melting from Greenland. Similarly, Gehrels and Woodworth (2013) suggested that the larger magnitude of the early 20th century sea level acceleration observed in Australia and New Zealand, as compared with the North Atlantic, may represent a fingerprint of the increased melt contributions of Greenland and Arctic glaciers in the 1930s. Nevertheless, current rates of ice-sheet melting are difficult to distinguish from dynamic variability (Kopp et al., 2010; Hay et al., 2013), but it is *likely* that with further ice-sheet melting they will begin to dominate the regional patterns of sea level change toward the end of the 21st century, especially under climate forcing conditions for which ice-sheet melting contributes to more than 20-cm equivalent sea level rise (Kopp et al., 2010).

These changes are in addition to the ongoing response to past changes (e.g., GIA in response to the last deglaciation; Figure 13.18).

Water mass redistributions associated with land hydrology changes other than those from land ice may also produce spatially variable ‘fingerprints’ in sea level (Fiedler and Conrad, 2010). In particular, regional changes in the terrestrial storage of water can lead to a sea level response on interannual and longer time scales, specifically near large river basins (Riva et al., 2010).

13.6.5 Net Regional Sea Level Changes

Net regional sea level change projections can be estimated from a combination of the various contributions to sea level change described above, emerging from the ocean, atmospheric pressure loading and the solid Earth.

Over the next few decades, net regional sea level changes over most parts of the world are *likely* to be dominated by dynamical changes (mass redistribution and steric components) resulting from natural variability, although exceptions are possible at sites near rapidly melting ice sheets where static effects could become large. However, toward the end of the 21st century, regional patterns in sea level from all other contributions will progressively emerge and eventually dominate over the natural variability.

Ensemble mean estimates of relative sea level change during the period 2081–2100 relative to 1986–2000 resulting from GIA and from glacier and ice-sheet melting for RCP4.5 and RCP8.5 scenarios (Figure 13.18) suggest that for the 21st century, past, present and future loss of land-ice mass will *very likely* be an important contributor to spatial patterns in sea level change, leading to rates of maximum rise at low-to-mid latitudes. Hu et al. (2011) and Sallenger et al. (2012) also suggested that steric and dynamical sea level changes can potentially increase the sea level near the northeastern coast of North America and in the western Pacific. Considerable uncertainties remain, however, in both the sea level budget and in the regional expression of sea level rise. In addition, local sea level rise can also partly be compensated by vertical land movement resulting from GIA, especially in some formerly glaciated high-latitudes regions where high rates of land uplift may lead to a decrease of relative sea level. For example, Johansson et al. (2013) reported a 29 cm sea level rise in Gulf of Finland and –27 cm fall in the Bay of Bothnia.

[INSERT FIGURE 13.18 HERE]

Figure 13.18: Ensemble mean regional contributions to sea level change (m) from (a) GIA, (b) glaciers and (c) ice-sheet SMB. Panels (b) and (c) are based on information available from scenario RCP4.5. All panels represent changes between the periods 1986–2000 and 2081–2100.

The ensemble mean net regional sea level change between 1986–2005 and 2081–2100 for the RCP4.5 scenario (not including the dynamic ocean contribution in response to the influx of freshwater associated with land-ice loss and changes in terrestrial ground water) reveals that many regions are *likely* to experience regional sea level changes that differ substantially from the global mean (Figure 13.19). Figure 13.20 shows ensemble mean net regional sea level change between 1986–2005 and 2081–2100 for RCPs 2.6, 6.0 and 8.5.

[INSERT FIGURE 13.19 HERE]

Figure 13.19: (a) Ensemble mean net regional sea level change (m) evaluated from 21 models of the CMIP5 scenario RCP4.5, including atmospheric loading, plus land-ice, GIA and terrestrial water sources, between 1986–2005 and 2081–2100. Global mean is 0.50 ± 0.13 m, with a total range of –1.71 to +0.83 m. (b) Lower 90% CL uncertainty bound ($p = 0.05$) for RCP4.5 scenario sea level rise (plus non-scenario components). (c) Upper 90% CL uncertainty bound ($p = 0.95$) for RCP4.5 scenario sea level rise (plus non-scenario components).

[INSERT FIGURE 13.20 HERE]

Figure 13.20: Ensemble mean net regional sea level change (m) evaluated from 21 CMIP5 models for the RCP scenarios (a) 2.6, (b) 4.5, (c) 6.0 and (d) 8.5 between 1986–2005 and 2081–2100. Each map includes effects of atmospheric loading, plus land-ice, GIA and terrestrial water sources.

It is *very likely* that over about 95% of the world ocean, regional sea level rise will be positive, while most regions experiencing a sea level fall are located near current and former glaciers and ice sheets. Figure 13.21b shows that over most of the oceans (except for limited regions around western Antarctica, Greenland,

and high Arctic regions), estimated regional sea level changes are significant at the 90% confidence limit. Local sea level changes deviate more than 10% and 25% from the global mean projection for as much as 30% and 9% of the ocean area, respectively, indicating that spatial variations can be very large. Regional changes in sea level reach values of up to 30% above the global mean value in the Southern Ocean and around North America, between 10–20% in equatorial regions, and up to 50% below the global mean in the Arctic region and some regions near Antarctica (Figure 13.21a).

[INSERT FIGURE 13.21 HERE]

Figure 13.21: (a) Percentage of the deviation of the ensemble mean net regional sea level change between 1986–2005 and 2081–2100 from the global mean value. The figure was computed for RCP4.5, but to first order is representative for all RCPs. (b) Total RCP4.5 sea level change (plus all other components) divided by the combined standard error of all components (see Supplementary Material Section 13.SM.2). Assuming a normal distribution, or a t-distribution given the number of models as an approximation of the number of degrees of freedom, a region passes the 90% confidence level where the change is greater than 2 standard errors, which is most of the ocean except for limited regions around western Antarctica, Greenland, and high Arctic regions.

Figure 13.22 shows that, between 1986–2005 and 2081–2100, sea level changes along the world's coastlines associated with the RCP4.5 and RCP8.5 scenarios have a substantially skewed non-Gaussian distribution, with significant coastal deviations from the global mean. When the coastlines around Antarctica and Greenland are excluded (Figure 13.22b), most negative changes disappear, but the general structures of the global histograms remain. In general, changes along the coastlines will range from about 20 cm to 50 cm for an RCP4.5 scenario, peaking near 40 cm, and from about 40 cm to more than 80 cm under a RCP8.5 scenario, peaking near 75 cm. About 68% and 72% of the coastlines will experience a sea level change within $\pm 20\%$ of the GMSL change for RCP4.5 and RCP8.5, respectively. In both cases, the maximum of the histogram is slightly higher than the GMSL, whereas the arithmetic mean is lower. Only some coastlines will experience a sea level rise of up to 50% above the GMSL change.

[INSERT FIGURE 13.22 HERE]

Figure 13.22: (a) Histograms of the deviation of the ensemble mean net regional sea level change (Figure 13.20) along all coastlines (represented by the closest model grid point) between 1986–2005 and 2081–2100 from the global mean value. Shown are results for RCP4.5 (blue) and RCP8.5 (pink), respectively. (b) Same as in (a) but excluding Antarctic and Greenland coastlines. Vertical dashed lines represent global mean sea level changes for the two RCPs.

Figure 13.23 shows the combination of the natural variability (annual mean) and the CMIP5 projected sea level rise for the RCP4.5 scenario for a number of locations distributed around the world. For example, at Pago Pago (14°S, 195°E) in the western equatorial Pacific, the historical record indicates that annual variability in mean sea level has been about 21 cm (5–95% range). Projections by individual climate models indicate that it is *very likely* that a similar range of natural variability will continue through the 21st century (Figure 13.15b). However, by 2100, the average projected sea level for the RCP4.5 scenario of 0.53 [0.34–0.74] m is greater than any observations of annual mean sea level in the instrumental record. Of all the examples shown, the greatest sea level increase will be in New York, which is representative of the enhanced sea level rise there due to ocean processes and GIA in the region (compare Figures 13.16. and 13.18). The figure also reveals the large spatial inhomogeneity of interannual to decadal variability. In each case, monthly variability and extreme sea levels from winds and waves associated with weather phenomena (Section 13.7) need to be considered in addition to these projections of regional sea level.

[INSERT FIGURE 13.23 HERE]

Figure 13.23: Observed and projected relative net sea level change (compare Figure 13.20) near nine representative coastal locations for which long tide-gauge measurements are available. The observed in situ relative sea level records from tide gauges (since 1970) are plotted in yellow, and the satellite record (since 1993) is provided as purple lines. The projected range from 21 CMIP5 RCP4.5 scenario runs (90% uncertainty) is shown by the shaded region for the period 2006–2100, with the bold line showing the ensemble mean. Colored lines represent three individual climate model realizations drawn randomly from three different climate models used in the ensemble. Station locations of tide gauges are: (a) San Francisco: 37.8°N, 122.5°W; (b) New York: 40.7°N, 74.0°W; (c) Ijmuiden: 52.5°N, 4.6°E; (d) Haldia: 22.0°N, 88.1°E; (e) Kanmen, China: 28.1°N, 121.3°E; (f) Brest: 48.4°N, 4.5°W; (g) Mar del Plata, Argentina: 38.0°S, 57.5°W; (h) Fremantle: 32.1°S, 115.7°E; (i) Pago Pago: 14.3°S, 170.7°W. Vertical bars at the right sides of each panel represent the ensemble mean and ensemble spread (5–95%) of the likely (medium confidence) sea level change at each respective location at the year 2100 inferred from the four RCPs 2.6 (dark blue), 4.5 (light blue), 6.0 (yellow), and 8.5 (red).

13.6.6 Uncertainties and Sensitivity to Ocean/Climate Model Formulations and Parameterizations

Uncertainties of climate models are discussed in detail in Chapter 9. Sea level is a property of the ocean connected to nearly all dynamical and thermodynamical processes over the full ocean column, from the surface fluxes to the ocean bottom. While many of the processes are to first order correctly simulated in climate models, differences between models (Figure 13.24) indicate that uncertainties in simulated and projected steric sea level (globally and regionally) remain poorly understood. Moreover, the ocean heat uptake efficiency differs between models leading to a spread of 50% in heat storage changes (Kuhlbrodt and Gregory, 2012). In addition, some processes are not part of the CMIP5 simulations, such as the dynamical response of the ocean to meltwater input or the GIA/rotational/gravitational processes associated with this ice mass loss. Stammer and Hüttemann (2008) showed that coupled climate models that do not include the effect of changes in atmospheric moisture content on sea level pressure will underestimate future regional atmospheric pressure loading effects by up to 2 cm. Other uncertainties result from GIA/rotational/gravitational effects as well as from uncertainties in air-sea fluxes.

[INSERT FIGURE 13.24 HERE]

Figure 13.24: Projected relative sea level change (in m) from the combined global steric plus dynamic topography and glacier contributions for the RCP4.5 scenario over the period from 1986–2005 to 2081–2100 for each individual climate model used in the production of Figure 13.16a.

Improvements in the skill of a sea level projection require (1) better parameterizations of unresolved physical processes, (2) improved numerical algorithms for such processes as temperature and salinity advection, (3) refined grid resolution to better represent such features as boundary currents and mesoscale eddies, and (4) the elimination of obsolete assumptions that have a direct impact on sea level (Griffies and Greatbatch, 2012). Among the many limiting approximations made in ocean models, the Boussinesq approximation has been found to only marginally impact regional patterns (i.e., deviations from global mean) when directly compared to non-Boussinesq simulations (Losch et al., 2004), thus lending greater confidence in Boussinesq models for addressing questions of regional sea level change. Furthermore, for global sea level, the now-standard *a posteriori* adjustment (Greatbatch, 1994; Griffies and Greatbatch, 2012) accurately incorporates the missing global steric effect. The representation of dense overflows can also affect sea level simulations, and is particularly problematic in many ocean models used for climate studies, with direct impacts on the simulated vertical patterns of ocean heat uptake (Legg et al., 2009).

Coarse-resolution ocean-climate simulations require a parameterization of mesoscale and smaller eddies, but the parameterizations as well as the details of their numerical implementations can greatly impact the simulation. As shown by Hallberg and Gnanadesikan (2006) and Farneti et al. (2010), coarse-resolution climate models may be over-estimating the Antarctic Circumpolar Current response to wind changes. Better implementations of eddy parameterizations reduce such biases (Farneti and Gent, 2011; Gent and Danabasoglu, 2011), and they form the basis for some, but not all, of the CMIP5 simulations. Moreover, Vinogradov and Ponte (2011) suggested that as one considers regional sea level variability and its relevant dynamics and forcing, mesoscale ocean features become important factors on a sub-decadal time scale. Suzuki et al. (2005) compared changes in mean dynamic sea level in 2080–2100 relative to 1980–2000 as obtained from a low- and a high-resolution ocean component of a coupled model and concluded that while changes are comparable between runs, the high-resolution model captures enhanced details due to resolving ocean eddy dynamics.

Even with a perfect ocean model, skill in sea level projections depends on skill of the coupled climate model in which errors impacting sea level may originate from non-ocean components. Furthermore, initialization is fundamental to the prediction problem, particularly for simulation of low-frequency climate variability modes (Meehl et al., 2010). Projections of land-ice melting and the resultant sea level rise patterns also have large uncertainties, with additional uncertainties arising from GIA models such as the mantle viscosity structure. Each of the many uncertainties and errors results in considerable spread in the projected patterns of sea level changes (Figure 13.15) (Pardaens et al., 2011a; Slangen et al., 2012). In addition to ocean/climate model formulations and parameterizations, uncertainty in predictions of sea level change may be associated with specified freshwater forcing. Whether or not an ocean model is coupled with an ice-sheet model, the

forcing should distinguish between runoff and iceberg flux. Martin and Adcroft (2010) reported the only attempt thus far to explicitly represent iceberg drift and melting in a fully coupled climate model.

13.7 Projections of 21st Century Sea Level Extremes and Waves

Climate change will affect sea levels extremes and ocean waves in two principal ways. First, because extra-tropical and tropical storms are one of the key drivers of sea level extremes and waves, future changes in intensity, frequency, duration, and path of these storms will impact them. Second, sea level rise adds to the heights of sea level extremes, regardless of any changes in the storm-related component. MSL change may also accentuate the threat of coastal inundation due to changes in wave runup. Observations of changes in sea level extremes and waves are discussed in Chapter 3. Sea level extremes at the coast occur mainly in the form of storm surges and tsunamis, but because the latter are not climate driven, we only assess projections for sea level extremes based on estimates of future storminess and MSL change.

13.7.1 Observed Changes in Sea Level Extremes

As discussed in the AR4 (Bindoff et al., 2007) and confirmed by more recent studies (Menéndez and Woodworth, 2010), statistical analyses of tide-gauge observations have shown an increase in observed sea level extremes worldwide that are caused primarily by an increase in MSL (Chapter 3). Dominant modes of climate variability, particularly ENSO and NAO, also have a measureable influence on sea level extremes in many regions (Lowe et al., 2010; Walsh et al., 2011). These impacts are due to sea level anomalies associated with climate modes, as well as mode-related changes in storminess. There has been some indication that the amplitude and phase of major tidal constituents have exhibited long-term change (Jay, 2009; Muller et al., 2011), but their impacts on extreme sea level are not well understood. Using particle size analysis of cores collected in the Mackenzie Delta in the Arctic region, Vermaire et al. (2013) inferred increased storm surge activity in the region during the last ~150 years, which they related to annual mean temperature anomaly in the Northern Hemisphere and a decrease in summer sea-ice extent.

13.7.2 Projections of Sea Level Extremes

13.7.2.1 Recent Assessments of Projections of Sea Level Extremes

The AR4 assessed projections of storm surges for a few regions (Europe, Australia, the Bay of Bengal) based on a limited number of dynamical modeling studies (Christensen et al., 2007). Although these results generally indicated higher magnitude surges in future scenarios, there was *low confidence* in these projections because of the wide spread in underlying AOGCM and RCM projections.

Studies since the AR4 have further assessed the relative contributions of sea level rise and storminess on projected sea level extremes. Lowe et al. (2010) concluded that the increases in the observed sea level extremes in the 20th century occurred primarily through an increase in MSL, and that the same applies to projections for the 21st century. The SREX assessment concluded that it is *very likely* that MSL rise will contribute to an increase in future sea level extremes (Seneviratne et al., 2012). It noted that changes in storminess may also affect sea level extremes but the limited geographical coverage of studies and uncertainties associated with storminess changes prevent a general assessment. The global tropical cyclone frequency will *likely* decrease or remain roughly constant, but it is *more likely than not* that the frequency of the most intense storms will increase in some ocean basins (Chapter 14). Uncertainties in projections of cyclone frequency and tracks make it difficult to project how these changes will impact particular regions. Similarly, while the SREX and the current assessment (Chapter 14) find that it is *likely* that there has been a poleward shift in the main northern and southern extra-tropical cyclone tracks during the last 50 years, and that regional changes may be substantial, there is only low confidence in region-specific projections.

13.7.2.2 Projections Based on Dynamical and Statistical Approaches

Projected changes in storm surges (relative to MSL) have been assessed by applying climate-model forcing to storm-surge models. Return periods of sea level extremes (see Glossary), exceeding a given threshold level, referred to as return levels, are used in quantifying projected changes. Using three regionally downscaled GCMs for A2, B2 and A1B scenarios, Debernard and Roed (2008) found an 8–10% increase in

the 99th percentile surge heights between 1961–1990 and 2071–2100, mainly during the winter season, along the coastlines of the eastern North Sea and the northwestern British Isles, and decreases south of Iceland. Using a downscaled GCM under an A1B scenario, Wang et al. (2008) projected a significant increase in wintertime storm surges around most of Ireland between 1961–1990 and 2031–2060. Sterl et al. (2009) concatenated the output from a 17-member ensemble of A1B simulations from a GCM over the periods 1950–2000 and 2050–2100 into a single longer time series to estimate 10,000-year return levels of surge heights along the Dutch coastline. No statistically significant change in this value was projected for the 21st century because projected wind-speed changes were not associated with the maximum surge-generating northerlies. Using an ensemble of three climate models under A2 simulations, Colberg and McInnes (2012) found that changes in 95th percentile sea level height across the southern Australian coast in 2081–2100 compared to 1981–2000 were small (± 0.1 m), mostly negative, and despite some inter-model differences, resembled the changes in wind patterns simulated by the climate models (McInnes et al., 2011). These studies demonstrate that the results are sensitive to the particular choice of GCM or RCM, therefore identifying uncertainties associated with the projections. For the tropical east coast of Australia, Harper et al. (2009) found that a 10% increase in tropical cyclone intensity for 2050 led to increases in the 100-year return level (including tides) that at most locations were smaller than 0.1 m.

Several regional storm-surge studies have considered the relative contribution of the two main causative factors on changes in future sea level extremes (e.g., McInnes et al. (2009; 2013) for the southeastern coast of Australia; Brown et al. (2010) for the eastern Irish Sea; Woth et al. (2006) for the North Sea; Lowe et al. (2009) for the United Kingdom coast). They concluded that sea level rise has a greater potential than meteorological changes to increase sea level extremes by the end of the 21st century in these locations. Unnikrishnan et al. (2011) used RCM simulations to force a storm-surge model for the Bay of Bengal and found that the combined effect of MSL rise of 4 mm/yr and RCM projections for the A2 scenario (2071–2100) gave an increase in 100-year return levels of total sea level (including tides) between 0.40–0.67 m (about 15–20%) along the northern part of the east coast of India, except around the head of the bay, compared to those in the base line (1961–1990) scenario.

Using six hypothetical hurricanes producing approximate 100-year return levels, Smith et al. (2010) found that in the regions of large surges on the southeastern Louisiana coast, the effect of MSL rise on simulated surges was linear. Yet in the regions of moderate surges (2–3 m), particularly in wetland-fronted areas, the increase in surges was larger by 1–3 m than the present values. They showed that sea level rise alters the speed of propagation of surges and their amplification in different regions of the coast. For the Gulf of Mexico, Mousavi et al. (2011) developed a simple relationship between hurricane-induced storm surges, sea level rise and hurricane intensification through increased SSTs for three modeled major historical cyclones, concluding that the dynamic interaction of surge and sea level rise lowered or amplified the surge at different points within a shallow coastal bay.

Higher mean sea levels can significantly decrease the return period for exceeding given threshold levels. For a network of 198 tide gauges covering much of the globe, Hunter (2012) determined the factor by which the frequency of sea levels exceeding a given height would be increased for a MSL rise of 0.5 m (Figure 13.25a). The above calculations have been repeated here using regional RSL projections and their uncertainty using the RCP4.5 scenario (Section 13.6, Figure 13.19a). This multiplication factor depends exponentially on the inverse of the Gumbel scale parameter (a factor which describes the statistics of sea level extremes caused by the combination of tides and storm surges) (Coles and Tawn, 1990). The scale parameter is generally large where tides and/or storm surges are large, leading to a small multiplication factor, and vice versa. Figure 13.25a shows that a 0.5 m MSL rise would *likely* result in the frequency of sea level extremes increasing by an order of magnitude or more in some regions. The multiplication factors are found to be slightly higher, in general, when accounting for regional MSL projections (Figure 13.25b). However, in regions having higher regional projections of MSL, such as the east coast of Canada and the US (where GIA results in a larger sea level rise), the multiplication factor is higher, whereas in regions having lower regional projections of MSL, such as the northwest region of North America (where the land is rising due to present changes in glaciers and icecaps), the multiplication factor is lower. In another study, large increases in the frequency of sea level extremes for 2050 were found for a network of sites around the US coastline based on semi-empirical MSL rise projections and 20th century statistics of extremes (Tebaldi et al., 2012). Cayan et al. (2008) reached a similar conclusion for the California coast, using projected time series of tides, MSL rise, components for sea level fluctuations from projected MSLP and wind stress fields

and a contribution for ENSO variability through projected SSTs for the 21st century, and showed that for high-end scenarios of MSL rise, the frequency and magnitude of extremes increases considerably relative to those experienced in the 20th century.

[INSERT FIGURE 13.25 HERE]

Figure 13.25: The estimated multiplication factor (shown at tide gauge locations by red circles and triangles), by which the frequency of flooding events of a given height increase for (a) a MSL rise of 0.5 m (b) using regional projections of MSL for the RCP4.5 scenario, shown in Figure 13.19a. The Gumbel scale parameters are generally large in regions of large tides and/or surges resulting in a small multiplication factor and vice versa.

13.7.3 Projections of Ocean Waves

Changes in ocean wave conditions are determined by changes in the major wind systems, especially in the main areas affected by tropical and extra-tropical storms. Based on *in situ* and satellite altimeter observations and wave-model hindcasts, it is *likely* that mean significant wave heights (SWH, defined as the average of the highest one-third of wave heights) have increased in regions of the North Pacific and the North Atlantic over the past half century, and in the Southern Ocean since the mid 1980s (Chapter 3, Seneviratne et al., 2012). The limited observational wave record makes it difficult to separate long-term trends from multi-decadal variability (Young et al., 2011). A number of studies have related changes in wind-wave climatologies to modes of climate variability such as ENSO (Allan and Komar, 2006; Adams et al., 2008; Menéndez et al., 2008), the NAO (Woolf et al., 2002; Izaguirre et al., 2010), and the Southern Annular Mode (SAM) (Hemer et al., 2010; Izaguirre et al., 2011). Although anthropogenic influences have been considered (Wang et al., 2009), it is *likely* that reported SWH trends over the past half-century largely reflect natural variations in wind forcing. Recent reductions in summer sea-ice extent have resulted in enhanced wave activity in the Arctic Ocean due to increased fetch area and longer duration of the open-water season (Francis et al., 2011; Overeem et al., 2011).

In general, there is *low confidence* in projections of future storm conditions (Chapters 12 and 14) and hence in projections of ocean waves. Nevertheless, there has been continued progress in translating climate model outputs into wind-wave projections. In the AR4, projected changes in global SWHs were based on a single statistical model (Wang and Swail, 2006). The projected conditions were consistent with increased wind speeds associated with mid-latitude storms, but they considered only a limited five-member ensemble for a single future emission scenario (SRES A2); wave parameters other than SWH were not considered.

Since the AR4, global wave-climate projections for the end of the 21st century have been made by dynamically downscaling CMIP3 AOGCM results. A multi-model ensemble based on dynamical models forced with various greenhouse gas emission scenarios (SRES A1B: Mori et al. (2010), Fan et al. (2013), Semedo et al. (2013); SRES A2: Hemer et al. (2012a), as well as the statistical model of Wang and Swail (2006) forced with emission scenarios IS92a and SRES A2 and B2, has been constructed as part of the Coordinated Ocean Wave Climate Project (COWCLIP) (Hemer et al., 2013). In general, the ensemble projected changes of annual mean SWH (Figure 13.26a) resemble the statistical projections of Wang and Swail (2006) under an A2 scenario. The largest change is projected to be in the Southern Ocean, where mean SWHs at the end of the 21st century are approximately 5–10% higher than the present-day mean. SWH increase in this region reflects the projected strengthening of the westerlies over the Southern Ocean, particularly during austral winter (Figure 13.26c). Another region of SWH increase in the ensembles is in the tropical South Pacific associated with a projected strengthening of austral winter easterly trade winds in the CMIP3 multi-model dataset (Figure 13.26c). Negligible change or a mean SWH decrease is projected for all other ocean basins, with decreases identified in the trade wind region of the North Pacific, the mid-latitude westerlies in all basins, and in the trade and monsoon wind regions of the Indian Ocean. Hemer et al. (2013) found that variance of wave-climate projections associated with wave downscaling methodology dominated other sources of variance within the projections such as climate scenario of climate model uncertainties. Mori et al. (2013) reported similar findings.

Three CMIP3-based model projections (Mori et al., 2010; Hemer et al., 2012b; Fan et al., 2013) were used to compare projections of wave direction and period (Hemer et al., 2013). Wave direction (Figure 13.26d) exhibits clockwise rotation in the tropics, consistent with a higher contribution from northward propagating swell from the Southern Ocean. Wave period (Figure 13.26e) shows an increase over the eastern Pacific,

which is also attributed to enhanced wave generation in the Southern Ocean and northward swell propagation. A projected decrease in wave periods in the North Atlantic and western and central North Pacific is symptomatic of weaker wind forcing in these regions.

SWH projections based on CMIP5 winds for emission scenarios RCP4.5 and RCP8.5 (Dobrynin et al., 2012) exhibit similar regional patterns for the end of the 21st century to the CMIP3 results presented in Figure 13.26A. Dobrynin et al. (2012) reported SWH increases in the Arctic Ocean, an area not considered by Hemer et al. (2013), and in basins connected to the Southern Ocean, particularly for RCP8.5. The probability of extreme wave heights is projected to increase in the Southern Hemisphere, the Arctic and Indian Oceans, but decrease in the North and Equatorial Atlantic and in the Pacific. In addition to wind changes, the projected loss of summer sea-ice extent in the Arctic Ocean is expected to increase overall wave activity there (Manson and Solomon, 2007; Overeem et al., 2011).

Model intercomparisons are starting to identify common features of global wave projections yet in general there is low confidence in wave-model projections because of uncertainties regarding future wind states, particularly storm geography, the limited number of model simulations used in the ensemble averages, and the different methodologies used to downscale climate model results to regional scales (Hemer et al., 2012a). Despite these uncertainties, it appears *likely (medium confidence)* that enhanced westerly surface winds in the Southern Hemisphere (discussed in Chapter 12) will lead to enhanced wave generation in that region by the end of the 21st century.

A number of dynamical wave-projection studies have been carried out with a regional focus. For the Mediterranean Sea, Lionello et al. (2008; 2010) projected a widespread shift of the wave-height distribution to lower values by the mid-21st century under an SRES A1B scenario, implying a decrease in mean and extreme wave heights. Caires et al. (2008) and Debernard and Røed (2008) reported a decrease (4–6% of present values) in the annual 99th percentile SWH south of Iceland by the end of the 21st century, and an increase (6–8%) along the North Sea east coast (SRES A2, B2, A1B scenarios). Grabemann and Weisse (2008) (Grabemann and Weisse, 2008) found increases (up to 18% of present values) in annual 99th percentile SWH in the North Sea by the end of the 21st century, with an increase in the frequency of extreme wave events over large areas of the southern and eastern North Sea (SRES A2, B2 scenarios). Charles et al. (2012) projected a general decrease in wave heights in the Bay of Biscay by the end of the 21st century (SRES A2, A1B, B1 scenarios), accompanied by clockwise rotations in winter swell (attributed to a projected northward shift in North Atlantic storm tracks) and summer sea and intermediate waves (attributed to a projected slackening of westerly winds). Along the Portuguese coast, Andrade et al. (2007) found little projected change in SWH and a tendency for a more northerly wave direction than present (SRES A2 scenario).

In the Pacific, multi-model projections by Graham et al. (2013) (SRES A2 scenario) indicate a decrease in boreal winter upper-quantile SWHs over the mid-latitude North Pacific by the end of the 21st century associated with a projected decrease in wind speeds along the southern flank of the main westerlies. There is a less robust tendency for higher extreme waves at higher latitudes. On the southeastern Australian coast, Hemer et al. (2012b) used multi-model projections (SRES A2 and B1 scenarios) to identify a decrease in mean SWH (<0.2 m) by the end of the 21st century compared to present due to a projected decrease in regional storm wave energy, and a shift to a more southerly wave direction, consistent with a projected southward shift of the sub-tropical ridge in the forcing fields.

[INSERT FIGURE 13.26 HERE]

Figure 13.26: Projected changes in wind-wave conditions (~2075–2100 compared with ~1980–2009) derived from the Coordinated Ocean Wave Climate Projection (COWCLIP) Project (Hemer et al., 2013). (a) Percentage difference in annual mean significant wave height. (b) Percentage difference in January-March mean significant wave height. (c) Percentage difference in July-September mean significant wave height. Hashed regions indicate projected change is greater than the 5-member ensemble standard deviation. (d) As for (a), but displaying absolute changes in mean wave direction, with positive values representing projected clockwise rotation relative to displayed vectors, and colours shown only where ensemble members agree on sign of change. (e) As for (a), but displaying absolute changes in mean wave period. The symbol ~ is used to indicate that the reference periods differ slightly for the various model studies considered.

13.8 Synthesis and Key Uncertainties

There has been significant progress in our understanding of sea level change since the AR4. Paleo data now provide *high confidence* that sea levels were substantially higher when greenhouse gas concentrations were higher or surface temperatures were warmer than pre-industrial. The combination of paleo sea level data and long tide gauge records confirms that the rate of rise has increased from low rates of change during the late Holocene (order tenths of mm yr^{-1}) to rates of almost 2 mm yr^{-1} averaged over the 20th century, with a *likely* continuing acceleration during the 20th century (Figure 13.27). Since 1993, the sum of observed contributions to sea level rise are in good agreement with the observed rise.

[INSERT FIGURE 13.27 HERE]

Figure 13.27: Compilation of paleo sea level data, tide gauge data, altimeter data (from Figure 13.3), and central estimates and likely ranges for projections of global-mean sea level rise for RCP2.6 (blue) and RCP8.5 (red) scenarios (Section 13.5.1), all relative to pre-industrial values.

Understanding of the components that contribute to total sea level rise have improved significantly. For the 20th century, the range from an ensemble of such process-based models encompasses the observed rise when allowances are made for lack of inclusion of volcanic forcing in AOGCM control simulations, natural climate variability, and a possible small long-term ice-sheet contribution. Ice-sheet contributions to the 20th century sea level rise were small, however, and this agreement is thus not an evaluation of ice-sheet models. Nevertheless, there has been significant improvement in accounting for important physical processes in ice-sheet models, particularly of the dynamic response of individual glacier systems to warmer ocean waters in the immediate vicinity of the outlet glaciers. While there are as yet no complete simulations of regional ocean temperature changes and of the ice-sheet response to realistic climate change forcing, the publications to date have allowed an assessment of the *likely* range of sea level rise for the 21st century (Figure 13.27).

These observations, together with our current scientific understanding and projections of future climate and sea level, imply that it is *virtually certain* that sea level will continue to rise during the 21st century and beyond. For the first few decades of the 21st century, regional sea level change will be dominated by climate variability superimposed on the climate change signal. For all scenarios, the rate of 21st century GMSL rise is *very likely* to exceed the average rate during the 20th century. For the RCP8.5 scenario, the projected rate of GMSL rise by the end of the 21st century will approach average rates experienced during the deglaciation of the Earth after the Last Glacial Maximum. These rates imply a significant transfer of mass from the ice sheets to the oceans and associated regional departures of sea level rise from the global average, in addition to the regional patterns from changing atmosphere-ocean interactions.

Sea level rise has already led to a significant increase in the return frequency of extreme high sea levels at many locations, and this will continue during the 21st century, although there is *low confidence* in projections of changes in storminess. The first assessment of surface waves indicates a *likely* increase in the height of waves in the Southern Ocean.

Despite this progress, significant uncertainties remain, particularly related to the magnitude and rate of the ice-sheet contribution for the 21st century and beyond, the regional distribution of sea level rise, and the regional changes in storm frequency and intensity. For coastal planning, sea level rise needs to be considered in a risk management framework, requiring knowledge of the frequency of sea level variability (from climate variability and extreme events) in future climates, projected changes in mean sea level, and the uncertainty of the sea level projections (Hunter, 2010, 2012), as well as local issues such as the compaction of sediments in deltaic regions and the changing supply of these sediments to maintain the height of the deltas (Syvitski et al., 2009). While improved understanding has allowed the projection of a *likely* range of sea level rise during the 21st century, it has not been possible to quantify a very likely range or give an upper bound to future rise. The potential collapse of ice shelves, as observed on the Antarctic Peninsula (Rignot et al., 2004; Scambos et al., 2004; Rott et al., 2011), could lead to a larger 21st century rise of up to several tenths of a meter.

Sea level will continue to rise for centuries, even if greenhouse gas concentrations are stabilised, with the amount of sea level rise dependent on future greenhouse gas emissions. For higher emission scenarios and warmer temperatures, surface melting of the Greenland Ice Sheet is projected to exceed accumulation, leading to its long-term decay and a sea level rise of metres, consistent with paleo sea level data.

Review Editors: Jean Jouzel (France), Roderik van de Wal (Netherlands), Philip L. Woodworth (UK), Cunde Xiao (China)

Date of Draft: 7 June 2013

Figures

Figure 13.1: Climate sensitive processes and components that can influence global and regional sea level and are considered in this chapter. Changes in any one of the components or processes shown will result in a sea level change. The term ‘ocean properties’ refers to ocean temperature, salinity and density, which influence and are dependent on ocean circulation. Both relative and geocentric sea level vary with position. Note that the geocenter is not shown.

Figure 13.2: Schematic representation of key linkages between processes and components that contribute to sea level change and are considered in this report. Colouring of individual boxes indicates the types of models and approaches used in projecting the contribution of each process or component to future sea level change. The diagram also serves as an index to the sections in this report that are relevant to the assessment of sea level projections via the section numbers given at the bottom of each box. Note gravity and solid Earth effects change the shape of the ocean floor and surface and thus are required to infer changes in ocean water volume from both relative and geocentric sea level observations.

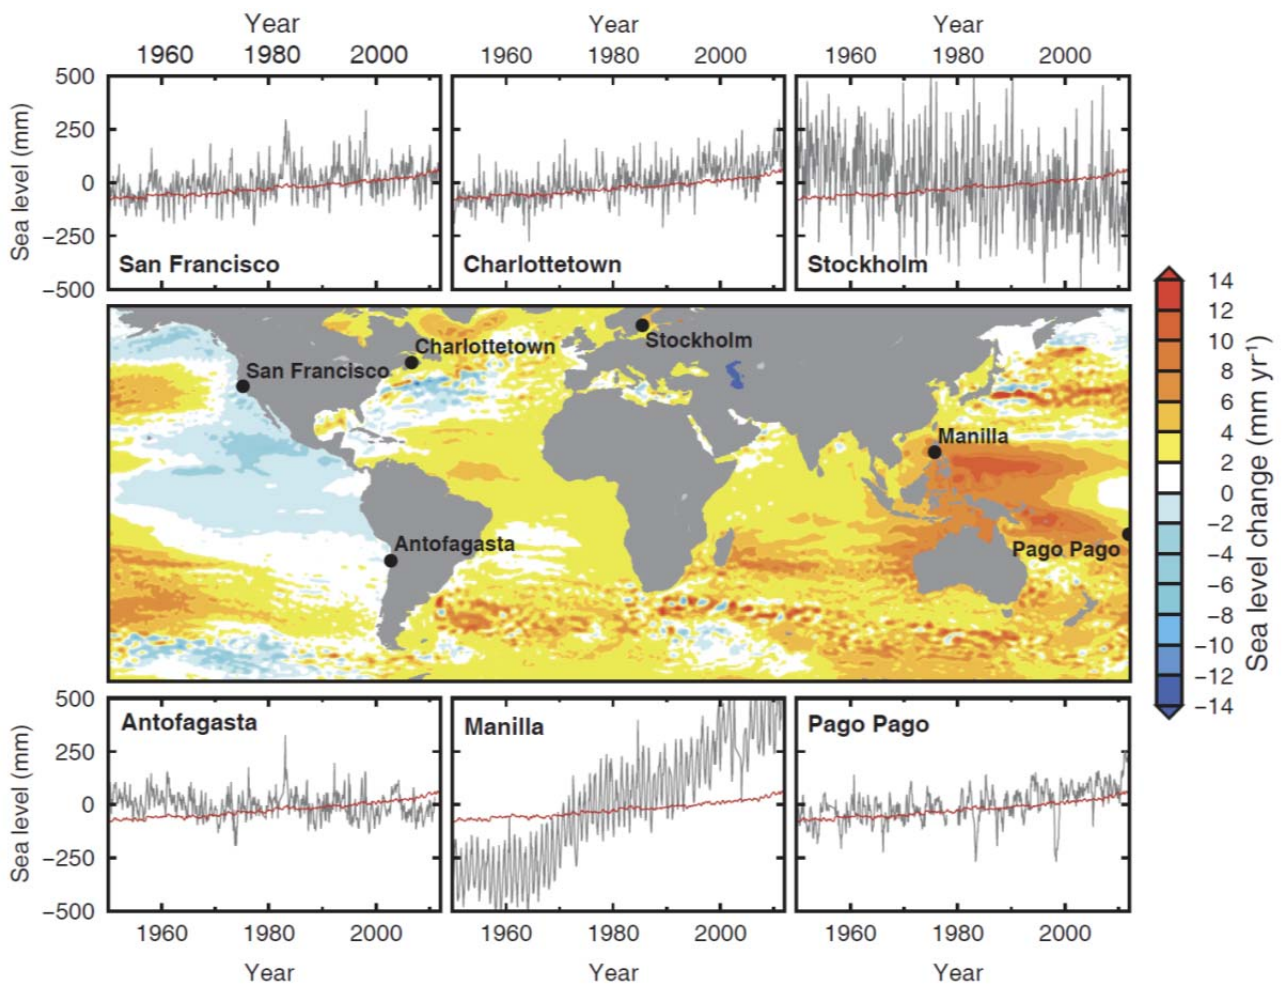

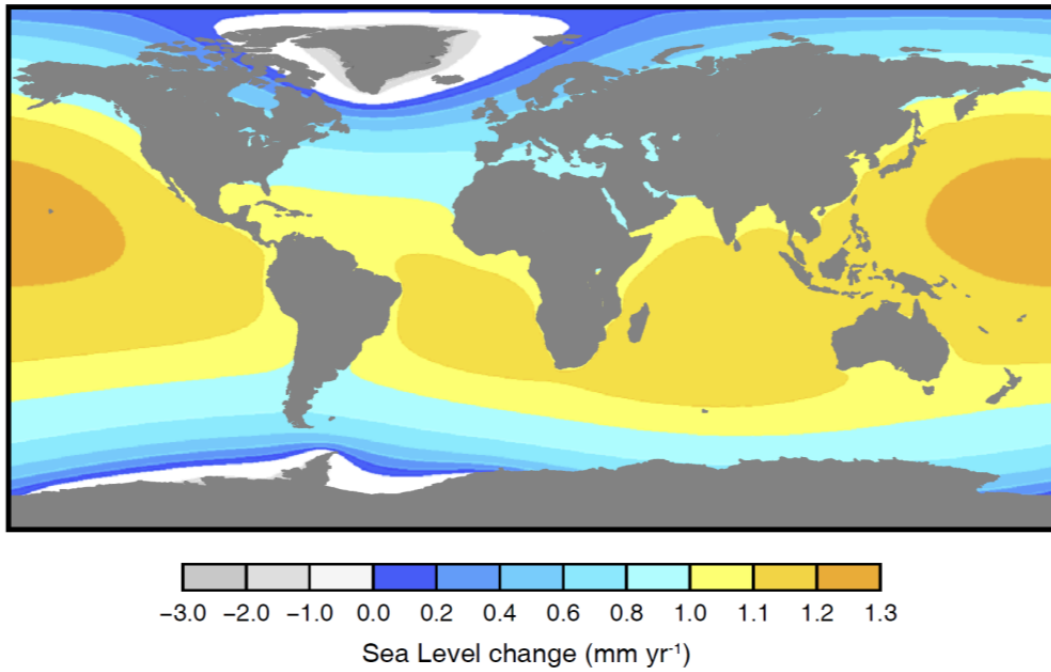

Figure 13.3: (a) Paleo sea level data for last 3000 years from Northern and Southern Hemisphere sites. The effects of glacial isostatic adjustment (GIA) have been removed from these records. Light green = Iceland (Gehrels et al., 2006), purple = Nova Scotia (Gehrels et al., 2005), bright blue = Connecticut (Donnelly et al., 2004), blue = Nova Scotia (Gehrels et al., 2005), red = United Kingdom (Gehrels et al., 2011), green = North Carolina (Kemp et al., 2011), brown = New Zealand (Gehrels et al., 2008), gray = mid-Pacific Ocean (Woodroffe et al., 2012). (b) Paleo sea level data from salt marshes since 1700 from Northern and Southern Hemisphere sites compared to sea level reconstruction from tide gauges (blue time series with uncertainty) (Jevrejeva et al., 2008). The effects of GIA have been removed from these records. Green and light green = North Carolina (Kemp et al., 2011), orange = Iceland (Gehrels et al., 2006), purple = New Zealand (Gehrels et al., 2008), dark green = Tasmania (Gehrels et al., 2012), brown = Nova Scotia (Gehrels et al., 2005). (c) Yearly average GMSL reconstructed from tide gauges (1900–2010) by three different approaches. Orange from Church and White (2011), blue from Jevrejeva et al. (2008), green from Ray and Douglas (2011) (see Section 13.7). (d) Altimetry data sets from five groups (CU, NOAA, GSFC, AVISO, CSIRO) with mean of the five shown as bright blue line (see Section 13.7). (e) Comparison of the paleo data from salt marshes (purple symbols, from panel b), with tide gauge and altimetry data sets (same line colors as in panels c and d). All paleo data were shifted by mean of 1700–1850 derived from the Sand Point, North Carolina data. The Jevrejeva et al. (2008) tide gauge data were shifted by their mean for 1700–1850; other two tide gauge data sets were shifted by same amount. The altimeter time series has been shifted vertically upwards so that their mean value over the 1993–2007 period aligns with the mean value of the average of all three tide gauge time series over the same period.

FAQ13.1, Figure 1: Map of rates of change in sea surface height (geocentric sea level) for the period 1993–2012 from satellite altimetry. Also shown are relative sea level changes (grey lines) from selected tide gauge stations for the period 1950–2012. For comparison, an estimate of global mean sea level change is also shown (red lines) with each tide gauge time series. The relatively large, short-term oscillations in local sea level (grey lines) are due to the natural climate variability described in the main text. For example, the large, regular deviations at Pago Pago are associated with the El Niño-Southern Oscillation.

FAQ13.1, Figure 2: Model output showing relative sea level change due to melting of the Greenland Ice Sheet and the West Antarctic Ice Sheet at rates of 0.5 mm yr⁻¹ each (giving a global mean value for sea level rise of 1 mm yr⁻¹). The modelled sea level changes are less than the global mean value in areas near the melting ice but enhanced further afield. Adapted from Milne et al. (2009).

Figure 13.4: Comparison of modelled and observed components of global mean sea level change since 1900. Changes in glaciers, ice sheets and land water storage are shown as positive sea level rise when mass is added to the ocean. (a) Ocean thermal expansion. Individual CMIP5 AOGCM simulations are shown in grey, the AOGCM average is black, observations in teal with the 5–95% uncertainties shaded. (b) Glaciers (excluding Antarctic peripheral glaciers). Model simulations by Marzeion et al. (2012a) with input from individual AOGCMs are shown in grey with the average of these results in bright purple. Model simulations by Marzeion et al. (2012a) forced by observed climate are shown in light blue. The observational estimates by Cogley (2009b) are shown in green (dashed) and by Leclercq et al. (2011) in red (dashed). (c) Changes in land water storage (yellow/orange, the sum of groundwater depletion and reservoir storage) start at zero in 1900. The Greenland Ice sheet (green), the Antarctic Ice Sheet (blue) and the sum of the ice-sheets (red), start at zero at the start of the record 1991. (d) The rate of change (19 year centred trends) for the terms in (a) to (c), and for the ice sheets (5 year centred trends). All curves in (a) and (b) are shown with zero time-mean over the period 1986–2005 and the colours in (d) are matched to earlier panels. Updated from Church et al. (2013).

Figure 13.5: Annual-mean surface mass balance (accumulation minus ablation) for the Greenland Ice Sheet, simulated by regional climate models for the period 1960–2010.

Figure 13.6: Global mean sea level from altimetry from 2005 to 2012 (blue line). Ocean mass changes are shown in green (as measured by GRACE) and thermosteric sea level changes (as measured by Argo) are shown in red. The black line shows the sum of the ocean mass and thermosteric contributions (updated from Boening et al. (2012)).

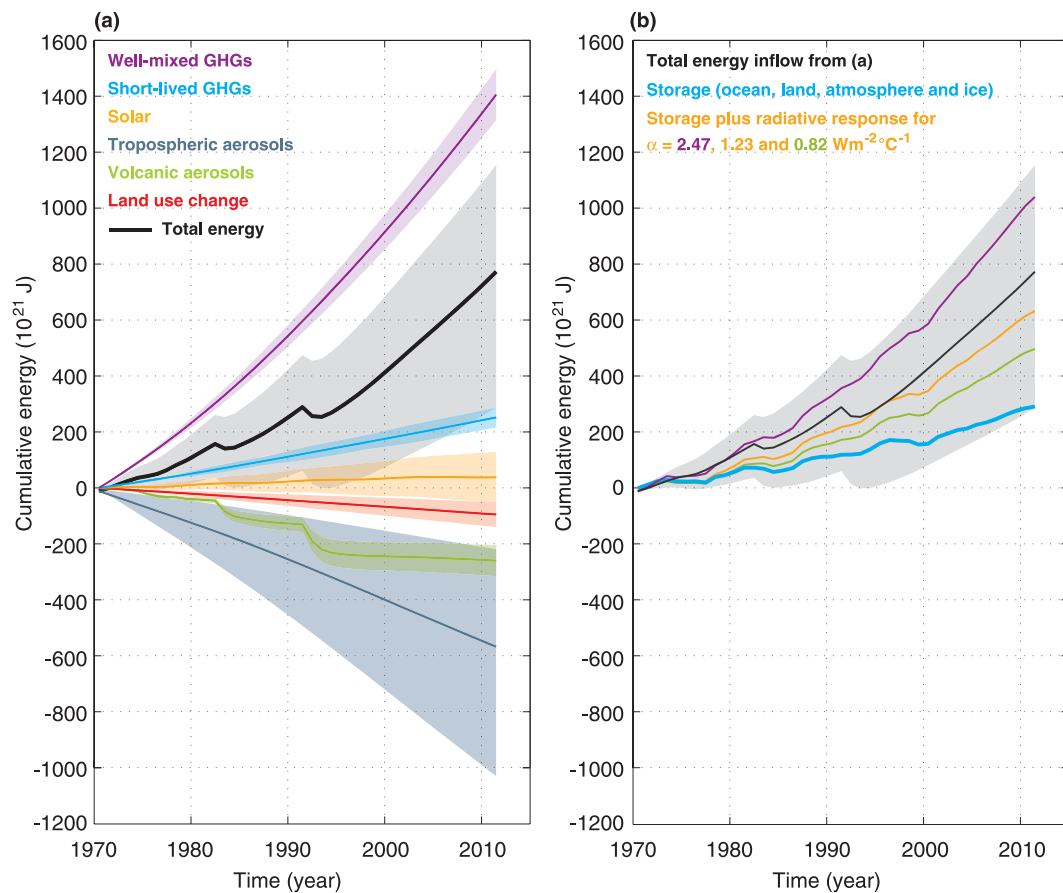

Figure 13.7: Comparison of the observed global mean sea level rise with the sum of the modelled contributions from ocean thermal expansion, glaciers (excluding glaciers peripheral to the Antarctic ice sheet; from Marzeion et al. (2012a)) and changes in land-water storage. In panels (a)-(d): the grey lines are results for individual CMIP5 AOGCMs; the black line is the model mean plus a correction for the omission of volcanic forcing in the AOGCM control experiments (see Section 13.3.1.2); the adjusted model mean (dashed black line) is the sum of the corrected model mean thermal expansion, the change in land-water storage, the Marzeion et al. (2012a) glacier estimate using observed (rather than modelled) climate, and an illustrative long-term ice-sheet contribution (of 0.1 mm yr^{-1}); the adjusted model mean including the observed ice sheet contribution (dotted black line) begins in 1993 and includes the ice-sheet contributions (from Section 4.4), but excludes the glaciers peripheral to the both the Greenland Ice Sheet and the Antarctic Ice Sheet, to avoid double counting because the observational ice-sheet estimates include the peripheral glaciers; the estimates of global mean sea level are from Church and White (2011), Ray and Douglas (2011) and Jevrejeva et al. (2008), with the shading indicating the uncertainty estimates (two standard deviations); the satellite altimeter data since 1993 are shown in red. The modelled sea level is given (a) for the period 1900 to 2010, (b) the rates of sea level change for the same period, with the satellite altimeter data shown as a red dot for the rate, (c) for 1961 to 2010 and (d) for 1990 to 2010. Panel (e) compares the sum of the observed contributions (orange) and the observed sea level from the satellite altimeter data (red). (Figure and caption updated from Church et al. (2013))

Box 13.1, Figure 1: The Earth's energy budget from 1970 through 2011. (a) The cumulative energy flux into the Earth system from changes in well-mixed and short-lived greenhouse gases, solar forcing, changes in tropospheric aerosol forcing, volcanic forcing and surface albedo, (relative to 1860–1879) are shown by the coloured lines and these are added to give the cumulative energy inflow (black; including black carbon on snow and combined contrails and contrail induced cirrus, not shown separately). (b) The cumulative total energy inflow from (a), (black) is balanced by the sum of the warming of the Earth system (blue; energy absorbed in warming the ocean, the atmosphere and the land and in the melting of ice) and an increase in outgoing radiation inferred from changes in the global averaged surface temperature. The sum of these two terms is given for a climate feedback parameter α of 0.82, 1.23 and 2.47 $\text{W m}^{-2} \text{ } ^\circ\text{C}^{-1}$, (corresponding to an equilibrium climate sensitivity of 4.5, 3.0 and 1.5 $^\circ\text{C}$). The energy budget would be closed for a particular value of α if that line coincided with the total energy inflow. For clarity, all uncertainties (shading) shown are for a likely range.

Figure 13.8: Heat uptake by the climate system during the 21st century relative to 1986–2005 projected by CMIP5 AOGCMs under RCP scenarios ($1 \text{ YJ} = 10^{24} \text{ J}$). The heat uptake is diagnosed by two different methods. The thick solid lines, and the coloured ranges for RCP2.6 and RCP8.5, are the time- and global integral of the net downward radiative flux perturbation at the top of the atmosphere, from the 21 AOGCMs used to make the global mean sea level projections (in some cases estimated from other scenarios, as described in the Supplementary Material). The broken solid lines, and the thin solid lines delimiting ranges for RCP2.6 and RCP8.5, are the global volume integral of ocean temperature change, in a smaller and different set of AOGCMs for each scenario. The difference between the two diagnoses is due partly to the different sets of models (which is a consequence of diagnostics available in the CMIP5 dataset), and partly to heat uptake in other parts of the simulated climate system than the ocean water. In both methods, climate drift in the pre-industrial control run has been subtracted.

Figure 13.9: Time series plots for process-based model projections of sea level contributions from global glaciers (in mm), including peripheral glaciers surrounding the Greenland Ice Sheet but excluding the glaciers surrounding the Antarctic Ice Sheet. Projections are grouped by forcing scenario as indicated on the plots. Results are plotted for a common time interval of 2011 to 2099. Colors correspond to particular model analyses: red = Marzeion et al. (2012a); blue = Slangen and van de Wal (2011); green = Radić et al. (2013); black = Giesen and Oerlemans (2013). Individual AOGCM model projections are plotted for each analysis, so the ranges of the curves at 2099 are different than those listed in Table 13.3, where 5–95% confidence limits are shown. In the panel showing results for RCP6.0 and A1B forcings, only Geisen and Oerlemans (black lines) use the A1B forcing.

Box 13.2, Figure 1: Schematic of the processes leading to the potentially unstable retreat of a grounding line showing (a) geometry and ice fluxes of a marine ice sheet, (b) the grounding line in steady state, (c) climate change triggering mass outflow from the ice sheet and the start of grounding line retreat, and (d) self-sustained retreat of the grounding line.

FAQ 13.2, Figure 1: Illustrative synthesis of projected changes in SMB and outflow by 2100 for (a) Greenland and (b) Antarctic ice sheets. Colours shown on the maps refer to projected SMB change between 1990–2009 and 2079–2098 using the RACMO2 regional climate model under scenarios A1B (Antarctic) and RCP4.5 (Greenland) AOGCMs. For Greenland, average equilibrium line altitudes during both these time periods are shown in purple and green, respectively. Ice perimeter and grounding lines are shown as black lines, as are ice sheet sectors. For Greenland, results of flow-line modelling for four major outlet glaciers are shown as inserts, while for Antarctica the coloured rings reflect projected change in outflow on the basis of a statistical extrapolation of observed trends. The outer and inner radius of each ring indicate the 17th and 83rd percentiles, respectively (scale in upper right); red refers to mass loss (sea level rise) while blue refers to mass gain (sea level fall). Finally, total sea level contribution is shown for each ice sheet (insert located above maps) with light grey referring to SMB (model experiment used to generate the SMB map is shown as a dashed line) and dark grey to outflow. All projections refer to the 17–83% probability range across all scenarios. Data provided by F. M. Nick, C. M. Little, J. H. van Angelen, S. R. M. Ligtenberg, J. T. M. Lenaerts and M. R. van den Broeke.

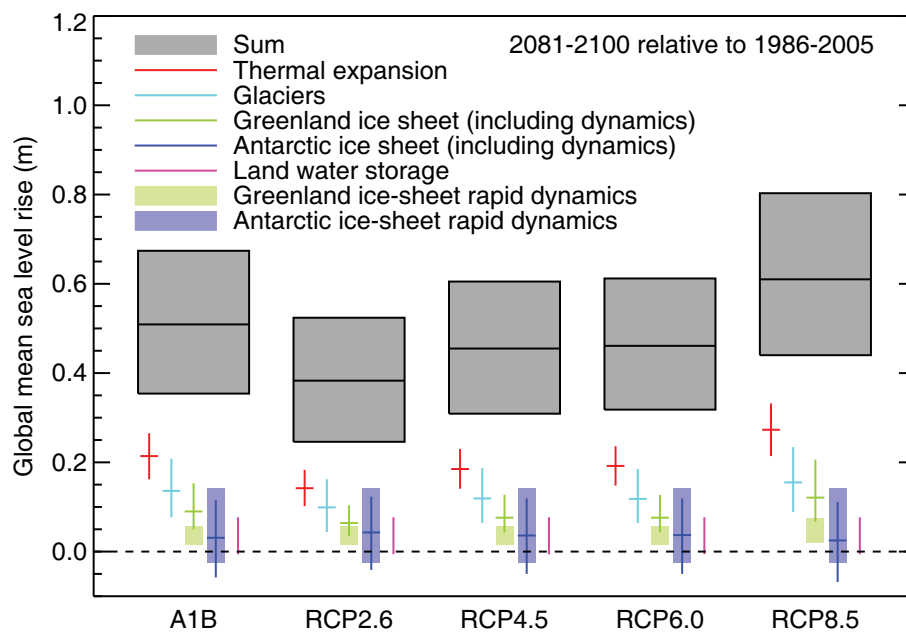

Figure 13.10: Projections from process-based models with likely ranges and median values for global-mean sea level rise and its contributions in 2081–2100 relative to 1986–2005 for the four RCP scenarios and scenario SRES A1B used in the AR4. The contributions from ice sheets include the contributions from ice-sheet rapid dynamical change, which are also shown separately. The contributions from ice-sheet rapid dynamics and anthropogenic land water storage are treated as having uniform probability distributions, and as independent of scenario (except that a higher rate of change is used for Greenland ice-sheet outflow under RCP8.5). This treatment does not imply that the contributions concerned will not depend on the scenario followed, only that the current state of knowledge does not permit a quantitative assessment of the dependence. See discussion in Sections 13.5.1 and 13.5.3 and Supplementary Material for methods. Only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause GMSL to rise substantially above the likely range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise.

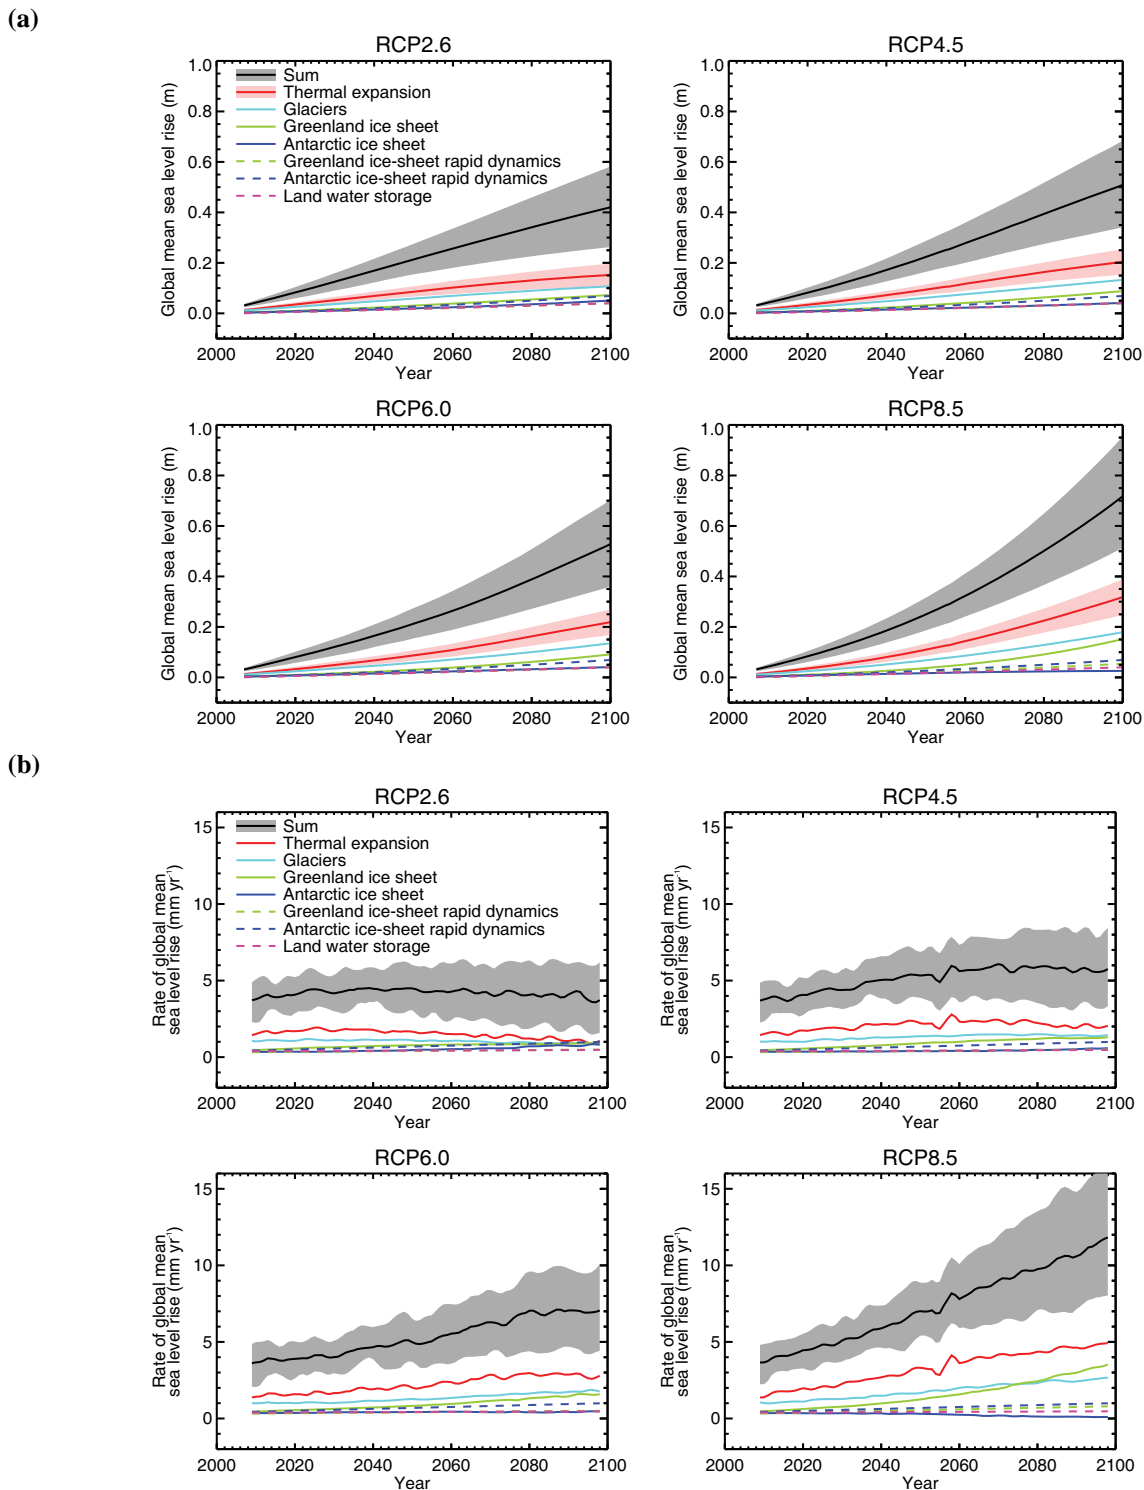

Figure 13.11: Projections from process-based models of (a) GMSL rise relative to 1986–2005 and (b) the rate of GMSL rise and its contributions as a function of time for the four RCP scenarios and scenario SRES A1B. The lines show the median projections. For GMSL rise and the thermal expansion contribution, the likely range is shown as a shaded band. The contributions from ice sheets include the contributions from ice-sheet rapid dynamical change, which are also shown separately. The time series for GMSL rise plotted in (a) are tabulated in Annex II (Table AII.7.7), and the time series of GMSL rise and all its contributions are available in the Supplementary Material. The rates in (b) are calculated as linear trends in overlapping 5-year periods. Only the collapse of the marine-based sectors of the Antarctic Ice Sheet, if initiated, could cause GMSL to rise substantially above the likely range during the 21st century. This potential additional contribution cannot be precisely quantified but there is *medium confidence* that it would not exceed several tenths of a meter of sea level rise.

Figure 13.12: Range (5–95%) for projections of global-mean sea level rise (m) in 2081–2100 relative to 1986–2005 by semi-empirical models for (a) RCP2.6, (b) RCP4.5, (c) RCP6.0, and (d) RCP8.5. Blue bars are results from the models using RCP temperature projections, red bars are using RCP radiative forcing. The numbers on the horizontal axis refer to the literature source of the projection and the sea level reconstruction used for calibration (for studies using RCP temperature projections) or reconstruction of radiative forcing (for studies using RCP radiative forcing). (1) Rahmstorf et al. (2012a), with Kemp et al. (2011); (2) Schaeffer et al. (2012); (3) Rahmstorf et al. (2012a), with Church and White (2006); (4) Rahmstorf et al. (2012a), with Church and White (2011); (5) Rahmstorf et al. (2012a), with Jevrejeva et al. (2008); (6) Grinsted et al. (2010), with Moberg et al. (2005); (7) Jevrejeva et al. (2012a), with Goosse et al. (2005); (8) Jevrejeva et al. (2012a), with Crowley et al. (2003); (9) Jevrejeva et al. (2012a) with Tett et al. (2007). Also shown for comparison is the median (thick black line) and *likely* range (horizontal gray bar) from the process-based projections (Table 13.5), which are assessed as having *medium confidence*, in contrast to SEMs, which are assessed as having *low confidence* (Section 13.5.3).

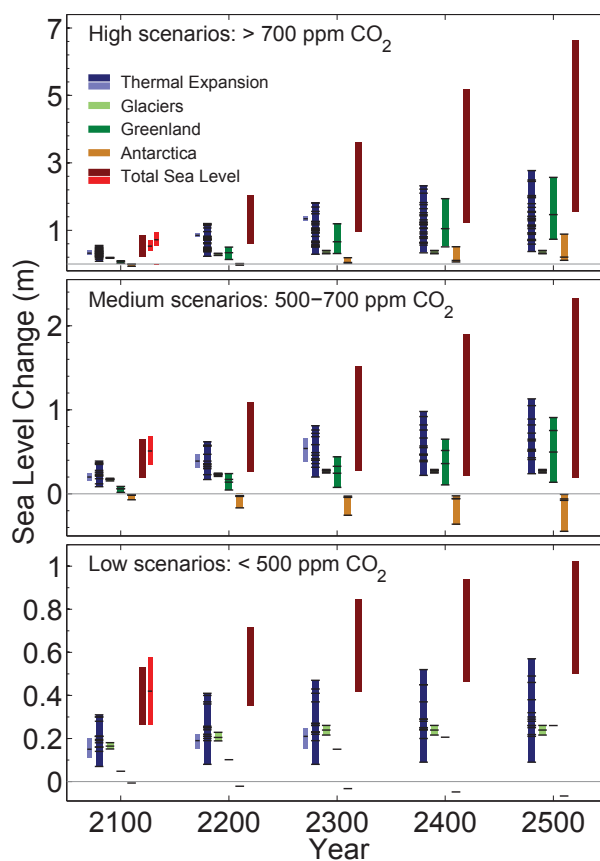

Figure 13.13: Sea level projections beyond the year 2100 are grouped into three categories according to the concentration of GHG concentration (in CO₂-equivalent) in the year 2100 (upper panel: >700 ppm; middle panel: 500–700 ppm; lower panel: <500 ppm). Colored bars show the full model spread. Horizontal lines provide the specific model simulations. The different contributions are given from left to right as thermal expansion, glaciers, Greenland Ice Sheet, Antarctic Ice Sheet and the total contribution. The range provided for the total sea level change represents the maximum possible spread that can be obtained from the four different contributions. Light red shaded bars exhibit the likely range for the 21st century total sea level projection from Figure 13.10 with the median as the horizontal line. Light blue bars provide the model spread of the thermal expansion of the CMIP5 simulations as used for the 21st century projections (Section 13.5.1), with the median indicated by the horizontal bar.

Figure 13.14: Left column: multi-millennial sea level commitment per degree of warming as obtained from physical model simulations of (a) ocean warming, (b) mountain glaciers, (c) the Greenland and (d) the Antarctic ice sheet. (e) The corresponding total sea level commitment, compared to paleo-estimates from past warm periods (PI = pre-industrial, LIG = last interglacial period, M11 = Marine Isotope Stage 11, Plio = Mid-Pliocene). Temperatures are relative to pre-industrial. Dashed lines provide linear approximations in (d) & (e) constant slopes of 1.2, 1.8 and 2.3 m °C⁻¹. Shading as well as the vertical line represents the uncertainty range as detailed in the text. Right column: 2000-year-sea level commitment. The difference in total sea level commitment (j) compared to the fully equilibrated situation (e) arises from the Greenland Ice Sheet which equilibrates on tens of thousands of years. After 2000 years one finds a non-linear dependence on the temperature increase (h) consistent with coupled climate-ice-sheet simulations by Huybrechts et al. (2011) (black dot). The total sea level commitment after 2000 years is quasi-linear with a slope of 2.3 m °C⁻¹.

Figure 13.15: (a) RMS interannual dynamic sea level variability (mm) in a CMIP5 multi-model ensemble (21 models), built from the historically forced experiments during the period 1951–2005; (b) Changes in the ensemble average interannual dynamic sea level variability (std. dev.; in mm) evaluated over the period 2081–2100 relative to the reference period 1986–2005. The projection data (2081–2100) are from the CMIP5 RCP4.5 experiment.

Figure 13.16: (a) Ensemble mean projection of the time-averaged dynamic and steric sea level changes for the period 2081–2100 relative to the reference period 1986–2005, computed from 21 CMIP5 climate models (in m), using the RCP4.5 experiment. The figure includes the globally averaged steric sea level increase of 0.18 ± 0.05 m. (b) RMS spread (deviation) of the individual model result around the ensemble mean (m).

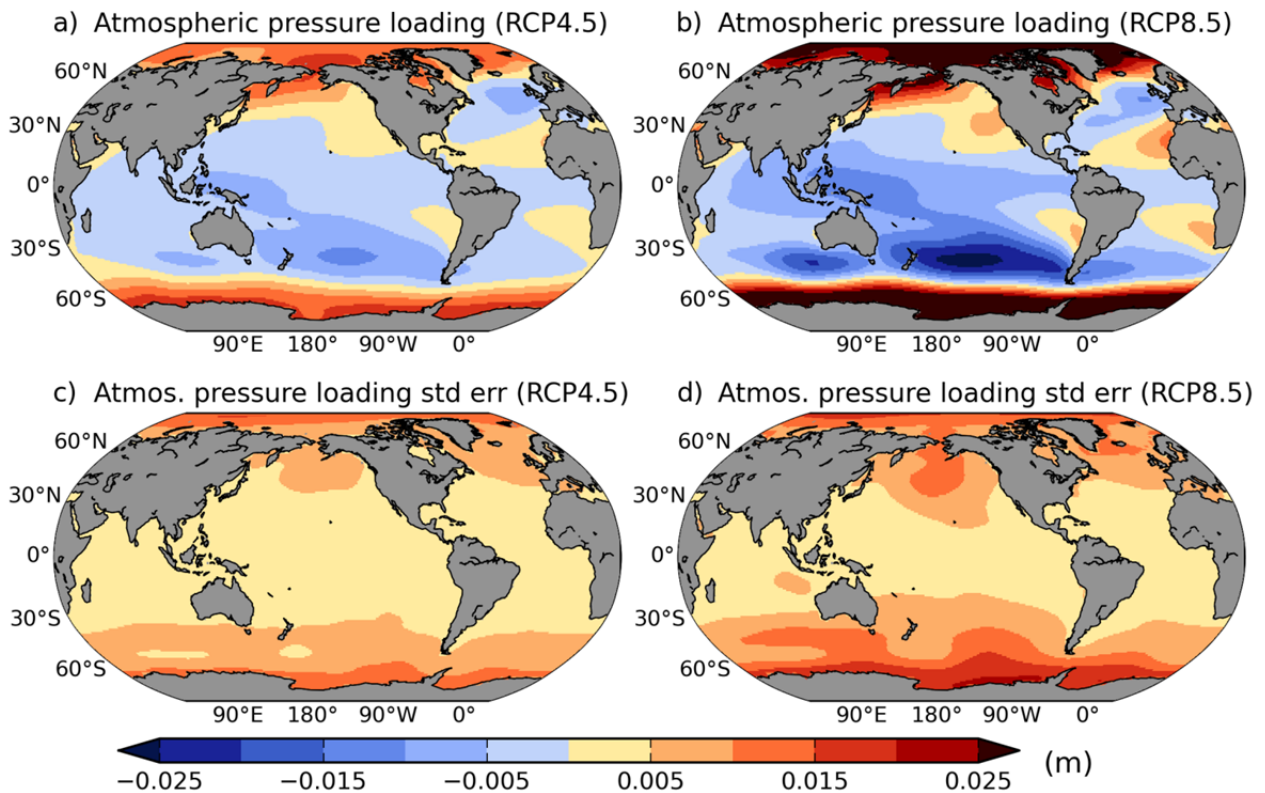

Figure 13.17: Projected ensemble mean sea level change (m) due to changes in atmospheric pressure loading over the period from 1986–2005 to 2081–2100 for (a) RCP4.5 and (b) RCP8.5 (contour interval is 0.01 m). Standard deviation of the model ensemble due to the atmospheric pressure loading for (c) RCP4.5 and (d) RCP8.5 (contour interval is 0.005 m).

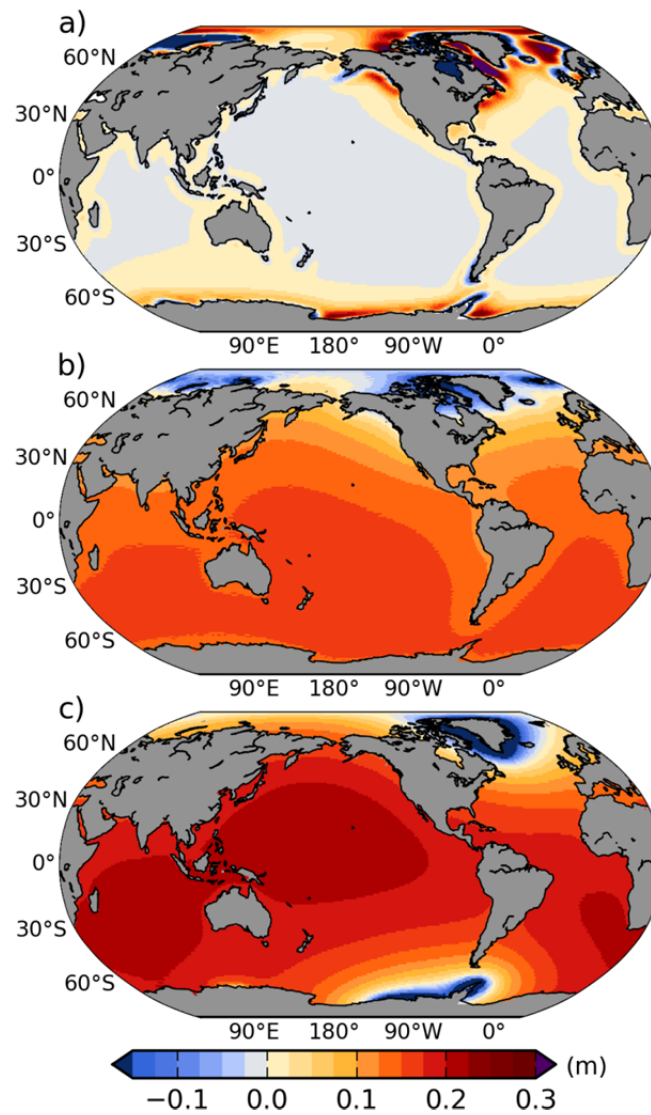

Figure 13.18: Ensemble mean regional contributions to sea level change (m) from (a) GIA, (b) glaciers and (c) ice-sheet SMB. Panels (b) and (c) are based on information available from scenario RCP4.5. All panels represent changes between the periods 1986–2000 and 2081–2100.

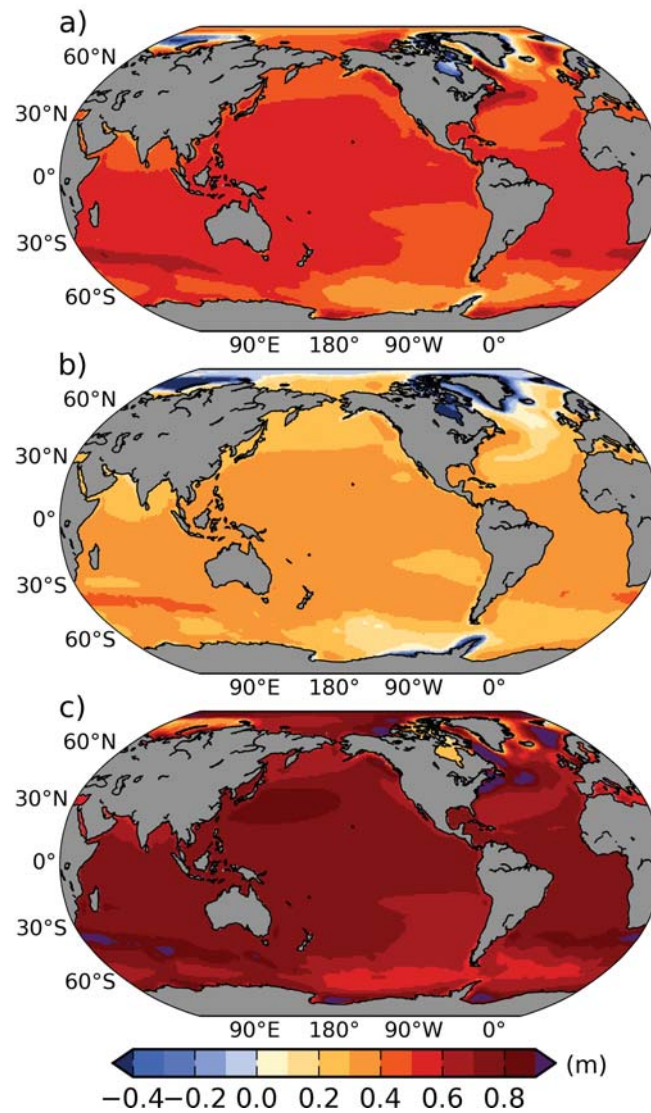

Figure 13.19: (a) Ensemble mean net regional sea level change (m) evaluated from 21 models of the CMIP5 scenario RCP4.5, including atmospheric loading, plus land-ice, GIA and terrestrial water sources, between 1986–2005 and 2081–2100. Global mean is 0.50 ± 0.13 m, with a total range of -1.71 to $+0.83$ m. (b) Lower 90% CL uncertainty bound ($p = 0.05$) for RCP4.5 scenario sea level rise (plus non-scenario components). (c) Upper 90% CL uncertainty bound ($p = 0.95$) for RCP4.5 scenario sea level rise (plus non-scenario components).

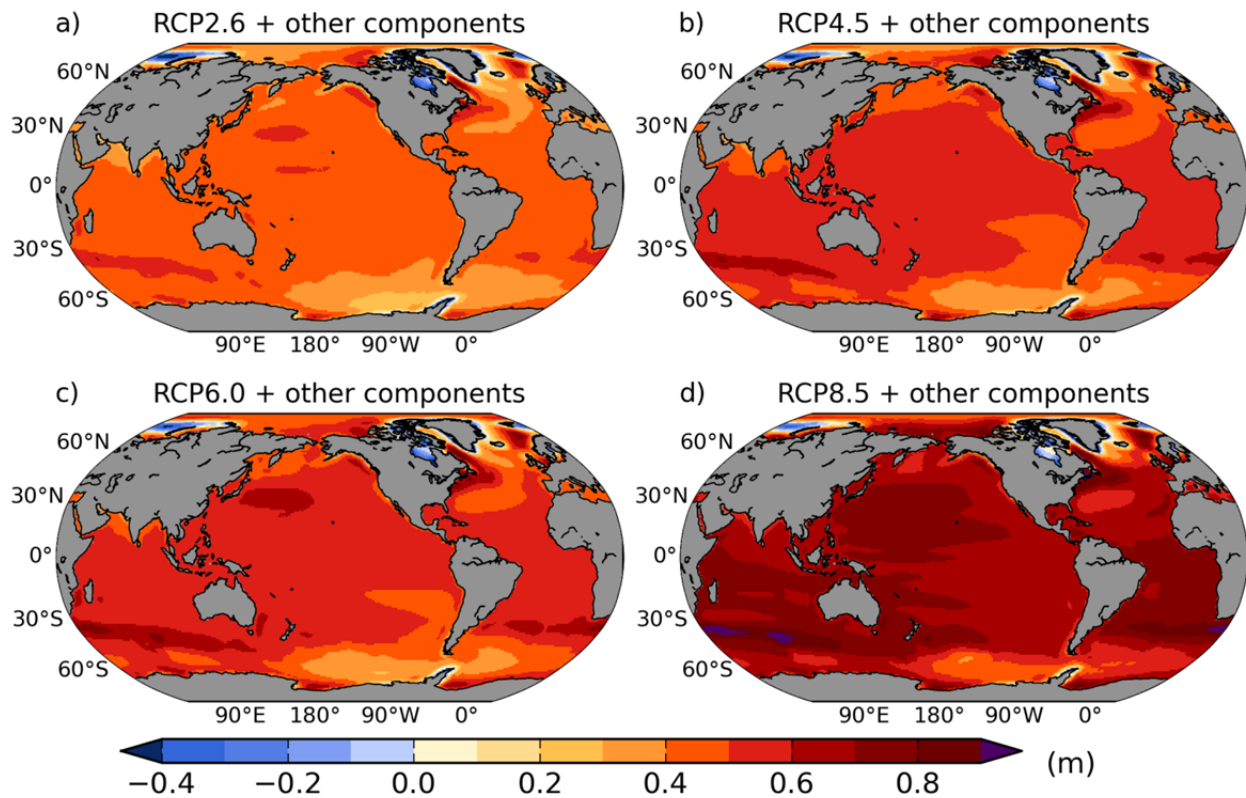

Figure 13.20: Ensemble mean net regional sea level change (m) evaluated from 21 CMIP5 models for the RCP scenarios (a) 2.6, (b) 4.5, (c) 6.0 and (d) 8.5 between 1986–2005 and 2081–2100. Each map includes effects of atmospheric loading, plus land-ice, GIA and terrestrial water sources.

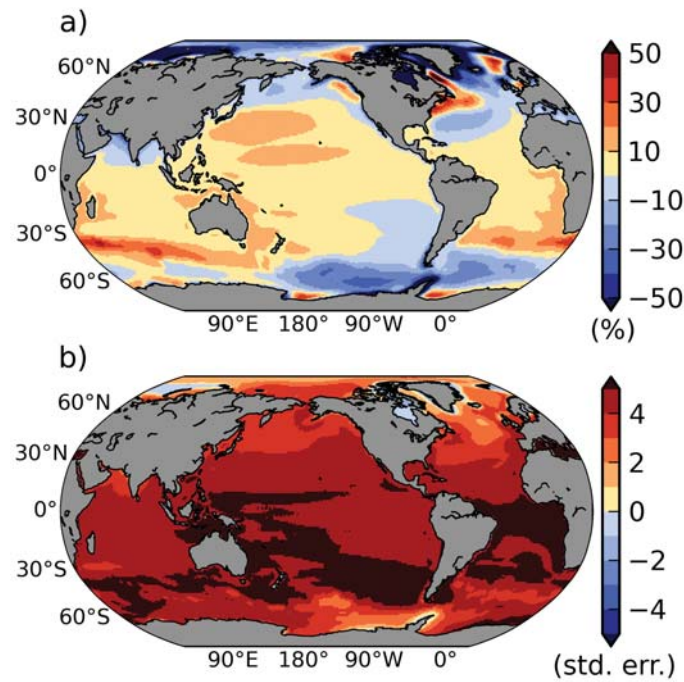

Figure 13.21: (a) Percentage of the deviation of the ensemble mean net regional sea level change between 1986–2005 and 2081–2100 from the global mean value. The figure was computed for RCP4.5, but to first order is representative for all RCPs. (b) Total RCP4.5 sea level change (plus all other components) divided by the combined standard error of all components (see Supplementary Material Section 13.SM.2). Assuming a normal distribution, or a t-distribution given the number of models as an approximation of the number of degrees of freedom, a region passes the 90% confidence level where the change is greater than 2 standard errors, which is most of the ocean except for limited regions around western Antarctica, Greenland, and high Arctic regions.

Figure 13.22: (a) Histograms of the deviation of the ensemble mean net regional sea level change (Figure 13.20) along all coastlines (represented by the closest model grid point) between 1986–2005 and 2081–2100 from the global mean value. Shown are results for RCP4.5 (blue) and RCP8.5 (pink), respectively. (b) Same as in (a) but excluding Antarctic and Greenland coastlines. Vertical dashed lines represent global mean sea level changes for the two RCPs.

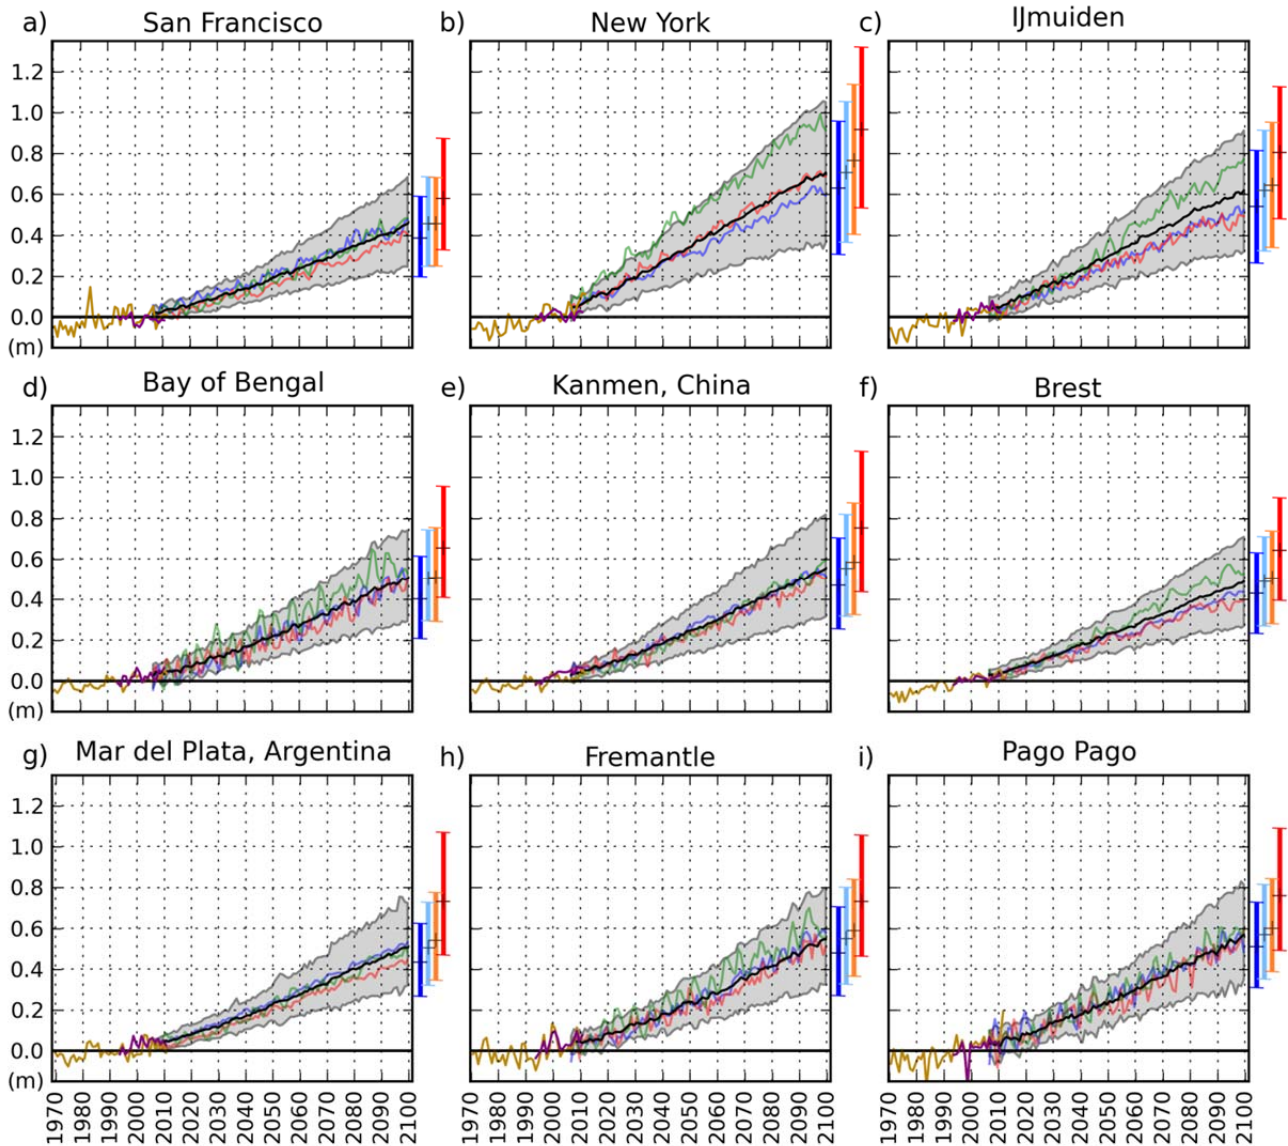

Figure 13.23: Observed and projected relative net sea level change (compare Figure 13.20) near nine representative coastal locations for which long tide-gauge measurements are available. The observed in situ relative sea level records from tide gauges (since 1970) are plotted in yellow, and the satellite record (since 1993) is provided as purple lines. The projected range from 21 CMIP5 RCP4.5 scenario runs (90% uncertainty) is shown by the shaded region for the period 2006–2100, with the bold line showing the ensemble mean. Colored lines represent three individual climate model realizations drawn randomly from three different climate models used in the ensemble. Station locations of tide gauges are: (a) San Francisco: 37.8°N, 122.5°W; (b) New York: 40.7°N, 74.0°W; (c) Ijmuiden: 52.5°N, 4.6°E; (d) Haldia: 22.0°N, 88.1°E; (e) Kanmen, China: 28.1°N, 121.3°E; (f) Brest: 48.4°N, 4.5°W; (g) Mar del Plata, Argentina: 38.0°S, 57.5°W; (h) Fremantle: 32.1°S, 115.7°E; (i) Pago Pago: 14.3°S, 170.7°W. Vertical bars at the right sides of each panel represent the ensemble mean and ensemble spread (5–95%) of the likely (medium confidence) sea level change at each respective location at the year 2100 inferred from the four RCPs 2.6 (dark blue), 4.5 (light blue), 6.0 (yellow), and 8.5 (red).

Figure 13.24: Projected relative sea level change (in m) from the combined global steric plus dynamic topography and glacier contributions for the RCP4.5 scenario over the period from 1986–2005 to 2081–2100 for each individual climate model used in the production of Figure 13.16a.

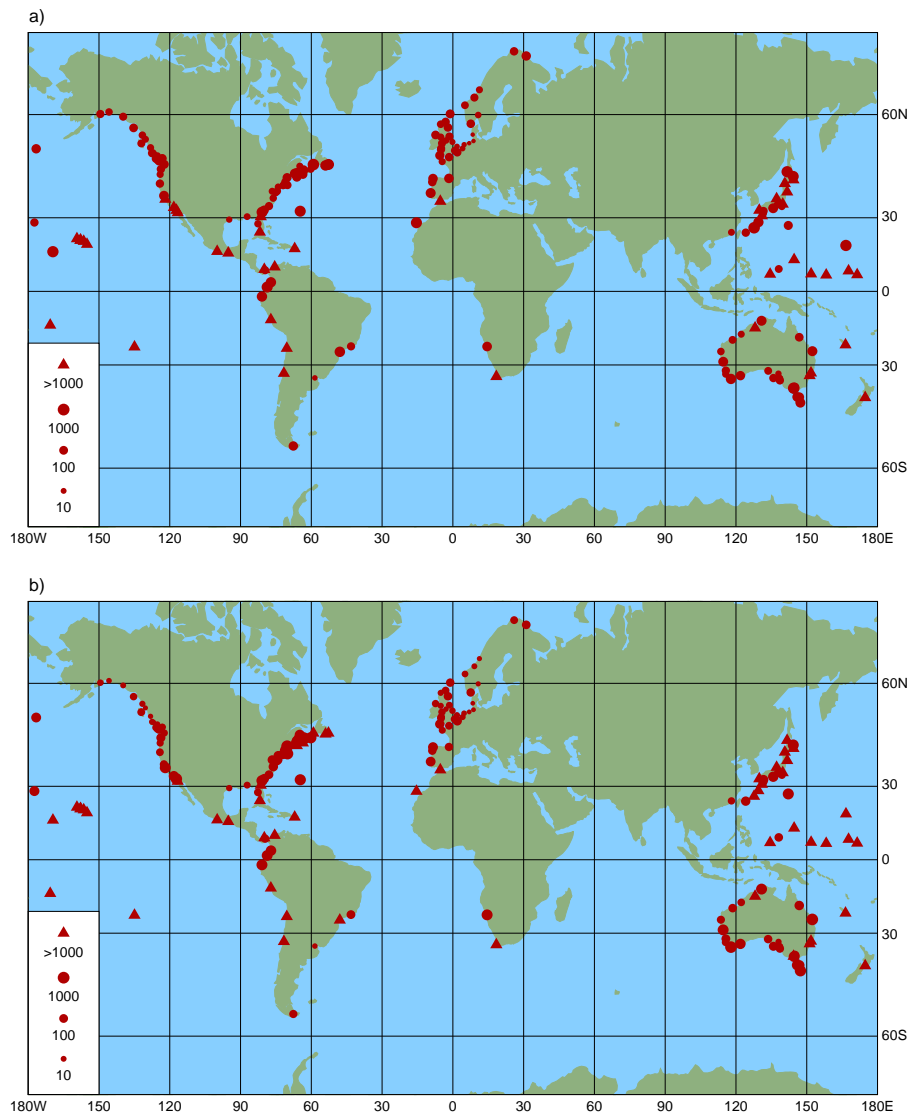

Figure 13.25: The estimated multiplication factor (shown at tide gauge locations by red circles and triangles), by which the frequency of flooding events of a given height increase for (a) a MSL rise of 0.5 m (b) using regional projections of MSL for the RCP4.5 scenario, shown in Figure 13.19a. The Gumbel scale parameters are generally large in regions of large tides and/or surges resulting in a small multiplication factor and vice versa.

Figure 13.26: Projected changes in wind-wave conditions ($\sim 2075\text{--}2100$ compared with $\sim 1980\text{--}2009$) derived from the Coordinated Ocean Wave Climate Projection (COWCLIP) Project (Hemer et al., 2013). (a) Percentage difference in annual mean significant wave height. (b) Percentage difference in January-March mean significant wave height. (c) Percentage difference in July-September mean significant wave height. Hashed regions indicate projected change is greater than the 5-member ensemble standard deviation. (d) As for (a), but displaying absolute changes in mean wave direction, with positive values representing projected clockwise rotation relative to displayed vectors, and colours shown only where ensemble members agree on sign of change. (e) As for (a), but displaying absolute changes in mean wave period. The symbol \sim is used to indicate that the reference periods differ slightly for the various model studies considered.

Figure 13.27: Compilation of paleo sea level data, tide gauge data, altimeter data (from Figure 13.3), and central estimates and likely ranges for projections of global-mean sea level rise for RCP2.6 (blue) and RCP8.5 (red) scenarios (Section 13.5.1), all relative to pre-industrial values.

Executive Summary

This chapter assesses the scientific literature on projected changes in major climate phenomena contingent on global mean temperatures continue to rise and more specifically their relevance for future change in regional climates.

Regional climates are the complex result of processes which vary strongly with location and so respond differently to changes in global-scale influences. The following large-scale climate phenomena are increasingly well-simulated by climate models and so provide a scientific basis for understanding and developing credibility in future regional climate change. A phenomenon is considered relevant to regional climate change if there is confidence¹ that it has influence on the regional climate and there is confidence that the phenomenon will change, particularly under the RCP4.5 or higher end scenarios. [Table 14.3]

Monsoon Systems

There is growing evidence of improved skill of climate models in reproducing climatological features of the global monsoon. Taken together with identified model agreement on future changes, the global monsoon, aggregated over all monsoon systems, is *likely*² to strengthen in the 21st century with increases in its area and intensity, while the monsoon circulation weakens. Monsoon onset dates are *likely* to become earlier or not to change much and monsoon retreat dates are *very likely* to delay, resulting in lengthening of the monsoon season. [14.2.1]

Future increase in precipitation extremes related to the monsoon is *very likely* in South America, Africa, East Asia, South Asia, Southeast Asia and Australia. Lesser model agreement results in *medium confidence* that monsoon-related interannual precipitation variability will increase in the future. [14.2.1, 14.8.5, 14.8.7, 14.8.9, 14.8.11, 14.8.12, 14.8.13]

Model skill in representing regional monsoons is lower compared to the global monsoon and varies across different monsoon systems. There is *medium confidence* that overall precipitation associated with the Asian-Australian monsoon will increase but with a north-south asymmetry: Indian and East Asian monsoon precipitation is projected to increase, while projected changes in Australian summer monsoon precipitation are small. There is *medium confidence* that the Indian summer monsoon circulation will weaken, but this is compensated by increased atmospheric moisture content, leading to more precipitation. For the East Asian summer monsoon, both monsoon circulation and precipitation are projected to increase. There is *medium confidence* that the increase of the Indian summer monsoon rainfall and its extremes throughout the 21st century will be the largest among all monsoons. [14.2.2, 14.8.9, 14.8.11, 14.8.13]

There is *low confidence* in projections of changes in precipitation amounts for the North American and South American monsoons, but *medium confidence* that the North American monsoon will arrive and persist later in the annual cycle, and *high confidence* in expansion of the South American Monsoon area. [14.2.3, 14.8.3, 14.8.4, 14.8.5]

There is *low confidence* in projections of a small delay in the development of the West African rainy season and an intensification of late-season rains. Model limitations in representing central features of the West African monsoon result in *low confidence* in future projections. [14.2.4, 14.8.7]

¹ In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

² In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

Tropical Phenomena

Based on models' ability to reproduce general features of the Indian Ocean Dipole and agreement on future projections, the tropical Indian Ocean is *likely* to feature a zonal (east-west) pattern of change in the future with reduced warming and decreased precipitation in the east, and increased warming and increased precipitation in the west, directly influencing East Africa and Southeast Asia precipitation. [14.3, 14.8.7, 14.8.12]

A newly-identified robust feature in model simulations of tropical precipitation over oceans gives *medium confidence* that annual precipitation change follows a 'warmer-get-wetter' pattern, increasing where warming of sea surface temperature exceeds the tropical mean and vice versa. There is *medium confidence* in projections showing an increase in seasonal-mean precipitation on the equatorial flank of the Inter-Tropical Convergence Zone affecting parts of Central America, the Caribbean, South America, Africa and West Asia despite shortcomings in many models in simulating the Inter Tropical Convergence Zone. There is *medium confidence* that the frequency of zonally-oriented South Pacific Convergence Zone events will increase, with the South Pacific Convergence Zone lying well to the northeast of its average position, a feature commonly reproduced in models that simulate the South Pacific Convergence Zone realistically, resulting in reduced precipitation over many South Pacific island nations. Similarly there is *medium confidence* that the South Atlantic Convergence Zone will shift southwards, leading to an increase in precipitation over south-eastern South America and a reduction immediately north thereof. [14.3, 14.8.4, 14.8.5, 14.8.7, 14.8.11, 14.8.14]

There is *low confidence* in projections of future changes in the Madden-Julian Oscillation due to poor skill in models' ability to simulate it and its sensitivity to ocean warming patterns. The implications for future projections of regional climate extremes in West Asia, South Asia, Southeast Asia and Australia are therefore highly uncertain when associated with the Madden-Julian Oscillation. [14.3, 14.8.10, 14.8.11, 14.8.12, 14.8.13]

There is *low confidence* in the projections for the tropical Atlantic, both for the mean and interannual modes, because of systematic errors in model simulations of current climate. The implications for future changes in Atlantic hurricanes, tropical South American and West African precipitation are therefore uncertain. [14.3, 14.6.1, 14.8.5, 14.8.7]

The realism of the representation of El Niño-Southern Oscillation in climate models is increasing and models simulate on-going El Niño-Southern Oscillation variability in the future. Therefore El Niño-Southern Oscillation *very likely* remains as the dominant mode of interannual variability in the future and due to increased moisture availability, the associated precipitation variability on regional scales *likely* intensifies. An eastward shift in the patterns of temperature and precipitation variations in the North Pacific and North America related to El Niño and La Niña (teleconnections), a feature consistently simulated by models, is *likely* in the future, while other regional implications including those in Central and South America, the Caribbean, Africa, most of Asia, Australia and most Pacific Islands are more uncertain. However, natural modulations of the variance and spatial pattern of El Niño-Southern Oscillation are so large in models that confidence in any specific projected change in its variability in the 21st century remains *low*. [14.4, 14.8.3, 14.8.4, 14.8.5, 14.8.7, 14.8.9, 14.8.11, 14.8.12, 14.8.13, 14.8.14]

Cyclones

Based on process understanding and agreement in 21st century projections, it is *likely* that the global frequency of occurrence of tropical cyclones will either decrease or remain essentially unchanged, concurrent with a *likely* increase in both global mean tropical cyclone maximum wind speed and precipitation rates. The future influence of climate change on tropical cyclones is *likely* to vary by region, but the specific characteristics of the changes are not yet well quantified and there is *low confidence* in region-specific projections of frequency and intensity. However, better process understanding and model agreement in specific regions indicate that precipitation will *likely* be more extreme near the centres of tropical cyclones making landfall in North and Central America, East Africa, West, East, South and Southeast Asia as well as in Australia and many Pacific islands. Improvements in model resolution and downscaling techniques increase confidence in projections of intense storms, and the

frequency of the most intense storms will *more likely than not* increase substantially in some basins. [14.6, 14.8.3, 14.8.4, 14.8.7, 14.8.9, 14.8.10, 14.8.11, 14.8.12, 14.8.13, 14.8.14]

Despite systematic biases in simulating storm tracks, most models and studies are in agreement on the future changes in the number of extra tropical cyclones. The global number of extra-tropical cyclones is *unlikely* to decrease by more than a few per cent. A small poleward shift is *likely* in the Southern Hemisphere storm track. There is *medium confidence* that a projected poleward shift in the North Pacific storm track is *more likely than not*. However, it is *unlikely* that the response of the North Atlantic storm track is a simple poleward shift. There is *low confidence* in the magnitude of regional storm track changes, and the impact of such changes on regional surface climate. It is *very likely* that increases in Arctic, Northern European, North American, and southern hemisphere winter precipitation by the end of the century (2081–2100) will result from more precipitation in extra-tropical cyclones associated with enhanced extremes of storm-related precipitation. [14.6, 14.8.2, 14.8.3, 14.8.5, 14.8.6, 14.8.13 and 14.8.15]

Blocking

Increased ability in simulating blocking in models and higher agreement on projections indicate that there is *medium confidence* that the frequency of Northern and Southern Hemisphere blocking will not increase, while trends in blocking intensity and persistence remain uncertain. The implications for blocking-related regional changes in North America, Europe and Mediterranean and Central and North Asia are therefore also uncertain. [Box 14.2, 14.8.3, 14.8.6, 14.8.8]

Annular and Dipolar Modes of Variability

Models are generally able to simulate gross features of annular and dipolar modes. Model agreement in projections indicate that future boreal wintertime North Atlantic Oscillation is *very likely* to exhibit large natural variations and trends of similar magnitude to those observed in the past and is *likely* to become slightly more positive on average, with some, but not well documented, implications for winter conditions in the Arctic, North America and Eurasia. The austral summer/autumn positive trend in Southern Annular Mode is *likely* to weaken considerably as stratospheric ozone recovers through the mid-21st century with some, but not well documented, implications for South America, Africa, Australia, New Zealand and Antarctica. [14.5.1, 14.5.2, 14.8.2, 14.8.3, 14.8.5, 14.8.6, 14.8.7, 14.8.8, 14.8.13, 14.8.15]

Atlantic Multi-Decadal Oscillation

Multiple lines of evidence from paleo reconstructions and model simulations indicate that the Atlantic Multi-Decadal Oscillation is *unlikely* to change its behaviour in the future as the mean climate changes. However, natural fluctuations in the Atlantic Multi-Decadal Oscillation over the coming few decades are *likely* to influence regional climates at least as strongly as will human-induced changes with implications for Atlantic major hurricane frequency, the West African wet season, North American and European summer conditions. [14.7.6, 14.2.4, 14.6.1, 14.8.3, 14.8.6]

Pacific South American Pattern

Understanding of underlying physical mechanisms and the projected sea surface temperatures in the equatorial Indo-Pacific regions gives *medium confidence* that future changes in the mean atmospheric circulation for austral summer will project on this pattern thereby influencing the South American Convergence Zone and precipitation over southeastern South America. [14.7.2, 14.8.5]

14.1 Introduction

Regional climates are the complex outcome of local physical processes, and the non-local response to large-scale phenomena such as the El Niño-Southern Oscillation (ENSO) and other dominant modes of climate variability. The dynamics of regional climates are determined by local weather systems that control the net transport of heat, moisture, and momentum into a region. Regional climate is interpreted in the widest sense to mean the whole joint probability distribution of climate variables for a region including the time-mean state, the variance and co-variance, and the extremes.

This chapter assesses the physical basis of future regional climate change in the context of changes in the following types of phenomena: *monsoons and tropical convergence zones*, large-scale *modes of climate variability*, and *tropical and extra-tropical cyclones*. Assessment of future changes in these phenomena is based on climate model projections (e.g., the CMIP3 and CMIP5 multi-model ensembles described in Chapter 12) and an understanding of how well such models represent the key processes in these phenomena. More generic processes relevant to regional climate change, such as thermodynamic processes and land-atmosphere feedback processes are assessed in Chapter 12. Local processes such as snow-albedo feedback, moisture feedbacks due to local vegetation, effects of steep complex terrain etc. can be important for changes but are in general beyond the scope of this chapter. The main focus here is on large-scale atmospheric phenomena rather than more local feedback processes or impacts such as floods and droughts.

Sections 14.1.1–14.1.3 introduce the three main classes of phenomena addressed in this assessment and then Section 14.1.4 summarises their main impacts on precipitation and surface temperature. Specific climate phenomena are then addressed in Sections 14.2–14.7, which build on key findings from the Fourth Assessment Report, AR4 (IPCC, 2007a), provide an assessment of process understanding and how well models simulate the phenomenon, and an assessment of future projections for the phenomena. In Section 14.8, future regional climate changes are assessed, and where possible, interpreted in terms of future changes in phenomena. In particular the relevance of the various phenomena addressed in this chapter for future climate change in the regions covered in Annex I are emphasized. The regions are those defined in previous regional climate change assessments (IPCC, 2007a, 2007b, 2012). Regional Climate Models (RCMs) and other downscaling tools required for local impact assessments are assessed in Section 9.6 and results from these studies are used where such supporting information adds additional relevant details to the assessment.

14.1.1 Monsoons and Tropical Convergence Zones

The major monsoon systems are associated with the seasonal movement of convergence zones over land, leading to profound seasonal changes in local hydrological cycles. Section 14.2 assesses current understanding of monsoonal behaviour in the present and future climate, how monsoon characteristics are influenced by the large-scale tropical modes of variability and their potential changes, and how the monsoons in turn affect regional extremes. Convergence zones over the tropical oceans not only play a fundamental role in determining regional climates but also influence the global atmospheric circulation. Section 14.3 presents an assessment of these and other important tropical phenomena.

14.1.2 Modes of Climate Variability

Regional climates are strongly influenced by modes of climate variability (see Box 14.1 for definitions of mode, regime, and teleconnection). This chapter assesses major modes such as El Niño Southern Oscillation (ENSO, Section 14.4), the North Atlantic Oscillation/Northern Annular Mode (NAO/NAM) and Southern Annular Mode (SAM) in the extra-tropics (Section 14.5), and various other well-known modes such as the Pacific North American (PNA), Pacific Decadal Oscillation (PDO), Atlantic Multi-Decadal Oscillation (AMO), etc. (Section 14.7). Many of these modes are described in previous IPCC reports (e.g., Section 3.6 of AR4 WG1). Chapter 2 gives operational definitions of mode indices (Box 2.5, Table 1) and an assessment of observed historical behaviour (Section 2.7.8). Climate models are generally able to simulate the gross features of many of the modes of variability (Section 9.5), and so provide useful tools for understanding how modes might change in the future (Müller and Roeckner, 2008; Handorf and Dethloff, 2009).

Modes and regimes provide a simplified description of variations in the climate system. In the simplest paradigm, variations in climate variables are described by linear projection onto a set of mode indices

(Baldwin et al., 2009; Baldwin and Thompson, 2009; Hurrell and Deser, 2009). For example, a large fraction of interannual variance in Northern Hemisphere sea-level pressure is accounted for by linear combinations of the NAM and the PNA modes (Quadrelli and Wallace, 2004). Alternatively, the non-linear regime paradigm considers the probability distribution of local climate variables to be a multi-modal mixture of distributions related to a discrete set of regimes/types (Palmer, 1999; Cassou and Terray, 2001; Monahan et al., 2001). There is on-going debate on the relevance of the different paradigms (Stephenson et al., 2004; Christiansen, 2005; Ambaum, 2008; Fereday et al., 2008) and care is required when interpreting these constructs (Monahan et al., 2009; Takahashi et al., 2011).

Modes of climate variability may respond to climate change in one or more of the following ways:

- *No change* - the modes will continue to behave as they have done in the recent past.
- *Index changes* - the probability distributions of the mode indices may change (e.g., shifts in the mean and/or variance, or more complex changes in shape such as changes in local probability density e.g., frequency of regimes);
- *Spatial changes* - the climate patterns associated with the modes may change spatially (e.g., new flavours of ENSO, see Section 14.4 and Supplementary Material) or the local amplitudes of the climate patterns may change (e.g., enhanced precipitation for a given change in index (Bulic and Kucharski, 2012));
- *Structural changes* - the types and number of modes and their mutual dependencies may change - completely new modes could in principle emerge.

An assessment of changes in modes of variability can be problematic for several reasons. Firstly, interpretation depends on how one separates modes of variability from forced changes in the time mean or variations in the annual cycle (Pezzulli et al., 2005; Compo and Sardeshmukh, 2010). Modes of variability are generally defined using indices based on either detrended anomalies (Deser et al., 2010b) or anomalies obtained by removing the time mean over a historical reference period (see Box 2.5). The mode index in the latter approach will include changes in the mean, whereas by definition there is no trend in a mode index when it is based on detrended anomalies. Secondly, it can be difficult to separate natural variations from forced responses, for example, warming trends in the N. Atlantic during the 20th century that may be due to trends in aerosol and other forcings rather than natural internal variability (see Sections 14.6.2 and 14.7.1). Finally, modes of climate variability are non-linearly related to one another (Hsieh et al., 2006) and this relationship can change in time (e.g., trends in correlation between ENSO and NAO indices).

Even when the change in a mode of variability index does not contribute greatly to mean regional climate change, a climate mode may still play an important role in regional climate variability and extremes. Natural variations, such as those due to modes of variability, are a major source of uncertainty in future projections of mean regional climate (Deser et al., 2012). Furthermore, changes in the extremes of regional climate are *likely* to be sensitive to small changes in variance or shape of the distribution of the mode indices or the mode spatial patterns (Coppola et al., 2005; Scaife et al., 2008).

14.1.3 Tropical and Extra-Tropical Cyclones

Tropical and extra-tropical cyclones (TCs and ETCs) are important weather phenomena intimately linked to regional climate phenomena and modes of climate variability. Both types of cyclone can produce extreme wind speeds and precipitation (see Section 3.4, SREX (IPCC, 2012)). Sections 14.6.1 and 14.6.2 assess the recent progress in scientific understanding of how these important weather systems are *likely* to change in the future.

14.1.4 Summary of Climate Phenomena and their Impact on Regional Climate

Box 14.1, Figure 1 illustrates the large-scale climate phenomena assessed in this chapter. Many of the climate phenomena are evident in the map of annual mean rainfall (central panel). The most abundant annual rainfall occurs in the tropical convergence zones: ITCZ over the Pacific, Atlantic and African equatorial belt (see Section 14.3.1.1), SPCZ over central South Pacific (see Section 14.3.1.2) and SACZ over Southern South America and Southern Atlantic (see Section 14.3.1.3). In the global monsoon domain (white contours on the map), large amounts of precipitation occur but only in certain seasons (see Section 14.2.1). Local

maxima in precipitation are also apparent over the major storm track regions in mid-latitudes (see Section 14.7.2). Box 14.1 Figure 1 also illustrates surface air temperature (left panels) and precipitation (right panels) teleconnection patterns for ENSO (in December to February and June to August; see Section 14.4), NAO (in December to February; see Section 14.5.1), and SAM (in September to November; see Section 14.5.2). The teleconnection patterns were obtained by taking the correlation between monthly gridded temperature and precipitation anomalies and indices for the modes (see Box 14.1 definitions). It can be seen that all three modes have far-reaching effects on temperature and precipitation in many parts of the world. Box 14.1, Table 1 briefly summarises the main regional impacts of different well-known modes of climate variability.

[START BOX 14.1 HERE]

Box 14.1: Conceptual Definitions and Impacts of Modes of Climate Variability

This box briefly defines key concepts used to interpret modes of variability (below) and summarises regional impacts associated with well-known modes (Box 14.1, Table 1 and Box 14.1, Figure 1). The terms below are used to describe variations in time series variables reported at a set of geographically-fixed spatial locations e.g., a set of observing stations or model grid points (based on the more complete statistical and dynamical interpretation in Stephenson et al. (2004)).

Climate indices

Time series constructed from climate variables that provides an aggregate summary of the state of the climate system. For example, the difference between sea-level pressure in Iceland and the Azores provides a simple yet useful historical NAO index (see Section 14.5 and Box 2.5 for definitions of this and other well-known observational indices). Because of their maximum variance properties, climate indices are often defined using *principal components*.

Principal component

A linear combination of a set of time series variables that has maximum variance subject to certain normalisation constraints. Principal components are widely used to define optimal *climate indices* from gridded datasets (e.g., the AO index defined as the leading principal component of gridded Northern Hemisphere sea-level pressure; Section 14.5).

Climate pattern

A set of coefficients obtained by “projection” (regression) of climate variables at different spatial locations onto a *climate index* time series.

Empirical Orthogonal Function

The *climate pattern* obtained if the *climate index* is a *principal component*. It is an eigenvector of the covariance matrix of gridded climate data.

Teleconnection

A statistical association between climate variables at widely separated, geographically-fixed spatial locations. Teleconnections are caused by large spatial structures such as basin-wide coupled modes of ocean-atmosphere variability, Rossby wave-trains, mid-latitude jets and storm-tracks, etc.

Teleconnection pattern

A correlation map obtained by calculating the correlation between variables at different spatial locations and a climate index. It is the special case of a *climate pattern* obtained for standardised variables and a standardised *climate index* i.e., the variables and index are each centred and scaled to have zero mean and unit variance. One-point teleconnection maps are made by choosing a variable at one of the locations to be the climate index.

Mode of climate variability

Underlying space-time structure with preferred spatial pattern and temporal variation that helps account for the gross features in variance and for *teleconnections*. A mode of variability is often considered to be the product of a spatial *climate pattern* and an associated *climate index* time series.

Climate regime

A set of similar states of the climate system that occur more frequently than nearby states due to either more persistence or more often recurrence. In other words, a cluster in climate state space associated with a local maximum in the probability density function.

[INSERT BOX 14.1, FIGURE 1 HERE]

Box 14.1, Figure 1: Global distribution of average annual rainfall (in cm/year) from 1979–2010 GPCP data base, monsoon precipitation domain (white contours) as defined in Section 14.2.1, and winter storm-tracks in both hemispheres (black arrows). In left (right) column seasonal correlation maps of NAO, SOI (the atmospheric component of ENSO) and SAM mode indexes vs. monthly temperature (precipitation) anomalies in boreal winter (DJF), austral winter (JJA) and austral spring (SON). Black contours indicate a 99% significance level. The mode indexes were taken from NOAA (<http://www.esrl.noaa.gov/psd/data/climateindices/list/>), global temperatures from NASA GISTEMP (<http://data.giss.nasa.gov/gistemp/>) and global precipitations from GPCP (<http://www.esrl.noaa.gov/psd/data/gridded/data.gpcp.html>).

[END BOX 14.1 HERE]**14.2 Monsoon Systems**

Monsoons are a seasonal phenomenon responsible for producing the majority of summer rainfall within the tropics. The precipitation characteristics over The Asian-Australian, American and African monsoons can be viewed as an integrated global monsoon system, associated with a global-scale atmospheric overturning circulation (Trenberth et al., 2000). In Section 14.2.1, changes in precipitation of the global monsoon system are assessed. Changes in regional monsoons are assessed in Sections 14.2.2–14.2.4.

14.2.1 Global Overview

The global *land* monsoon precipitation displays a decreasing trend over the last half-century, with primary contributions from the weakened summer monsoon systems in the Northern Hemisphere (Wang and Ding, 2006). The combined global ocean-land monsoon precipitation has intensified during 1979–2008, mainly due to an upward trend in the Northern Hemisphere summer oceanic monsoon precipitation (Zhou et al., 2008b; Hsu et al., 2011; Wang et al., 2012b). Since the fractional increase in monsoon area is greater than that in total precipitation, the ratio of the latter to former (a measure of the global monsoon intensity) exhibits a decreasing trend (Hsu et al., 2011). CMIP models generally reproduce the observed global monsoon domain, but the disparity between the best and poorest models is large (Section 9.5.2.4).

In the CMIP models the global monsoon area (GMA), the global monsoon total precipitation (GMP), and the global monsoon precipitation intensity (GMI) are projected to increase by the end of the 21st century (2081–2100, Hsu et al., 2013; Kitoh et al., 2013; Figure 14.1). See Supplementary Material Section 14.SM.1.2 for the definitions of GMA, GMP, and GMI. The CMIP5 model projections show an expansion of GMA mainly over the central to eastern tropical Pacific, the southern Indian Ocean, and eastern Asia. In all RCP scenarios, GMA is *very likely* to increase, and GMI is *likely* to increase, resulting in a *very likely* increase in GMP, by the end of the 21st century (2081–2100). The 100-year median changes in GMP are +5%, +8%, +10%, and +16% in RCP2.6, RCP4.5, RCP6.0, and RCP8.5 scenarios, respectively. Indices of precipitation extremes such as simple daily precipitation intensity index (SDII), defined as the total precipitation divided by the number of days with precipitation greater than or equal to 1 mm, annual maximum 5-day precipitation total (R5d), and consecutive dry days (CDD) all indicate that intense precipitation will increase at larger rates than those of mean precipitation (Figure 14.1). The standard deviation of interannual variability in seasonal average precipitation (Psd) is *likely* to increase but some models show a decrease in Psd. This is related to uncertainties in projections of future changes in tropical sea surface temperature (SST). Regarding seasonality, CMIP5 models project that monsoon onset dates will come earlier or not change much while monsoon retreat dates will delay, resulting in a lengthening of the monsoon season.

[INSERT FIGURE 14.1 HERE]

Figure 14.1: (upper) Observed (thick contour) and simulated (shading) global monsoon domain, based on the definition

of Wang et al. (2011). The observations are based on GPCP v2.2 data (Huffman et al., 2009), and the simulations are based on 26 CMIP5 multi-model mean precipitation with a common 2.5 by 2.5 degree grid in the present-day (1986–2005) and the future (2080–2099; RCP8.5 scenario). Orange (dark blue) shading shows monsoon domain only in the present-day (future). Light blue shading shows monsoon domain in both periods. (lower) Projected changes for the future (2080–2099) relative to the present-day (1986–2005) in the global monsoon area (GMA) and global monsoon intensity (GMI), global monsoon total precipitation (GMP), standard deviation of inter-annual variability in seasonal average precipitation (Psd), simple daily precipitation intensity index (SDII), seasonal maximum 5-day precipitation total (R5d), seasonal maximum consecutive dry days (CDD), and monsoon season duration (DUR), under the RCP2.6 (dark blue; 18 models), RCP4.5 (light blue; 24 models), RCP6.0 (orange; 14 models), and RCP8.5 scenarios (red; 26 models). Units are % except for DUR (days). Box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles. All of the indices are calculated for the summer season (May to September in the Northern Hemisphere; November to March in the Southern Hemisphere). The indices of Psd, SDII, R5d, and CDD calculated for each model's original grid, and then averaged over the monsoon domains determined by each model at the present-day. The indices of DUR are calculated for 7 regional monsoon domains based on the criteria proposed by Wang and LinHo (2002) using regionally averaged climatological cycles of precipitation, and then their changes are averaged with weighting based on their area at the present-day.

CMIP5 models show a decreasing trend of lower-troposphere wind convergence (dynamical factor) throughout the 20th and 21st centuries (Figure 14.2d). With increased moisture (see also Section 12.4), the moisture flux convergence shows an increasing trend from 1980 through the 21st century (Figure 14.2c). Surface evaporation shows a similar trend (Figure 14.2b) associated with warmer SSTs. Therefore, the global monsoon precipitation increases (Figure 14.2a) due to increases in moisture flux convergence and surface evaporation despite a weakened monsoon circulation. Besides greenhouse gases, monsoons are affected by changes in aerosol loadings (Ramanathan et al., 2005). The aerosol direct forcing may heat the atmosphere but cools the surface, altering atmospheric stability and inducing horizontal pressure gradients that modulate the large-scale circulation and hence monsoon rainfall (Lau et al., 2008). However, the representation of aerosol forcing differs among models, and remains an important source of uncertainty (Chapter 7 and Section 12.2.2), particularly in some regional monsoon systems.

[INSERT FIGURE 14.2 HERE]

Figure 14.2: Time series of simulated anomalies over the global land monsoon domain for (a) precipitation (mm day^{-1}), (b) evaporation (mm day^{-1}), (c) water vapour flux convergence in the lower (below 500 hPa) troposphere (mm day^{-1}), and (d) wind convergence in the lower troposphere ($10^{-3} \text{ kg m}^{-2} \text{ s}^{-1}$), relative to the present-day (1986–2005), based on CMIP5 multi-model monthly outputs. Historical (grey; 29 models), RCP2.6 (dark blue; 20 models), RCP4.5 (light blue; 24 models), RCP6.0 (orange; 16 models), and RCP8.5 (red; 24 models) simulations are shown in the 10th and 90th percentile (shading), and in all model averages (thick lines).

14.2.2 Asian-Australian Monsoon

The seasonal variation in the thermal contrast between the large Eurasian landmass and the Pacific-Indian Oceans drives the powerful Asian-Australian monsoon (AAM) system (Figure 14.3), which consists of five major subsystems: Indian (also known as South Asian), East Asian, Maritime Continent, Australian, and Western North Pacific monsoons. More than 85% of CMIP5 models show an increase in mean precipitation of the East Asian summer (EAS) monsoon, while more than 95% of models project an increase in heavy precipitation events (Figure 14.4). All models and all scenarios project an increase in both the mean and extreme precipitation in the Indian summer monsoon (referred to as SAS in the figure). In these two regions, the interannual standard deviation of seasonal mean precipitation also increases. Over the Australian-Maritime Continent (AUSMC) monsoon region, agreement among models is low. Figure 14.5 shows the time-series of circulation indices representing EAS, Indian (IND), Western North Pacific (WNP) and Australian (AUS) summer monsoon systems. The Indian monsoon circulation index is *likely* to decrease in the 21st century, while a slight increase in the East Asian monsoon circulation is projected. Scatter among models is large for the western North Pacific and Australian monsoon circulation change.

[INSERT FIGURE 14.3 HERE]

Figure 14.3: Regional land monsoon domain based on 26 CMIP5 multi-model mean precipitation with a common 2.5 by 2.5 degree grid in the present-day (1986–2005). For regional divisions, the equator separates the northern monsoon domains (NAMS, NAF, SAS, and EAS) from the southern monsoon domains (SAMS, SAF, and AUSMC), 60°E separates NAF from SAS, and 20°N and 100°E separates SAS from EAS. All the regional domains are within 40°S to 40°N.

[INSERT FIGURE 14.4 HERE]

Figure 14.4: Changes in precipitation indices over the regional land monsoon domains of (upper) EAS, (middle) SAS, and (lower) AUSMC based on CMIP5 multi-models. (left) Time series of observed and model-simulated summer precipitation anomalies (%) relative to the present-day average. All the time series are smoothed with a 20-year running mean. For the time series of simulations, all model averages are shown by thick lines for the historical (grey; 40 models), RCP2.6 (dark blue; 24 models), RCP4.5 (light blue; 34 models), RCP6.0 (orange; 20 models), and RCP8.5 scenarios (red; 32 models). Their intervals between 10th and 90th percentiles are shown by shading for RCP2.6 and RCP8.5 scenarios. For the time series of observations, CRU TS3.2 (update from Mitchell and Jones, 2005; dark blue), GPCP v6 (Becker et al., 2013; deep green), (Beck et al., 2005; light green), APHRODITE v1101 (Yatagai et al., 2012; only for EAS and SAS regions; light blue), GPCP v2.2 (updated from Huffman et al., 2009; black), and CMAP v1201 (updated from Xie and Arkin, 1997; black with dots) are shown. GPCP v6 with dot line, GPCP VASCLimO, GPCP v2.2 and CMAP v1201 are calculated using all grids for the period of 1901–2010, 1951–2000, 1979–2010, 1979–2010, respectively. CRU TS3.2, GPCP v6 with solid line, and APHRODITE v1101, are calculated using only grid boxes (2.5 degree in longitude/latitude) where at least one observation site exists for more than 80% of the period of 1921–2005, 1921–2005, and 1951–2005, respectively. (right) Projected changes for the future (2080–2099) relative to the present-day average in averaged precipitation (Pav), standard deviation of inter-annual variability in seasonal average precipitation (Psd), simple precipitation daily intensity index (SDII), seasonal maximum 5-day precipitation total (R5d), seasonal maximum consecutive dry days (CDD), monsoon onset date (ONS), retreat date (RET), and duration (DUR), under the RCP2.6 (18 models), RCP4.5 (24 models), RCP6.0 (14 models), and RCP8.5 scenarios (26 models). Units are % in Pav, Psd, SDII, R5d, and CDD; days in ONS, RET, and DUR. Box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles. All of the indices are calculated for the summer season (May to September in the Northern Hemisphere; November to March in the Southern Hemisphere). The indices of Pav, Psd, SDII, R5d, and CDD calculated for each model's original grid, and then averaged over the monsoon domains determined by each model at the present-day. The indices of ONS, RET, and DUR are calculated for 7 regional monsoon domains based on the criteria proposed by Wang and LinHo (2002) using regionally averaged climatological cycles of precipitation.

[INSERT FIGURE 14.5 HERE]

Figure 14.5: Time series of summer monsoon indices (21-year running mean) relative to the base period average (1986–2005). Historical (gray), RCP4.5 (light blue) and RCP8.5 (red) simulations by 39 CMIP5 model ensembles are shown in 10th and 90th (shading), and 50th (thick line) percentile. (a) East Asian summer monsoon (Defined as June–July–August sea level pressure difference between 160°E and 110°E from 10°N to 50°N), (b) Indian summer monsoon (defined as meridional differences of the June–July–August 850 hPa zonal winds averaged over 5°N–15°N, 40°E–80°E and 20°N–30°N, 60°E–90°E), (c) western North Pacific summer monsoon (defined as meridional differences of the June–July–August 850 hPa zonal winds averaged over 5°N–15°N, 100°E–130°E and 20°N–30°N, 110°E–140°E), (d) Australian summer monsoon (defined as December–January–February 850 hPa zonal wind anomalies averaged over 10°S–0°, 120°E–150°E). (See Wang et al. (2004) and Zhou et al. (2009c) for indices definitions).

Factors that limit the confidence in quantitative assessment of monsoon changes include sensitivity to model resolution (Cherchi and Navarra, 2007; Klingaman et al., 2011), model biases (Levine and Turner, 2012; Bollasina and Ming, 2013), poor skill in simulating the MJO (Section 9.1.3.3), uncertainties in projected ENSO changes (Collins et al., 2010; Section 14.4) and in the representation of aerosol effects.

14.2.2.1 Indian Monsoon

The Indian summer monsoon is known to have undergone abrupt shifts in the past millennium, giving rise to prolonged and intense droughts (Meehl and Hu, 2006; Sinha et al., 2011; see also Chapter 2). The observed recent weakening tendency in seasonal rainfall and the regional re-distribution has been partially attributed to factors such as changes in black carbon and/or sulphate aerosols (Chung and Ramanathan, 2006; Lau et al., 2008; Bollasina et al., 2011), land use (Niyogi et al., 2010; see also Chapter 10) and SSTs (Annamalai et al., 2013). An increase in extreme rainfall events occurred at the expense of weaker rainfall events (Goswami et al., 2006) over the central Indian region, and in many other areas (Krishnamurthy et al., 2009). With a declining number of monsoon depressions (Krishnamurthy and Ajayamohan, 2010), the upward trend in extreme rainfall events may be due to enhanced moisture content (Goswami et al., 2006) or warmer SSTs in the tropical Indian Ocean (Rajeevan et al., 2008).

CMIP3 projections show suppressed rainfall over the equatorial Indian Ocean (Cai et al., 2011e; Turner and Annamalai, 2012), and an increase in seasonal mean rainfall over India (Ueda et al., 2006; Annamalai et al., 2007; Turner et al., 2007a; Kumar et al., 2011b; Sabade et al., 2011). These results are generally confirmed by CMIP5 projections (Chaturvedi et al., 2012). The projected changes in Indian monsoon rainfall increase with the anthropogenic forcing among RCPs (May, 2011; see Figure 14.4; SAS).

In a suite of models that realistically simulate ENSO–monsoon relationships, normal monsoon years are *likely* to become less frequent in the future, but there is no clear consensus about the occurrence of extreme monsoon years (Turner and Annamalai, 2012). CMIP3 models indicate ENSO–monsoon relationships to persist in the future (Kumar et al., 2011b), but there is low confidence in the projection of ENSO variability (Section 14.4). Sub-seasonal scale monsoon variability is linked to the MJO but again the confidence in the future projection of MJO remains low (Section 14.3.2).

CMIP5 models project an increase in mean precipitation as well as its interannual variability and extremes (Figure 14.4; SAS). All models project an increase in heavy precipitation events but disagree on CDD changes. Regarding seasonality, model agreement is high on an earlier onset and later retreat, and hence longer duration. The monsoon circulation weakens in the future (Figure 14.5; IND) but the precipitation increases. Like the global monsoon (Section 14.2.1), the precipitation increase is largely due to the increased moisture flux from ocean to land.

14.2.2.2 East Asian Monsoon

The East Asian monsoon is characterized by a wet season and southerly flow in summer and by dry cold northerly flow in winter. The East Asian summer (EAS) monsoon circulation has experienced an inter-decadal weakening from the 1960s to the 1980s (Hori et al., 2007; Li et al., 2010a), associated with deficient rainfall in North China and excessive rainfall in central East China along 30°N (Hu, 1997; Wang, 2001; Gong and Ho, 2002; Yu et al., 2004). The summer monsoon circulation has begun to recover in recent decades (Liu et al., 2012a; Zhu et al., 2012). The summer rainfall amount over East Asia shows no clear trend during the 20th century (Zhang and Zhou, 2011), although significant trends may be found in local station records (Wang et al., 2006). The winter monsoon circulation weakened significantly after the 1980s (Wang et al., 2009a; Wang and Chen, 2010). See Supplementary Material Sections 14.SM.1.3–14.SM.1.7 for additional discussions of natural variability.

CMIP3 models show reasonable skill in simulating large-scale circulation of the EAS monsoon (Boo et al., 2011), but their performance is poor in reproducing the monsoon rainband (Lin et al., 2008a; Li and Zhou, 2011). Only a few CMIP3 models reproduce the Baiu rainband (Ninomiya, 2012) and high-resolution models (Kitoh and Kusunoki, 2008) show better performance than low resolution CMIP3 type models in simulating the monsoon rainband (Kitoh and Kusunoki, 2008). CMIP3 models show large uncertainties in projections of monsoon precipitation and circulation (Ding et al., 2007; Kripalani et al., 2007a) but the simulation of interannual variability of the EAS monsoon circulation has improved from CMIP3 to CMIP5 (Sperber et al., 2012). Climate change may bring a change in the position of the monsoon rain band (Li et al., 2010a).

CMIP5 projections indicate a *likely* increase in both the circulation (Figure 14.5) and rainfall of the EAS monsoon (Figure 14.4) throughout the 21st century. This is different from other Asian-Australian monsoon subsystems, where the increase in precipitation (Figure 14.4) is generally associated with weakening monsoon circulation (Figure 14.5). Interannual variability of seasonal mean rainfall is *very likely* to increase except for RCP2.6 (Figure 14.4). Heavy precipitation events (SDII and R5d) are also *very likely* to increase. CMIP5 models project an earlier monsoon onset and longer duration but the spread among models is large (Figure 14.4).

14.2.2.3 Maritime Continent Monsoon

Interaction between land and water characterizes the Maritime Continent region located between the Asian continent and Australia. It provides a land bridge along which maximum convection marches from the Asian summer monsoon regime (generally peaking in June, July and August) to the Australian summer monsoon system (generally peaking in December, January and February).

Phenomena such as the MJO (Tangang et al., 2008; Section 14.3.2; Hidayat and Kizu, 2010; Salahuddin and Curtis, 2011), and ENSO (Aldrian and Djamil, 2008; Moron et al., 2010; Section 14.4) influence Maritime Continent Monsoon variability. Rainfall extremes in the Maritime Continent are strongly influenced by diurnal rainfall variability (Qian, 2008; Qian et al., 2010a; Robertson et al., 2011; Ward et al., 2011) as well

as the MJO. There have been no obvious trends in extreme rainfall indices in Indonesia, except evidence of a decrease in some areas in annual rainfall and an increase in the ratio of the wet to dry season rainfall (Aldrian and Djamil, 2008).

Modelling the Maritime Continent monsoon is a challenge because of the coarse resolution of contemporary large-scale coupled climate models (Aldrian and Djamil, 2008; Qian, 2008). Most CMIP3 models tend to simulate increasing precipitation in the tropical central Pacific but declining trends over the Maritime Continent for June to August (Ose and Arakawa, 2011), consistent with a decreasing zonal SST gradient across the equatorial Pacific and a weakening Walker circulation (Collins et al., 2010). Projections of CMIP5 models are consistent with those of CMIP3 models, with decreasing precipitation during boreal summer and increasing precipitation during boreal winter, but model agreement is not high (Annex I; Figure 12.22, but see also Figure 14.27).

14.2.2.4 Australian Monsoon

Some indices of the Australian summer monsoon (Wang et al., 2004; Li et al., 2012a) show a clear post-1980 reduction, but another index by Kajikawa et al. (2010) does not fully exhibit this change. Over northwest Australia, summer rainfall has increased by more than 50% (Rotstayn et al., 2007; Shi et al., 2008b; Smith et al., 2008), whereas over northeast Australia, summer rainfall has decreased markedly since around 1980 (Li et al., 2012a).

Models in general show skill in representing the gross spatial characteristics of Australian monsoon summer precipitation (Moise et al., 2005). Further, atmospheric GCMs forced by SST anomalies can skilfully reproduce monsoon-related zonal wind variability over recent decades (Zhou et al., 2009a). Recent analysis of the skill of a suite of CMIP3 models showed a divergence, with half the models overestimating Australian tropical rainfall and the other half underestimating it (Colman et al., 2011). Most CMIP models have biases in monsoon seasonality, but CMIP5 models generally perform better than CMIP3 (Jourdain et al., 2013).

In climate change projections, overall changes in tropical Australian rainfall are small, with substantial uncertainties (Figure 14.4; Moise et al., 2012; see also Figure 14.27). Using a group of CMIP5 models that exhibit a realistic present-day climatology, most projections using the RCP8.5 scenario produced 5% to 20% more monsoon rainfall by the late 21st century compared to the pre-industrial period (Jourdain et al., 2013). Most CMIP3 model projections suggest delayed monsoon onset and reduced monsoon duration over northern Australia. Weaker model agreement is seen over the interior of the Australian continent, where ensembles show an approximate 7-day delay of both the onset and retreat with little change in duration (Zhang et al., 2013a). CMIP5 model agreement in changes of monsoon precipitation seasonality is low (Figure 14.4).

14.2.2.5 Western North Pacific Monsoon

The western North Pacific summer monsoon (WNPSM) occupies a broad oceanic region of the South China and Philippine Seas, featuring a monsoon trough and a subtropical anticyclonic ridge to the north (Zhang and Wang, 2008).

The western North Pacific monsoon does not show any trend during 1950–1999. Since the late 1970s, the correlation has strengthened between interannual variability in the western North Pacific monsoon and ENSO (Section 14.4), a change mediated by Indian Ocean SST (Huang et al., 2010; Xie et al., 2010a). This occurred despite a weakening of the Indian monsoon-ENSO correlation in this period (Wang et al., 2008a).

CMIP5 models project little change in western North Pacific monsoon circulation (Figure 14.5) but enhanced precipitation (Annex I; Figure 12.22; but see also Figure 14.24) due to increased moisture convergence (Chapter 12).

14.2.3 American Monsoons

The American monsoons, the North America Monsoon System (NAMS) and the South America Monsoon System (SAMS) are associated with large inter-seasonal differences in precipitation, humidity, and

atmospheric circulation (Vera et al., 2006; Marengo et al., 2010a). NAMS and SAMS indices are often, though not always, defined in terms of precipitation characteristics (Wang and LinHo, 2002).

[INSERT FIGURE 14.6 HERE]

Figure 14.6: As in Figure 14.4, except for (upper) NAMS and (lower) SAMS.

14.2.3.1 North America Monsoon System

The warm season precipitation in northern Mexico and the southwestern USA is strongly influenced by the NAMS. It has been difficult to simulate many important NAMS-related phenomenon in global climate models (Castro et al., 2007; Lin et al., 2008b; Cerezo-Mota et al., 2011), though the models capture gross-scale features associated with the NAMS seasonal cycle (Liang et al., 2008b; Gutzler, 2009). See Supplementary Material Section 14.SM.1.8 for a more detailed discussion of NAMS dynamics.

In the NAMS core region, no distinct precipitation trends have been seen over the last half of the 20th century (Anderson et al., 2010; Arriaga-Ramirez and Cavazos, 2010), due to countervailing trends in increasing intensity and decreasing frequency of events, as well as the decreasing length of the monsoon season itself (Englehart and Douglas, 2006). However, monsoonal stream flow in western Mexico has been decreasing, possibly as a result of changing precipitation characteristics or antecedent hydrological conditions rather than overall precipitation amounts (Gochis et al., 2007). There has also been a systematic delay in monsoon onset, peak, and termination (Grantz et al., 2007) as well as an increase in extreme precipitation events associated with land-falling hurricanes (Cavazos et al., 2008). Finally, positive trends in NAMS precipitation amounts have been detected in the northern fringes of the core area, i.e. Arizona and western New Mexico (Anderson et al., 2010), consistent with northward NAMS expansion during relatively warm periods in the Holocene (Petersen, 1994; Mock and Brunelle-Daines, 1999; Harrison et al., 2003; Poore et al., 2005; Metcalfe et al., 2010).

Over the coming century, CMIP5 simulations generally project a precipitation reduction in the core zone of the monsoon (Annex I and Figure 14.6), but this signal is not particularly consistent across models, even under the RCP8.5 scenario (Cook and Seager, 2013). Thus confidence in projections of monsoon precipitation changes is currently low. CMIP5 models have no consensus on future changes of monsoon timing (Figure 14.6). Temperature increases are consistently projected in all models (Annex I). This will likely increase the frequency of extreme summer temperatures (Diffenbaugh and Ashfaq, 2010; Anderson, 2011; Duffy and Tebaldi, 2012), together with projected increase in consecutive dry days (Figure 14.6).

14.2.3.2 South America Monsoon System

The SAMS mainly influences precipitation in the South American tropics and subtropics (Figure 14.1). The main characteristics of SAMS onset are increased humidity flux from the Atlantic Ocean over northern South America, an eastward shift of the subtropical high, strong northwesterly moisture flux east of the tropical Andes, and establishment of the Bolivian High (Raia and Cavalcanti, 2008; Marengo et al., 2010a; Silva and Kousky, 2012). Recent SAMS indices have been calculated based on different variables, such as a large scale index (Silva and Carvalho, 2007), moisture flux (Raia and Cavalcanti, 2008), and wind (Gan et al., 2006), in addition to precipitation (Nieto-Ferreira and Rickenbach, 2010; Seth et al., 2010; Kitoh et al., 2013). As seen below, conclusions regarding SAMS changes can depend on the index chosen.

SAMS duration and amplitude obtained from the observed large scale index have both increased in the last 32 years (Jones and Carvalho, 2013). Increase of extreme precipitation and consecutive dry days have been observed in the SAMS region from 1969 to 2009 (Skansi et al., 2013). The overall annual cycle of precipitation in the SAMS region, including SAMS onset and demise, is generally well represented by models (Bombardi and Carvalho, 2009; Seth et al., 2010; Kitoh et al., 2013). Extreme precipitation indices in SAMS region are also well simulated by CMIP5 models (Kitoh et al., 2013). CMIP5 models subjected to historical forcing show increases in SAMS amplitude, earlier onset, and later demise during the 1951–2005 period (Jones and Carvalho, 2013). Using a precipitation based index, precipitation increases in austral summer but decreases in austral spring, indicating delayed SAMS onset in the CMIP3 projections (Seth et al., 2011). CMIP5 projections based on the global precipitation index (Section 14.2.1) consistently show small precipitation increases and little change in onset and retreat (Kitoh et al., 2013; Figure 14.6). On the

other hand, when using a different index, an earlier onsets and later demises and thus, longer durations of the SAMS by the end of the 21st century (2081–2100) has been found (Jones and Carvalho, 2013). Thus there is medium confidence that SAMS overall precipitation will remain unchanged. The different estimates of changes in timing underscores potential uncertainties related to SAMS timing due to differences in SAMS indices. The models do show significant and robust increases in extreme precipitation indices in the SAMS region, such as seasonal maximum 5-day precipitation total and number of consecutive dry days (Figure 14.6), leading to medium confidence in projections of these characteristics.

14.2.4 African Monsoon

In Africa, monsoon circulation affects precipitation in West Africa where notable upper air flow reversals are observed. East and south African precipitation is generally described by variations in the tropical convergence zone rather than as a monsoon feature. This section covers the West African monsoon, and Section 14.8.7 also covers the latter two regions.

The West African monsoon develops during northern spring and summer, with a rapid northward jump of the rainfall belt from along the Gulf of Guinea at 5°N in May to June to the Sahel at 10°N in July to August. Factors influencing the West African monsoon include interannual to decadal variations, land processes and the direct response to radiative forcing. Cross-equatorial tropical Atlantic SST patterns influence the monsoon flow and moistening of the boundary layer, so that a colder northern tropical Atlantic induces negative rainfall anomalies (Biasutti et al., 2008; Giannini et al., 2008; Xue et al., 2010; Rowell, 2011).

In CMIP3 simulations, rainfall is projected to decrease in the early part but increase towards the end of the rainy season, implying a small delay in the monsoon season and an intensification of late-season rains (Biasutti and Sobel, 2009; Biasutti et al., 2009; Seth et al., 2010). CMIP5 models on the other hand simulate the variability of tropical Atlantic SST patterns with little credibility (Section 9.4.2.5.2) and model resolution is known to limit the ability to capture the mesoscale ‘squall line’ systems that form a central element in the maintenance of the rainy season (Ruti and Dell’Aquila, 2010; see also Section 14.8.7). Therefore, projections of the West African monsoon rainfall appear to be uncertain, reflected by considerable model deficiencies and spread in the projections (Figure 14.7). Note that this figure is based on a somewhat eastward extended area for the West African monsoon (NAF in Figure 14.3), seen as a component of the global monsoon system (Section 14.2.1). The limitations of model simulations in the region arising from the lack of convective organization (Kohler et al., 2010) leading to the underestimation of interannual variability (Scaife et al., 2009) imply that confidence in projections of the African monsoon is *low*.

[INSERT FIGURE 14.7 HERE]

Figure 14.7: As in Figure 14.4, except for (upper) NAF and (lower) SAF.

The limited information that could be deduced from CMIP3 has not improved much in CMIP5. Figure 14.7 largely confirms the findings based on CMIP3. The CMIP5 model ensemble projects a modest change in the onset date (depending on the scenario) and a small delay in the retreat date, leading to a small increase in the duration of the rainy season. The delay in the monsoon retreat is larger in the high-end emission scenarios. The interannual variance and the 5-day rain intensity show a robust increase, while a small increase in dry day periods is less significant.

14.2.5 Assessment Summary

There is *high confidence* that global monsoon precipitation is *likely* to strengthen in the 21st century with increase in its area and intensity while the monsoon circulation weakens. Precipitation extremes including precipitation intensity and consecutive dry days are *likely* to increase at higher rates than those of mean precipitation. Overall, CMIP5 models project that the monsoon onset will be earlier or not change much and the monsoon retreat dates will delay, resulting in a lengthening of the monsoon season. Such features are *likely* to occur in most of Asian-Australian Monsoon regions.

There is *medium confidence* that overall precipitation associated with the Asian-Australian monsoon will increase but with a north-south asymmetry: Indian and East Asian monsoon precipitation is projected to increase, while projected changes in Australian summer monsoon precipitation are small. There is *medium*

confidence that the Indian summer monsoon circulation will weaken, but this is compensated by increased atmospheric moisture content, leading to more precipitation. For the East Asian summer monsoon, both monsoon circulation and precipitation are projected to increase. There is *low confidence* that over the Maritime Continent boreal summer rainfall will decrease and boreal winter rainfall will increase. There is *low confidence* that changes in the tropical Australian monsoon rainfall are small. There is *low confidence* that Western North Pacific summer monsoon circulation changes are small, but with increased rainfall due to enhanced moisture. There is *medium confidence* in an increase of Indian summer monsoon rainfall and its extremes throughout the 21st century under all RCP scenarios. Their percentage change ratios are the largest and model agreement is highest among all monsoon regions.

There is *low confidence* in projections of American monsoon precipitation changes but there is high confidence in increases of precipitation extremes, of wet days and consecutive dry days. It is *likely* that precipitation associated with the NAMS will arrive later in the annual cycle, and persist longer. Future changes in the timing and duration of the SAMS are also *likely*, but details of these changes remain uncertain. There is *high confidence* in the expansion of SAMS, resulting from increased temperature and humidity. There is *low confidence* in precipitation changes in SAMS but it is *likely* that precipitation extremes of wet days and consecutive dry days increase.

Based on how models represent known drivers of the West African monsoon, there is *low confidence* in projections of its future development based on CMIP5. Confidence is *low* in projections of a small delay in the onset of the West African rainy season with an intensification of late-season rains.

14.3 Tropical Phenomena

14.3.1 Convergence Zones

Section 7.6 presents a radiative perspective of changes in convection (including the differences between GHG and aerosol forcings), and Section 12.4.5.2 discusses patterns of precipitation change on the global scale. The emphasis here is on regional aspects of tropical changes. Tropical convection over the oceans, averaged for a month or longer, is organized into long and narrow convergence zones, often anchored by SST structures. Latent heat release in convection drives atmospheric circulation and affects global climate. In model experiments where spatially-uniform SST warming is imposed, precipitation increases in these tropical convergence zones (Xie et al., 2010b), following the ‘wet-get-wetter’ paradigm (Held and Soden, 2006). On the flanks of a convergence zone, rainfall may decrease because of the increased horizontal gradient in specific humidity and the resultant increase in dry advection into the convergence zone (Neelin et al., 2003).

While these arguments based on moist atmospheric dynamics call for changes in tropical convection to be organized around the climatological rain band, studies since AR4 show that such changes in a warmer climate also depend on the spatial pattern of SST warming. As a result of the SST pattern effect, rainfall change does not generally project onto the climatological convergence zones, especially for the annual mean. In CMIP3/5 model projections, annual rainfall change over tropical oceans follows a ‘warmer-get-wetter’ pattern, increasing where the SST warming exceeds the tropical mean and vice versa (Figure 14.8, Xie et al., 2010b; Sobel and Camargo, 2011; Chadwick et al., 2012). Differences among models in the SST warming pattern are an important source of uncertainty in rainfall projections, accounting for a third of inter-model variability in annual precipitation change in the tropics (Ma and Xie, 2013).

Figure 14.8 presents selected indices for several robust patterns of SST warming for RCP8.5. They include: greater warming in the northern than the southern hemisphere, a pattern favouring rainfall increase at locations north of the equator and decreases to the south (Friedman et al., 2013); enhanced equatorial warming (Liu et al., 2005) that anchors a pronounced rainfall increase in the equatorial Pacific; reduced warming in the subtropical Southeast Pacific that weakens convection there; decreased zonal SST gradient across the equatorial Pacific (see Section 14.4) and increased westward SST gradient across the equatorial Indian Ocean (see Section 14.3.3) that together contribute to the weakened Walker cells.

Changes in tropical convection affect the pattern of SST change (Chou et al., 2005) and such atmospheric and oceanic perturbations are inherently coupled. The SST pattern effect dominates the annual rainfall

change while the wet-get-wetter effect becomes important for seasonal mean rainfall in the summer hemisphere (Huang et al., 2013). This is equivalent to an increase in the annual range of precipitation in a warmer climate (Chou et al., 2013). Given uncertainties in SST warming pattern, the confidence is generally higher for seasonal than annual mean changes in tropical rainfall.

[INSERT FIGURE 14.8 HERE]

Figure 14.8: Upper panel: Annual-mean precipitation percentage change ($\delta P/P$ in green/gray shade and white contours at 20% intervals), and relative SST change (colour contours at intervals of 0.2°C; negative shaded) to the tropical (20°S–20°N) mean warming in RCP8.5 projections, shown as 23 CMIP5 model ensemble mean. Lower panel: SST warming pattern indices in the 23-model RCP8.5 ensemble, shown as the 2081–2100 minus 1986–2005 difference. From left: Northern (EQ–60°N) minus Southern (60°S–EQ) Hemisphere; equatorial (120°E–60°W, 5°S–5°N) and Southeast (130°W–70°W, 30°S–15°S) Pacific relative to the tropical mean warming; zonal SST gradient in the equatorial Pacific (120°E–180°E minus 150°W–90°W, 5°S–5°N) and Indian (50°E–70°E, 10°S–10°N minus 90°E–110°S, 10°S–EQ) Oceans. Rightmost: spatial correlation (r) between relative SST change and precipitation percentage change ($\delta P/P$) in the tropics (20°S–20°N) in each model. (The spatial correlation for the multi-model ensemble mean fields in the upper panel is 0.63). The circle and error bar indicate the ensemble mean and ± 1 standard deviation, respectively. The upper panel is a CMIP5 update of Ma and Xie (2013), and see text for indices in the lower panel.

14.3.1.1 Inter-Tropical Convergence Zone

The Inter-Tropical Convergence Zone (ITCZ) is a zonal band of persistent low-level convergence, atmospheric convection, and heavy rainfall. Over the Atlantic and eastern half of the Pacific, the ITCZ is displaced north of the equator due to ocean-atmosphere interaction (Xie et al., 2007) and extratropical influences (Kang et al., 2008; Fučkar et al., 2013). Many models show an unrealistic double-ITCZ pattern over the tropical Pacific and Atlantic, with excessive rainfall south of the equator (Section 9.4.2.5.1). This bias needs to be kept in mind in assessing ITCZ changes in model projections, especially for boreal spring when the model biases are largest.

The global zonal mean ITCZ migrates back and forth across the equator following the sun. In CMIP5, seasonal-mean rainfall is projected to increase on the equatorward flank of the ITCZ (Figure 14.9). The co-migration of rainfall increase with the ITCZ is due to the wet-get-wetter effect while the equatorward displacement is due to the SST pattern effect (Huang et al., 2013).

[INSERT FIGURE 14.9 HERE]

Figure 14.9: Seasonal cycle of zonal-mean tropical precipitation change (2081–2100 in RCP8.5 minus 1986–2005) in CMIP5 multimodel ensemble (MME) mean. Eighteen CMIP5 models were used. Stippling indicates that more than 90% models agree on the sign of MME change. The red curve represents the meridional maximum of the climatological rainfall. Adapted from Huang et al. (2013).

14.3.1.2 South Pacific Convergence Zone

The South Pacific Convergence Zone (SPCZ, Widlansky et al., 2011) extends south-eastward from the tropical western Pacific to French Polynesia and the Southern Hemisphere mid-latitudes, contributing most of the yearly rainfall to the many South Pacific island nations under its influence. The SPCZ is most pronounced during austral summer (DJF).

Zonal and meridional SST gradients, trade wind strength, and subsidence over the eastern Pacific are important mechanisms for SPCZ orientation and variability (Takahashi and Battisti, 2007; Lintner and Neelin, 2008; Vincent et al., 2011; Widlansky et al., 2011). Many GCMs simulate the SPCZ as lying east-west, giving a ‘double-ITCZ’ structure and missing the southeastward orientation (Brown et al., 2012a).

The majority of CMIP models simulate increased austral summer mean precipitation in the SPCZ, with decreased precipitation at the eastern edge of the SPCZ (Brown et al., 2012a; Brown et al., 2012b). The position of the SPCZ varies on interannual to decadal time scales, shifting northeast in response to El Niño (Folland et al., 2002; Vincent et al., 2011). Strong El Niño events induce a zonally-oriented SPCZ located well northeast of its average position, while more moderate ENSO (Section 14.4) events are associated with movement of the SPCZ to the northeast or southwest, without a change in its orientation.

Models from both CMIP3 and CMIP5 that simulate the SPCZ well show a consistent tendency towards much more frequent zonally-oriented SPCZ events in future (Cai et al., 2012b). The mechanism appears to be associated with a reduction in near-equatorial meridional SST gradient, a robust feature of modelled SST response to anthropogenic forcing (Widlansky et al., 2013). An increased frequency of zonally-oriented SPCZ events would have major implications for regional climate, possibly leading to longer dry spells in the southwest Pacific.

14.3.1.3 South Atlantic Convergence Zone

The South Atlantic Convergence Zone (SACZ) extends from the Amazon region through southeastern Brazil towards the Atlantic Ocean during austral summer (Cunningham and Cavalcanti, 2006; Carvalho et al., 2011; de Oliveira Vieira et al., 2013). Floods or dry conditions in southeastern Brazil are often related to SACZ variability (Muza et al., 2009; Lima et al., 2010; Vasconcellos and Cavalcanti, 2010). A subset of CMIP models simulate the SACZ (Vera and Silvestri, 2009; Seth et al., 2010; Yin et al., 2012) and its variability as a dipolar structure (Junquas et al., 2011; Cavalcanti and Shimizu, 2012).

A southward displacement of SACZ and intensification of the southern centre of the precipitation dipole are suggested in projections of CMIP3 and CMIP5 models (Seth et al., 2010; Junquas et al., 2011; Cavalcanti and Shimizu, 2012). This displacement is consistent with the increased precipitation over Southeastern South America, south of 25°S, projected for the second half of the 21st century, in CMIP3, CMIP5 and regional models (Figure AI.34, Figure 14.21). It is also consistent with the southward displacement of the Atlantic subtropical high (Seth et al., 2010) related to the southward expansion of the Hadley cell (Lu et al., 2007). Pacific SST warming and the strengthening of the PSA-like wave train (Section 14.6.2) are potential mechanisms for changes in the dipolar pattern resulting in SACZ change (Junquas et al., 2011). This change is also supported by the intensification and increased frequency of the low level jet over South America in future projections (Soares and Marengo, 2009; Seth et al., 2010).

14.3.2 Madden Julian Oscillation

The Madden-Julian Oscillation (MJO) is the dominant mode of tropical intraseasonal (20–100 days) variability (Zhang, 2005). The MJO modulates tropical cyclone activity (Frank and Roundy, 2006), contributes to intraseasonal fluctuations of the monsoons (Maloney and Shaman, 2008), and excites teleconnection patterns outside the tropics (L'Heureux and Higgins, 2008; Lin et al., 2009). Simulation of the MJO by GCMs remains challenging, but with some improvements made in recent years (Section 9.5.2.3).

Possible changes in the MJO in a future warmer climate have just begun to be explored with models that simulate the phenomenon. In the Max Planck Institute Earth System Model, MJO variance increases appreciably with increasing warming (Schubert et al., 2013). The change in MJO variance is highly sensitive to the spatial pattern of SST warming (Maloney and Xie, 2013). In light of the low skill in simulating MJO, and its sensitive to SST warming pattern, which in itself is subject to large uncertainties, confidence is *low* in assessing how MJO will change in a warmer climate.

14.3.3 Indian Ocean Modes

The tropical Indian Ocean SST exhibits two modes of interannual variability (Schott et al., 2009; Deser et al., 2010b): the Indian Ocean Basin (IOB) mode featuring a basin-wide structure of the same sign, and the Indian Ocean dipole (IOD) mode with largest amplitude in the eastern Indian Ocean off Indonesia, and weaker anomalies of the opposite polarity over the rest of the basin (Box 2.5). Both modes are statistically significantly correlated with ENSO (Section 14.4). CMIP models simulate both modes well (Section 9.5.3.4.2).

The formation of IOB is linked to ENSO via an atmospheric bridge and surface heat flux adjustment (Klein et al., 1999; Alexander et al., 2002). Ocean-atmosphere interactions within the Indian Ocean are important for the long persistence of this mode (Izumo et al., 2008; Wu et al., 2008; Du et al., 2009). The basin mode affects the termination of ENSO events (Kug and Kang, 2006), it induces coherent atmospheric anomalies in the summer following El Niño (Xie et al., 2009), including suppressed convection (Wang et al., 2003) and reduced tropical cyclone activity (Du et al., 2011) over the Northwest Pacific, and anomalous rainfall over

East Asia (Huang et al., 2004).

IOD develops in July–November and involves Bjerknes feedback between zonal SST gradient, zonal wind and thermocline tilt along the equator (Saji et al., 1999; Webster et al., 1999). A positive IOD event (with negative SST anomalies off Sumatra) is associated with droughts in Indonesia, reduced rainfall over Australia, intensified Indian summer monsoon, increased precipitation in East Africa, and anomalous conditions in the extratropical Southern Hemisphere (Yamagata et al., 2004). Most CMIP3 models are able to reproduce the general features of the IOD, including its phase lock onto the July–November season, while detailed analysis of CMIP5 simulations are not yet available (Section 9.5.3.4.2)

Basin-mean SST has risen steadily for much of the 20th Century, a trend captured by CMIP3 20th century simulations (Alory et al., 2007). The SST increase over the North Indian Ocean since about 1930 is noticeably weaker than for the rest of the basin. This spatial pattern is suggestive of the effects of reduced surface solar radiation due to Asian brown clouds (Chung and Ramanathan, 2006) and it affects Arabian Sea cyclones (Evan et al., 2011b). In the equatorial Indian Ocean, coral isotope records off Indonesia indicate a reduced SST warming and/or increased salinity during the 20th century (Abram et al., 2008). An easterly wind change especially during July–October has been observed over the past six decades, a result consistent with a reduction of marine cloudiness in the east and a decreasing precipitation trend over the maritime continent (Tokinaga et al., 2012). Atmospheric reanalysis products have difficulty representing these changes (Han et al., 2010).

The projected changes over the equatorial Indian Ocean include easterly wind anomalies, a shoaling thermocline (Vecchi and Soden, 2007a; Du and Xie, 2008) and reduced SST warming in the east (Stowasser et al., 2009), a result confirmed by CMIP5 multi-model analysis (Zheng et al., 2013; Figure 14.10). The change in zonal SST gradient, in turn, reinforces the easterly wind change, indicative of a positive feedback between them as envisioned by Bjerknes (1969). This coupled pattern is most pronounced during July–November, and is broadly consistent with the observed changes in the equatorial Indian Ocean.

[INSERT FIGURE 14.10 HERE]

Figure 14.10: September to November changes in a 22-model CMIP5 ensemble (2081–2100 in RCP8.5 minus 1986–2005 in historical run). (a) SST (colour contours at 0.1°C intervals) relative to the tropical mean (20°S–20°N), and precipitation (shading and white contours at 20 mm per month intervals). (b) Surface wind velocity (m s^{-1}), and sea surface height deviation from the global mean (contours, cm). Over the equatorial Indian Ocean, ocean-atmospheric changes form Bjerknes feedback, with the reduced SST warming and suppressed convection in the east. Updated with CMIP5 from Xie et al. (2010b).

In one CMIP3 model, the IOB mode and its capacitor effect persist longer, through summer into early fall towards the end of the century (2081–2100, Zheng et al., 2011). This increased persistence intensifies ENSO's influence on the Northwest Pacific summer monsoon. The confidence level of this relationship is *low* due to the lack of multi-model studies.

The IOD variability in SST remains nearly unchanged in CMIP future projections (Ihara et al., 2009; Figure 14.11a) despite the easterly wind change that lifts the thermocline (Figure 14.10b) and intensifies thermocline feedback on SST in the eastern equatorial Indian Ocean. The global increase in atmospheric dry static stability weakens the atmospheric response to zonal SST gradient changes, countering the enhanced thermocline feedback (Zheng et al., 2010). The weakened atmospheric feedback is reflected in a decrease in IOD variance in both zonal wind and the thermocline depth (Zheng et al., 2013; Figure 14.11b–c).

[INSERT FIGURE 14.11 HERE]

Figure 14.11: CMIP5 multi-model ensemble mean standard deviations of interannual variability for September to November in pre-industrial (PiControl; blue bars) and RCP8.5 (red) runs: (a) the Indian Ocean dipole index defined as the western (50°E–70°E, 10°S–10°N) minus eastern (90°E–110°E, 10°S–0°) SST difference; (b) zonal wind in the central equatorial Indian Ocean (70°E–90°E, 5°S–5°N); and (c) sea surface height in the eastern equatorial Indian Ocean (90°E–110°E, 10°S–0°). The standard deviation is normalized by the pre-industrial (PiControl) value for each model before ensemble average. Blue box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles of 51-year windows for PiControl, representing natural variability. Red box-whisker plots represent inter-model variability for RCP8.5 (red), based on the nearest rank. Adapted from Zheng et al. (2013).

14.3.4 Atlantic Ocean Modes

The Atlantic features a northward-displaced ITCZ (Section 14.3.1.1), and a cold tongue that develops in boreal summer. Climate models generally fail to simulate these characteristics of tropical Atlantic climate (Section 9.5.3.3). The biases severely limit model skill in simulating modes of Atlantic climate variability and in projecting future climate change in the Atlantic sector. In-depth analysis of the CMIP5 projections of Atlantic Ocean Modes has not yet been fully explored, but see Section 12.4.3.

The inter-hemispheric SST gradient displays pronounced interannual to decadal variability (Box 2.5, Figure 2), referred to as the Atlantic meridional mode (AMM; Servain et al., 1999; Chiang and Vimont, 2004; Xie and Carton, 2004). A thermodynamic feedback between surface winds, evaporation, and SST (WES; Xie and Philander, 1994) is fundamental to the AMM (Chang et al., 2006). This mode affects precipitation in northeastern Brazil by displacing the ITCZ (Servain et al., 1999; Chiang and Vimont, 2004; Xie and Carton, 2004), and Atlantic hurricane activity (Vimont and Kossin, 2007; Smirnov and Vimont, 2011).

The Atlantic Niño mode represents interannual variability in the equatorial cold tongue, akin to ENSO (Box 2.5, Figure 2). Bjerknes feedback is considered important for energizing the mode (Zebiak, 1993; Carton and Huang, 1994; Keenlyside and Latif, 2007). This mode affects the West Africa Monsoon (Vizy and Cook, 2002; Giannini et al., 2003).

Over the past century, the Atlantic has experienced a pronounced and persistent warming trend. The warming has brought detectable changes in atmospheric circulation and rainfall patterns in the region. In particular, the ITCZ has shifted southward and land precipitation has increased over the equatorial Amazon, equatorial West Africa, and along the Guinea coast, while it has decreased over the Sahel (Deser et al., 2010a; Tokinaga and Xie, 2011; see also Sections 2.5 and 2.7). Atlantic Niño variability has weakened by 40% in amplitude from 1960 to 1999, associated with a weakening of the equatorial cold tongue (Tokinaga and Xie, 2011).

The CMIP3 20th century climate simulations generally capture the warming trend of the basin-averaged SST over the tropical Atlantic. A majority of the models also seem to capture the secular trend in the tropical Atlantic SST inter-hemispheric gradient and, as a result, the southward shift of the Atlantic ITCZ over the past century (Chang et al., 2011).

Many CMIP3 model simulations with the A1B emission scenario show only minor changes in the SST variance associated with the AMM. However, the few models that give the best AMM simulation over the 20th Century project a weakening in future AMM activity (Breugem et al., 2006), possibly due to the northward shift of the ITCZ (Breugem et al., 2007). At present, model projections of future change in AMM activity is considered highly uncertain because of the poorly simulated Atlantic ITCZ. In fact, uncertainty in projected changes in Atlantic meridional SST gradient limits the confidence in regional climate projections surrounding the tropical Atlantic Ocean (Good et al., 2008).

A majority of CMIP3 models forced with the A1B emission scenario project no major change in Atlantic Niño activity in the 21st Century, while a few models project a sizable decrease in future activity (Breugem et al., 2006).

CMIP5 projections show an accelerated SST warming over much of the tropical Atlantic (Figure 12.11). RCP8.5 projections of the inter-hemispheric SST gradient change within the basin, however, are not consistent among CMIP5 models as future GHG increase dominates over the anthropogenic aerosol effect.

14.3.5 Assessment Summary

There is *medium confidence* that annual rainfall changes over tropical oceans follow a ‘warmer-get-wetter’ pattern, increasing where the SST warming exceeds the tropical mean and vice versa. One third of inter-model differences in precipitation projection are due to those in SST pattern. The SST pattern effect on precipitation change is a new finding since AR4.

The wet-get-wetter effect is more obvious in the seasonal than annual rainfall change in the tropics.

Confidence is generally higher in seasonal than in annual mean changes in tropical precipitation. There is *medium confidence* that seasonal rainfall will increase on the equatorward flank of the current ITCZ; that the frequency of zonally-oriented SPCZ events will increase, with the SPCZ lying well to the northeast of its average position during those events; and that the SACZ shifts southwards, in conjunction with the southward displacement of the South Atlantic subtropical high, leading to an increase in precipitation over southeastern South America.

Due to models' ability to reproduce general features of IOD and agreement on future projections, there is *high confidence* that the tropical Indian Ocean is *likely* to feature a zonal pattern with reduced (enhanced) warming and decreased (increased) rainfall in the east (west), a pattern especially pronounced during August-November. The Indian Ocean dipole mode will *very likely* remain active, with interannual variability unchanged in SST but decreasing in thermocline depth. There is low confidence in changes in the summer persistence of the Indian Ocean SST response to ENSO and in ENSO's influence on summer climate over the Northwest Pacific and East Asia.

The observed SST warming in the tropical Atlantic represents a reduction in spatial variation in climatology: the warming is weaker north than south of the equator; and the equatorial cold tongue weakens both in the mean and interannual variability. There is *low confidence* in projected changes over the tropical Atlantic - both for the mean and interannual modes, because of large errors in model simulations of current climate.

There is *low confidence* in how MJO will change in the future due to the poor skill of models in simulating MJO and the sensitivity of its change to SST warming patterns that are themselves subject to large uncertainties in the projections.

14.4 El Niño-Southern Oscillation

The El Niño-Southern Oscillation (ENSO) is a coupled ocean-atmosphere phenomenon naturally occurring at the inter-annual time scale over the tropical Pacific (See Box 2.5, Supplementary Material Section 14.SM.2, and Figure 14.12).

[INSERT FIGURE 14.12 HERE]

Figure 14.12: Idealized schematic showing atmospheric and oceanic conditions of the tropical Pacific region and their interactions during normal conditions, El Niño conditions, and in a warmer world. (a) Mean climate conditions in the tropical Pacific, indicating SSTs, surface wind stress and associated Walker circulation, the mean position of convection, and the mean upwelling and position of the thermocline. (b) Typical conditions during an El Niño event. SSTs are anomalously warm in the east; convection moves into the central Pacific; the trade winds weaken in the east and the Walker circulation is disrupted; the thermocline flattens and the upwelling is reduced. (c) The likely mean conditions under climate change derived from observations, theory and coupled GCMs. The trade winds weaken; the thermocline flattens and shoals; the upwelling is reduced although the mean vertical temperature gradient is increased; and SSTs (shown as anomalies with respect to the mean tropical-wide warming) increase more on the equator than off. Diagrams with absolute SST fields are shown on the left, diagrams with SST anomalies are shown on the right. For the climate change fields, anomalies are expressed with respect to the basin average temperature change so that blue colours indicate a warming smaller than the basin mean, not a cooling (Collins et al., 2010).

14.4.1 Tropical Pacific Mean State

SST in the western tropical Pacific has increased by up to 1.5°C per century, and the warm pool has expanded (Liu and Huang, 2000; Huang and Liu, 2001; Cravatte et al., 2009). Studies disagree on how the east-west SST gradient along the equator has changed, some showing a strengthening (Cane et al., 1997; Hansen et al., 2006; Karnauskas et al., 2009; An et al., 2011) and others showing a weakening (Deser et al., 2010a; Tokinaga et al., 2012), because of observational uncertainties associated with limited data sampling, changing measurement techniques, and analysis procedures. Most CMIP3 and CMIP5 models also disagree on the response of zonal SST gradient across the equatorial Pacific (Yeh et al., 2012).

The Pacific Ocean warms more near the equator than in the subtropics in CMIP3 and CMIP5 projections (Liu et al., 2005; Gastineau and Soden, 2009; Widlansky et al., 2013; Figure 14.12) because of the difference in evaporative damping (Xie et al., 2010b). Other oceanic changes include a basin-wide thermocline shoaling (Vecchi and Soden, 2007a; DiNezio et al., 2009; Collins et al., 2010; Figure 14.12), a weakening of surface

currents, and a slight upward shift and strengthening of the equatorial undercurrent (Luo and Rothstein, 2011; Sen Gupta et al., 2012). A weakening of tropical atmosphere circulation during the twentieth century was documented in observations and reanalyses (Vecchi et al., 2006; Zhang and Song, 2006; Vecchi and Soden, 2007a; Bunge and Clarke, 2009; Karnauskas et al., 2009; Yu and Zwiers, 2010; Tokinaga et al., 2012) and in CMIP models (Vecchi and Soden, 2007a; Gastineau and Soden, 2009). The Pacific Walker circulation, however, intensified during the most recent two decades (Mitas and Clement, 2005; Liu and Curry, 2006; Mitas and Clement, 2006; Sohn and Park, 2010; Li and Ren, 2011; Zahn and Allan, 2011; Zhang et al., 2011a), illustrating the effects of natural variability.

14.4.2 *El Niño Changes over Recent Decades and in the Future*

The amplitude modulation of ENSO at longer timescales has been observed in reconstructed instrumental records (Gu and Philander, 1995; Wang, 1995; Mitchell and Wallace, 1996; Wang and Wang, 1996; Power et al., 1999; An and Wang, 2000; Yeh and Kirtman, 2005; Power and Smith, 2007; Section 5.4.1), in proxy records (Cobb et al., 2003; Braganza et al., 2009; Li et al., 2011c; Yan et al., 2011), and is also simulated by coupled GCMs (Lau et al., 2008; Wittenberg, 2009). Some studies have suggested that the modulation was due to changes in mean climate conditions in the tropical Pacific (An and Wang, 2000; Fedorov and Philander, 2000; Wang and An, 2001, 2002; Li et al., 2011c), as observed since the 1980s (An and Jin, 2000; An and Wang, 2000; Fedorov and Philander, 2000; Kim and An, 2011). Since the late 1990s, the maximum SST warming during El Niño has been frequently observed in the central Pacific (Figure 14.13; Ashok et al., 2007; Kao and Yu, 2009; Kug et al., 2009; Section 9.5.3.4.1 and Supplementary Material Section 14.SM.2; Yeh et al., 2009), with global impacts that are distinct from ‘standard’ El Niño events where the maximum warming is over the eastern Pacific (Kumar et al., 2006a; Ashok et al., 2007; Kao and Yu, 2009; Hu et al., 2012b). During the past century, an increasing trend in ENSO amplitude was also observed (Li et al., 2011c; Vance et al., 2012), possibly caused by a warming climate (Zhang et al., 2008; Kim and An, 2011) although other reconstructions in this data-sparse region dispute this trend (Giese and Ray, 2011).

[INSERT FIGURE 14.13 HERE]

Figure 14.13: Intensities of El Niño and La Niña events for the last 60 years in the eastern equatorial Pacific (Niño3 region) and in the central equatorial Pacific (Niño4 region), and the estimated linear trends, obtained from ERSSTv3.

Long coupled GCM simulations show that decadal-to-centennial modulations of ENSO can be generated without any change in external forcing (Wittenberg, 2009; Yeh et al., 2011), with epochs of extreme ENSO behaviour lasting decades or even centuries. The modulations result from nonlinear processes in the tropical climate system (Timmermann et al., 2003), the interaction with the mean climate state (Ye and Hsieh, 2008; Choi et al., 2009; Choi et al., 2011; Choi et al., 2012), or from random changes in ENSO activity triggered by chaotic atmospheric variability (Power and Colman, 2006; Power et al., 2006). There is little consensus as to whether the decadal modulations of ENSO properties (amplitude and spatial pattern) during recent decades are due to anthropogenic effects or natural variability. Instrumental SST records are available back to the 1850s, but good observations of the coupled air-sea feedbacks that control ENSO behaviour – including subsurface temperature and current fluctuations, and air-sea exchanges of heat, momentum, and water – are available only after the late 1970s, making observed historical variations in ENSO feedbacks highly uncertain (Chen, 2003; Wittenberg, 2004).

[INSERT FIGURE 14.14 HERE]

Figure 14.14: Standard deviation of Niño3 SST anomalies from CMIP5 model experiments. PI, 20C, RCP4.5, RCP8.5 indicate pre-industrial control experiments, 20th century experiments, and 21st century experiment from the RCP4.5 and RCP8.5. Open dot and solid black line indicate multi-model ensemble mean and median, respectively, and the cross mark is 20th observation, respectively. Thick bar and thin outer bar indicate 50% and 75% percentile ranges, respectively.

CMIP5 models show some improvement compared to CMIP3, especially in ENSO amplitude (Section 9.5.3.4.1). Selected CMIP5 models that simulate well strong El Niño events show a gradual increase of El Niño intensity, especially over the central Pacific (Kim and Yu, 2012). CMIP3 models suggested a westward shift of SST variability in future projections (Boer, 2009; Yeh et al., 2009). Generally, however, future changes in El Niño intensity in CMIP5 models are model-dependent (Guilyardi et al., 2012; Kim and Yu, 2012; Stevenson et al., 2012), and not significantly distinguished from natural modulations (Stevenson, 2012; Figure 14.14). Because the change in tropical mean conditions (especially the zonal gradient) in a

warming climate is model dependent (Section 14.4.1), changes in ENSO intensity for the 21st century (Solomon and Newman, 2011; Hu et al., 2012a) are uncertain (Figure 14.14). Future changes in ENSO depend on competing changes in coupled ocean-atmospheric feedback (Philip and Van Oldenborgh, 2006; Collins et al., 2010; Vecchi and Wittenberg, 2010), and on the dynamical regime a given model is in. It is *very likely*, however, that ENSO will remain the dominant mode of natural climate variability in the 21st century (Collins et al., 2010; Figure 14.14). Due to enhanced moisture availability (Section 12.4.4) ENSO-induced rainfall variability on regional scales is therefore also *likely* to intensify.

14.4.3 Teleconnections

There is little improvement in the CMIP5 ensemble relative to CMIP3 in the amplitude and spatial correlation metrics of precipitation teleconnections in response to ENSO, in particular within regions of strong observed precipitation teleconnections (equatorial South America, the western equatorial Pacific and a southern section of North America; Langenbrunner and Neelin, 2013). Scenario projections in CMIP3 and CMIP5 showed a systematic eastward shift in both El Niño- and La Niña-induced teleconnection patterns over the extratropical Northern Hemisphere (Meehl and Teng, 2007; Stevenson et al., 2012), which might be due to the eastward migration of tropical convection centres associated with the expansion of the warm pool in a warm climate (Muller and Roeckner, 2006; Müller and Roeckner, 2008; Cravatte et al., 2009; Kug et al., 2010), or changes in the mid-latitude mean circulation (Meehl and Teng, 2007). Some models produced an intensified ENSO teleconnection pattern over the North Atlantic region in a warmer climate (Müller and Roeckner, 2008; Bulic et al., 2012) and a weakened teleconnection pattern over the North Pacific (Stevenson, 2012). It is unclear whether the eastward shift of tropical convection is related to longitudinal shifts in El Niño maximum SST anomalies (see Supplementary Material Section 14.SM.2) or to changes in the mean state in the tropical Pacific. Some coupled GCMs, which do not show an increase in the central Pacific warming during El Niño in response to a warming climate, do not produce a substantial change in the longitudinal location of tropical convection (Müller and Roeckner, 2008; Yeh et al., 2009).

[INSERT FIGURE 14.15 HERE]

Figure 14.15: Changes to sea level pressure teleconnections during DJF in the CMIP5 models. (a) SLP anomalies for El Niño during the 20th century. (b) SLP anomalies for La Niña during the 20th century. (c) SLP anomalies for El Niño during RCP4.5. (d) SLP anomalies for La Niña during RCP4.5. Maps in (a)-(d) are stippled where more than 2/3 of models agree on the sign of the SLP anomaly ((a),(b): 18 models; (c),(d): 12 models), and hatched where differences between the RCP4.5 multi-model mean SLP anomaly exceed the 60th percentile (red-bordered regions) or are less than the 40th percentile (blue-bordered regions) of the distribution of 20th century ensemble means. In all panels, El Niño (La Niña) periods are defined as years having DJF NINO3.4 SST above (below) one standard deviation relative to the mean of the detrended time series. For ensemble-mean calculations, all SLP anomalies have been normalized to the standard deviation of the ensemble-member detrended NINO3.4 SST. (e) Change in the "centre of mass" of the Aleutian Low SLP anomaly, RCP4.5 - 20th century. The Aleutian Low SLP centre of mass is a vector with two elements (lat, lon), and is defined as the sum of (lat, lon) weighted by the SLP anomaly, over all points in the region 180°E–120°E, 40°N–60°N having a negative SLP anomaly during El Niño.

14.4.4 Assessment summary

ENSO shows considerable inter-decadal modulations in amplitude and spatial pattern within the instrumental record. Models without changes in external forcing display similar modulations, and there is little consensus on whether the observed changes in ENSO are due to external forcing or natural variability (see also Section 10.3.3 for an attribution discussion).

It is *very likely* that ENSO will remain the dominant mode of interannual variability with global influences in the 21st century, and due to changes in moisture availability ENSO-induced rainfall variability on regional scales will intensify. There is *medium confidence* that ENSO-induced teleconnection patterns will shift eastward over the North Pacific and North America. There is *low confidence* in changes in the intensity and spatial pattern of El Niño in a warmer climate.

14.5 Annular and Dipolar Modes

The North Atlantic Oscillation (NAO), the North Pacific Oscillation (NPO), and the Northern and Southern Annular Modes (NAM and SAM) are dominant modes of variability in the extra-tropics. These modes are

the focus of much research attention, especially in impact studies, where they are often used as aggregate descriptors of past regional climate trends and variations over many parts of the world. For example, since IPCC (2007a) more than 2000 scientific articles have been published, which include NAO, AO, or NAM in either the title or abstract. This assessment focuses on recent research on these modes that is most relevant for future regional climate change. Past behaviour of these modes inferred from observations is assessed in Section 2.7.8.

14.5.1 Northern Modes

The North Atlantic Oscillation is a well-established dipolar mode of climate variability having opposite variations in sea-level pressure between the Atlantic subtropical high and the Iceland/Arctic low (Wanner et al., 2001; Hurrell et al., 2003; Budikova, 2009). It is strongly associated with the tropospheric jet, storms (see Section 14.6.2), and blocking that determine the weather and climate over the North Atlantic and surrounding continents (Hurrell and Deser, 2009; Box 14.2). The NAO exists in boreal summer as well as in boreal winter, albeit with different physical characteristics (Sun et al., 2008; Folland et al., 2009).

Over the North Pacific, there is a similar wintertime dipolar mode known as the North Pacific Oscillation, associated with north-south displacements of the Asian-Pacific jet stream and the Pacific storm track. The NPO influences winter air temperature and precipitation over much of western North America as well as sea ice over the Pacific sector of the Arctic, more so than either ENSO (Section 14.4) or the PNA (Linkin and Nigam, 2008).

These dipolar modes have been interpreted as the regional manifestation of an annular mode in sea-level pressure known as the Arctic Oscillation (AO; Thompson and Wallace, 1998) or the Northern Annular Mode (NAM; Thompson and Wallace, 2000). The AO (NAM at 1000hPa) index and the NAO index (see Box 2.5, Table 1) are strongly correlated but the AO spatial pattern is more zonally symmetric and so differs from the NAO over the N. Pacific (Ambaum et al., 2001; Feldstein and Franzke, 2006). Hereafter, the term NAO is used to denote NAO, AO and NAM in boreal winter unless further distinction is required.

Climate models are generally able to simulate the gross features of NAO and NPO (see Section 9.5.3.2). It has been argued that these modes may be a preferred pattern of response to climate change (Gerber et al., 2008). However, this is not supported by a detailed examination of the vertical structure of the simulated global warming response (Woollings, 2008). Hori et al. (2007) noted that NAO variability did not change substantially in the SRES-A1B and 20th century scenarios and so concluded that the trend in the NAO index (defined relative to a historical mean state) is a result of an anthropogenic trend in the basic mean state rather than due to changes in NAO variability. However, other research indicates that there is a coherent two-way interaction between the trend in the mean state and the NAO-like modes of variability – the mode and/or regime structure change due to changes in the mean state (Branstator and Selten, 2009; Barnes and Polvani, 2013). Section 14.6.2 assesses the jet and storm track changes associated with the projected responses.

Model simulations have underestimated the magnitude of the large positive trend from 1960–2000 in winter NAO observations, which now appears to be more likely due to natural variability rather than anthropogenic influences (see Section 10.3.3.2). Some studies have even considered NAO to be a source of natural variability that needs to be removed before detection and attribution of anthropogenic changes (Zhang et al., 2006). Detection of regional surface air temperature response to anthropogenic forcing has been found to be robust to the exclusion of model-simulated AO and PNA changes (Wu and Karoly, 2007). Model projections of wintertime European precipitation have been shown to become more consistent with observed trends after removal of trends due to NAO (Bhend and von Storch, 2008). Underestimation of trends in NAO can lead to biases in projections of regional climate e.g., Arctic sea ice (Koldunov et al., 2010).

Underestimation of NAO long-term variability may be due to missing or poorly represented processes in climate models. Recent observational and modelling studies have helped to confirm that the lower stratosphere plays an important role in explaining recent more negative NAO winters and long term trends in NAO (Scaife et al., 2005; Dong et al., 2011; Ouzeau et al., 2011; Schimanke et al., 2011). This is supported by evidence that seasonal forecasts of NAO can be improved by inclusion of the stratospheric QBO (Boer and Hamilton, 2008; Marshall and Scaife, 2010). Other studies have found that observed changes in stratospheric water vapour changes from 1965–1995 led to an impact on NAO simulated by a model, and

have suggested that changes in stratospheric water vapour may be another possible pathway for communicating tropical forcing to the extra-tropics (Joshi et al., 2006; Bell et al., 2009). There is growing evidence that future NAO projections are sensitive to how climate models resolve stratospheric processes and troposphere-stratosphere interactions (Sigmond and Scinocca, 2010; Scaife et al., 2011a; Karpechko and Manzini, 2012).

Several recent studies of historical data have found a positive association between solar activity and NAO (Haigh and Roscoe, 2006; Kodera et al., 2008; Lockwood et al., 2010), while other studies have found little imprint of solar and volcanic forcing on NAO (Casty et al., 2007). Positive associations between NAO and solar forcing have been reproduced in recent modelling studies (Lee et al., 2008; Ineson et al., 2011) but no significant changes were found in CMIP5 projections of NAO due to changes in solar irradiance or aerosol forcing.

Observational studies have noted weakening of NAO during periods of reduced Arctic sea ice (Strong et al., 2009; Wu and Zhang, 2010). Several modelling studies have also shown a negative NAO response to the partial removal of sea ice in the Arctic or high-latitudes (Kvamsto et al., 2004; Magnusdottir et al., 2004; Seierstad and Bader, 2009; Deser et al., 2010c; Screen et al., 2012). However, the strength and timing of the response to sea ice loss varies considerably between studies, and can be hard to separate from common responses to warming of the troposphere and from natural climate variability. The impact of sea ice loss in individual years on NAO is small and hard to detect (Bluthgen et al., 2012). Reviews of the emerging literature on this topic can be found in Budikova (2009) and Bader et al. (2011).

The NPO contributes to the excitation of ENSO events via the “Seasonal Footprinting Mechanism” (SFM; Anderson, 2003; Vimont et al., 2009; Alexander et al., 2010). Some studies indicate that warm events in the central tropical Pacific Ocean may in turn excite the NPO (Di Lorenzo et al., 2009).

Recent multi-model studies of NAO (Hori et al., 2007; Karpechko, 2010; Zhu and Wang, 2010; Gillett and Fyfe, 2013) reconfirm the small positive response of boreal winter NAO indices to greenhouse gas forcing noted in earlier studies reported in AR4 (Kuzmina et al., 2005; Miller et al., 2006; Stephenson et al., 2006). Projected trends in wintertime NAO indices are generally found to have small amplitude compared to natural internal variations (Deser et al., 2012). Furthermore, there is substantial variation in NAO projections from different climate models. For example, one study found no significant NAO trends in two simulations with ECHAM4/OPYC3 (Fischer-Bruns et al., 2009), whereas another study found a strong positive trend in NAO in the ECHAM5/MPI-OM SRES A1B simulations (Müller and Roeckner, 2008). The model-dependence of the response is an important source of uncertainty in the regional climate change response (Karpechko, 2010). A multi-model study of 24 climate model projections suggests that there are no major changes in the NPO due to greenhouse warming (Furtado et al., 2011).

Figures 14.16a,b summarise the wintertime NAO and NAM indices simulated by models participating in the CMIP5 experiment (Gillett and Fyfe, 2013). The multi-model mean of the NAO and NAM indices are similar and exhibit small linear trends in agreement with those shown for the NAM index in AR4 (AR4, Figure 10.17a). The multi-model mean projected increase of around 1–2 hPa from 1850 to 2100 is smaller than the spread of around 2–4 hPa between model simulations (Figure 14.16).

Some differences in model projections can be accounted for by changes in the NAO spatial pattern, for example, northeastward shifts in NAO centres of action have been found to be important for estimating the trend in the NAO index (Ulbrich and Christoph, 1999; Hu and Wu, 2004). Individual model simulations have shown the spatial extent of NAO influence decreases with greenhouse gas forcing (Fischer-Bruns et al., 2009), a positive feedback between jet and storm tracks that enhances a pole ward shift in the NAO pattern (Choi et al., 2010), and changes in the NAO pattern but with no changes in the propagation conditions for Rossby waves (Brandefelt, 2006). One modelling study found a trend in the correlation between NAO and ENSO during the 21st century (Muller and Roeckner, 2006). Such changes in the structure of NAO and/or its interaction with other modes of variability would could lead to important regional climate impacts.

[INSERT FIGURE 14.16 HERE]

Figure 14.16: Summary of multi-model ensemble simulations of wintertime (Dec-Feb) mean NAO, NAM and SAM sea-level pressure indices for historical and RCP4.5 scenarios produced by 39 climate models participating in CMIP5.

Panels a-c) show time series of the ensemble mean (black line) and inter-quartile range (grey shading) of the mean index for each model. Panels d-f) show scatter plots of individual model 2081–2100 time means versus 1986–2005 time means (black crosses) together with (–2,+2) standard error bars. The NAO index is defined here as the difference of regional averages: (90°W–60°E, 20°N–55°N) minus (90°W–60°E, 55°N–90°N) (see Stephenson et al., 2006). The NAM and SAM are defined as zonal indices: NAM as the difference in zonal mean SLP at 35°N and 65°N (Li and Wang, 2003) and SAM as the difference in zonal mean SLP at 40°S and 65°S (Gong and Wang, 1999). All indices have been centred to have zero time mean from 1861–1900. Comparison of simulated and observed trends from 1961–2011 is shown in Figure 10.12.

14.5.2 Southern Annular Mode

The Southern Annular Mode (SAM, also known as Antarctic Oscillation, AAO), is the leading mode of climate variability in the Southern Hemisphere extra-tropics, describing fluctuations in the latitudinal position and strength of the mid-latitude eddy-driven westerly jet (see Box 2.5; Section 9.5.3.2). SAM variability has a major influence on the climate of Antarctica, Australasia, southern South America and South Africa (Watterson, 2009; Thompson et al., 2011 and references therein).

The physical mechanisms of the SAM are well-understood, and the SAM is well-represented in climate models, although the detailed spatial and temporal characteristics vary between models (Raphael and Holland, 2006). In the past few decades the SAM index has exhibited a positive trend in austral summer and autumn (Figure 14.16, Marshall, 2007; Jones et al., 2009b), a change attributed to the effects of ozone depletion and, to a lesser extent, the increase in greenhouse gases (Thompson et al., 2011, see also Section 10.3.3.3). It is *likely* that these two factors will continue to be the principal drivers into the future, but as the ozone hole recovers they will be competing to push the SAM in opposite directions (Arblaster et al., 2011; Thompson et al., 2011; Bracegirdle et al., 2013), at least during late austral spring and summer, when ozone depletion has had its greatest impact on the SAM. The SAM is also influenced by teleconnections to the tropics, primarily associated with ENSO (Carvalho et al., 2005; L'Heureux and Thompson, 2006). Changes to the tropical circulation, and to such teleconnections, as the climate warms could further affect SAM variability (Karpechko et al., 2010). See Supplementary Material Section 14.SM.3.1 for further details on the observed variability of SAM.

The CMIP3 models projected a continuing positive trend in the SAM in both summer and winter (Miller et al., 2006). However, those models generally had poor simulations of stratospheric ozone, and tended to underestimate natural variability and to misrepresent observed trends in the SAM, indicating that care should be taken in interpretation of their future SAM projections (Fogt et al., 2009). Arblaster et al. (2011) showed that there can be large differences in the sensitivity of these models to CO₂ increases, which affects their projected trends in the SAM.

Since the AR4 a number of chemistry-climate models (CCMs) have been run that have fully interactive stratospheric chemistry, although unlike coupled atmosphere ocean models they are usually not coupled to the oceans (see also Sections 9.1.3.2.7 and 9.4.6.2). The majority of CCMs and coupled models, which generally compare well to reanalyses (Gerber et al., 2010) although many exhibit biases in their placement of the Southern Hemisphere eddy-driven jet (Wilcox et al., 2012; Bracegirdle et al., 2013), indicate that through to at least the mid-21st century the current observed SAM changes are neutralised or reversed during austral summer (Perlwitz et al., 2008; Son et al., 2010; Polvani et al., 2011; Bracegirdle et al., 2013). Figure 14.16 shows the projected ensemble-mean future SAM index evolution during DJF from a suite of CMIP5 models, suggesting that the recent positive trend will weaken considerably as stratospheric ozone concentrations recover over southern high latitudes.

Projected 21st century changes in the SAM, and the closely associated Southern Hemisphere eddy-driven jet position, vary by season (Gillett and Fyfe, 2013), and are sensitive to the rate of ozone recovery (Son et al., 2010; Eyring et al., 2013) and to greenhouse gas emissions scenario (Swart and Fyfe, 2012; Eyring et al., 2013). In the RCP2.6 scenario, with small increases in greenhouse gases, ozone recovery may dominate in austral summer giving a small projected equatorward jet shift (Eyring et al., 2013) with little change in the annual mean jet position (Swart and Fyfe, 2012). In RCP8.5 large greenhouse gas increases are expected to dominate, giving an on-going poleward shift of the Southern Hemisphere jet in all seasons (Swart and Fyfe, 2012; Eyring et al., 2013). In RCP4.5 the influences of ozone recovery and greenhouse gas increases are

expected to approximately balance in austral summer, with an on-going poleward jet shift projected in the other seasons (Swart and Fyfe, 2012; Eyring et al., 2013; Gillett and Fyfe, 2013).

14.5.3 Assessment Summary

Future boreal wintertime NAO is *very likely* to exhibit large natural variations and trends of similar magnitude to those observed in the past; is *very likely* to differ quantitatively from individual climate model projections; is *likely* to become slightly more positive (on average) due to increases in greenhouse gases. The austral summer/autumn positive trend in SAM is *likely* to weaken considerably as ozone depletion recovers through to the mid-21st century. There is *medium confidence* from recent studies that projected changes in NAO and SAM are sensitive to boundary processes, which are not yet well represented in many climate models currently used for projections e.g., stratosphere-troposphere interaction, ozone chemistry, solar forcing, and atmospheric response to Arctic sea ice loss. There is *low confidence* in projections of other modes such as the NPO due to the small number of modelling studies.

[START BOX 14.2 HERE]

Box 14.2: Blocking

Atmospheric blocking is associated with persistent, slow-moving high-pressure systems that interrupt the prevailing westerly winds of middle and high latitudes and the normal eastward progress of extratropical storm systems. Overall, blocking activity is more frequent at the exit zones of the jet stream and shows appreciable seasonal variability in both hemispheres, reaching a maximum in winter-spring and a minimum in summer-autumn (e.g., Wiedenmann et al., 2002). In the Northern Hemisphere, the preferred locations for winter blocking are the North Atlantic and North Pacific, whereas continental blocks are relatively more frequent in summer (Tyrlis and Hoskins, 2008; Barriopedro et al., 2010). Southern Hemisphere blocking is less frequent than in the Northern Hemisphere, and it tends to be concentrated over the Southeast Pacific and the Indian Ocean (Berrisford et al., 2007).

Blocking is a complex phenomenon that involves large- and small-scale components of the atmospheric circulation, and their mutual interactions. Although there is not a widely accepted blocking theory, transient eddy activity is considered to play an important role in blocking occurrence and maintenance through feedbacks between the large-scale flow and synoptic eddies (e.g., Yamazaki and Itoh, 2009).

Blocking is an important component of intraseasonal variability in the extratropics and causes climate anomalies over large areas of Europe (Trigo et al., 2004; Masato et al., 2012), North America (Carrera et al., 2004), East Asia (e.g., Wang et al., 2010; Cheung et al., 2012), high latitude regions of the Southern Hemisphere (Mendes et al., 2008) and Antarctica (Massom et al., 2004; Sarchilli et al., 2011). Blocking can also be responsible for extreme events (e.g., Buehler et al., 2011; Pfahl and Wernli, 2012), such as cold spells in winter (e.g., 2008 in China, Zhou et al., 2009d; or 2010 in Europe, Cattiaux, 2010) and summer heat waves in the Northern Hemisphere (e.g., 2010 in Russia, Matsueda, 2011; Lupo et al., 2012) and in southern Australia (Pezza et al., 2008).

At interannual time scales, there are statistically significant relationships between blocking activity and several dominant modes of atmospheric variability, such as the NAO (Section 14.5.1) and wintertime blocking in the Euro-Atlantic sector (Crocini-Maspoli et al., 2007a; Luo et al., 2010), the winter PNA (Section 14.7.1) and blocking frequency in the north Pacific (Crocini-Maspoli et al., 2007a), or the SAM (Section 14.5.2) and winter blocking activity near the New Zealand sector (Berrisford et al., 2007). Multi-decadal variability in winter blocking over the north Atlantic and the north Pacific seem to be related, respectively, with the AMOC (Häkkinen et al., 2011; Section 14.7.6) and the PDO (Chen and Yoon, 2002; Section 14.7.5), although this remains an open question.

Other important scientific issues related to the blocking phenomenon include the mechanisms of blocking onset and maintenance, two-way interactions between blocking and stratospheric processes (e.g., Martius et al., 2009; Woollings et al., 2010), influence on blocking of slowly-varying components of the climate system (SST, sea ice, etc., Liu et al., 2012b), and external forcings.

The most consistent long-term observed trends in blocking for the second half of the 20th century are the reduced winter activity over the North Atlantic (e.g., Croci-Maspoli et al., 2007b), which is consistent with the observed increasing NAO trend from the 1960's to the mid-1990's (Section 2.7.8), as well as an eastward shift of intense winter blocking over the Atlantic and Pacific oceans (Davini et al., 2012). The apparent decreasing trend in Southern Hemisphere blocking activity (e.g., Dong et al., 2008) seems to be in agreement with the upward trend in the SAM.

The AR4 (Section 8.4.5) reported a tendency for GCMs to underestimate Northern Hemisphere blocking frequency and persistence, although most models were able to capture the preferred locations for blocking occurrence and their seasonal distributions. Several intercomparison studies based on a set of CMIP3 models (Scaife et al., 2010; Vial and Osborn, 2012) revealed some progress in the simulation of Northern Hemisphere blocking activity, mainly in the North Pacific, but only modest improvements in the North Atlantic. In the SH, blocking frequency and duration was also underestimated, particularly over the Australia-New Zealand sector (Matsueda et al., 2010). CMIP5 models still show a general blocking frequency underestimation over the Euro-Atlantic sector, and some tendency to overestimate north Pacific blocking (Section 9.5.2.2), with considerable inter-model spread (Box 14.2, Figure 1).

Model biases in the mean flow, rather than in variability, can explain a large part of the blocking underestimation and they are usually evidenced as excessive zonality of the flow or systematic shifts in the latitude of the jet stream (Matsueda et al., 2010; Scaife et al., 2011b; Barnes and Hartmann, 2012; Vial and Osborn, 2012; Anstey et al., 2013; Dunn-Sigouin and Son, 2013). Increasing the horizontal resolution in atmospheric GCMs with prescribed SSTs has been shown to significantly reduce blocking biases, particularly in the Euro-Atlantic sector and Australasian sectors (e.g., Matsueda et al., 2010; Jung et al., 2011; Dawson et al., 2012; Berckmans et al., 2013), while north Pacific blocking could be more sensitive to systematic errors in tropical SSTs (Hinton et al., 2009). Also blocking biases are smaller in those CMIP5 models with higher horizontal and vertical resolution (Anstey et al., 2013). However, the improvement of blocking simulation with increasing horizontal resolution is less clear in coupled models than in atmospheric GCMs with prescribed SSTs, indicating that both SSTs and the relative coarse resolution in OGCM (Scaife et al., 2011b) are important causes of blocking biases.

Most CMIP3 models projected significant reductions in Northern Hemisphere annual blocking frequency (Barnes et al., 2012), particularly during winter, but CMIP5 models seem to indicate weaker decreases in the future (Dunn-Sigouin and Son, 2013) and a more complex response than that reported by CMIP3 models, including possible regional increases of blocking frequency in summer (Cattiaux et al., 2013; Masato et al., 2013). There is high agreement that winter blocking frequency over north Atlantic and north Pacific is *unlikely* to increase under enhanced GHG concentrations (Barnes et al., 2012; Dunn-Sigouin and Son, 2013). Future strengthening of the zonal wind and meridional jet displacements may partially account for some of the projected changes in blocking frequency over the ocean basins of both hemispheres (Matsueda et al., 2010; Barnes and Hartmann, 2012; Dunn-Sigouin and Son, 2013). Future trends in blocking intensity and persistence are even more uncertain, with no clear signs of significant changes. How the location and frequency of blocking events will evolve in future are both critically important for understanding regional climate change in particular with respect to extreme conditions (e.g., Sillmann et al., 2011; de Vries et al., 2013).

In summary, the increased ability in simulating blocking in some models indicate that there is *medium confidence* that the frequency of Northern and Southern Hemisphere blocking will not increase, while trends in blocking intensity and persistence remain uncertain. The implications for blocking related regional changes in North America, Europe and Mediterranean and Central and North Asia are therefore also uncertain [Box 14.2 and 14.8.3, 14.8.6, 14.8.8]

[INSERT FIGURE BOX 14.2, FIGURE 1 HERE]

Box 14.2, Figure 1: Annual mean blocking frequency in the Northern Hemisphere (expressed in % of time, i.e., 1% means ~4 days per year) as simulated by a set of CMIP5 models (colour lines) for the 1961–1990 period of one run of the historical simulation. Grey shading shows the mean model result plus/minus one standard deviation. Black thick line indicates the observed blocking frequency derived from the NCEP/NCAR reanalysis. Only CMIP5 models with available 500 hPa geopotential height daily data at <http://pcmdi3.llnl.gov/esgcat/home.htm> have been used. Blocking is defined as in Barriopedro et al. (2006), which uses a modified version of the index. Daily data was interpolated to a common regular $2.5^\circ \times 2.5^\circ$ longitude-latitude grid before detecting blocking.

[END BOX 14.2 HERE]

14.6 Large-Scale Storm Systems

14.6.1 Tropical Cyclones

The potential for regional changes in future tropical cyclone frequency, track and intensity is of great interest, not just because of the associated negative effects, but also because tropical cyclones can play a major role in maintaining regional water resources (Jiang and Zipser, 2010; Lam et al., 2012; Prat and Nelson, 2012). Past and projected increases in human exposure to tropical cyclones in many regions (Peduzzi et al., 2012) heightens the interest further.

14.6.1.1 Understanding the Causes of Past and Projected Regional Changes

Detection of past trends in measures of tropical cyclone activity is constrained by the quality of historical records and uncertain quantification of natural variability in these measures (Knutson et al., 2010; Lee et al., 2012; Seneviratne et al., 2012). Observed regional climate variability generally represents a complex convolution of natural and anthropogenic factors, and the response of tropical cyclones to each factor is not yet well understood (see also Section 10.6.1.5 and Supplementary Material Section 14.SM.4.1.2). For example, the steady long-term increase in tropical Atlantic SST due to increasing greenhouse gas can be dominated by shorter-term decadal variability forced by both external and internal factors (Mann and Emanuel, 2006; Baines and Folland, 2007; Evan et al., 2009; Ting et al., 2009; Zhang and Delworth, 2009; Chang et al., 2011; Evan et al., 2011a; Solomon and Newman, 2011; Booth et al., 2012; Camargo et al., 2012; Villarini and Vecchi, 2012). Similarly, tropical upper-tropospheric temperatures, which modulate tropical cyclone potential intensity (Emanuel, 2010), can be forced by slowly-evolving changes in the stratospheric circulation of ozone (Brewer–Dobson circulation) due to climate change with occasional large amplitude and persistent changes forced by volcanic eruptions (Thompson and Solomon, 2009; Evan, 2012). This convolution of anthropogenic and natural factors, as represented in a climate model, has also been shown to be useful in prediction of Atlantic tropical storm frequency out to a few years (Smith et al., 2010).

In addition to greenhouse warming scenarios, tropical cyclones can also respond to anthropogenic forcing via different and possibly unexpected pathways. For example, increasing anthropogenic emissions of black carbon and other aerosols in South Asia has been linked to a reduction of SST gradients in the Northern Indian Ocean (Chung and Ramanathan, 2006; Meehl et al., 2008), which has in turn been linked to a weakening of the vertical wind shear in the region. Evan et al. (2011b) linked the reduced wind shear to the observed increase in the number of very intense storms in the Arabian Sea, including five very severe cyclones that have occurred since 1998, but the fundamental cause of this proposed linkage is not yet certain (Evan et al., 2012; Wang et al., 2012a). Furthermore, it is possible that a substantial part of the multi-decadal variability of North Atlantic SST is radiatively forced, via the cloud albedo effect, by what are essentially pollution aerosols emitted from North America and Europe (Baines and Folland, 2007; Booth et al., 2012), although the relative contribution of this forcing to the observed variability has been questioned (Zhang et al., 2013b). Note that in the North Atlantic, the evidence suggests that the *reduction* of pollution aerosols since the United States Clean Air Act and Amendments during and after the 1970s (with further contribution from the European Commission’s Air Quality Framework Directive) is linked to tropical SST increases, while in the northern Indian Ocean, *increases* in aerosol pollution have been linked to reduced vertical wind shear. Both of these effects (increasing SST and reduced shear) have been observed to be related to increased tropical cyclone activity.

Finally, in addition to interannual-to-multidecadal forcing of tropical Atlantic SST via radiative dimming (Evan et al., 2009; Evan et al., 2011a), dust aerosols have a large and more immediate *in situ* effect on the regional thermodynamic and kinematic environment (Dunion and Marron, 2008; Dunion, 2011), and Saharan dust storms—whose frequency has been linked to atmospheric CO₂ concentration (Mahowald, 2007)—have also been linked to reduced strengthening of tropical cyclones (Dunion and Velden, 2004; Wu, 2007). Direct *in situ* relationships have also been identified between aerosol pollution concentrations and tropical cyclone structure and intensity (Khain et al., 2008; Khain et al., 2010; Rosenfeld et al., 2011). Thus, when assessing changes in tropical cyclone activity, it is clear that detection and attribution aimed simply at

long-term linear trends forced by increasing well-mixed greenhouse gasses is not adequate to provide a complete picture of the potential anthropogenic contributions to the changes in tropical cyclone activity that have been observed.

14.6.1.2 Regional Numerical Projections

Similar to observational analyses, confidence in numerical simulations of tropical cyclone activity (Supplementary Material Tables 14.SM.1–14.SM.4) is reduced when model spatial domain is reduced from global to region-specific (IPCC SREX Box 3.2; see also Section 9.5.4.3). The assessment provided by Knutson et al. (2010) of projections based on the SRES A1B scenario concluded that it is *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged while mean intensity (as measured by maximum wind speed) increases by +2 to +11% and tropical cyclone rainfall rates increase by about 20% within 100 km of the cyclone centre. However, inter-model differences in regional projections lead to lower confidence in basin-specific projections, and confidence is particularly low for projections of frequency within individual basins. For example, a recent assessment by Ying et al. (2012) showed that numerical projections of 21st century changes in tropical cyclone frequency in the western North Pacific range broadly from –70% to +60%, while there is better model agreement in measures of mean intensity and precipitation, which are projected to change in the region by –3% to +18% and +5% to +30%, respectively. The available modelling studies that are capable of producing very strong cyclones typically project substantial increases in the frequency of the most intense cyclones and it is *more likely than not* that this increase will be larger than 10% in some basins (Emanuel et al., 2008; Bender et al., 2010; Knutson et al., 2010; Yamada et al., 2010; Murakami et al., 2012; Knutson et al., 2013). It should be emphasized that this metric is generally more important to physical and societal impacts than overall frequency or mean intensity.

As seen in Tables 14.SM.1–14.SM.4 of the Supplementary Material, as well as the previous assessments noted above, model projections often vary in the details of the models and the experiments performed, and it is difficult to objectively assess their combined results to form a consensus, particularly by region. It is useful to do this after normalising the model output using a combination of objective and subjective expert judgements. The results of this are shown in Figure 14.17, and are based on a subjective normalisation of the model output to four common metrics under a common future scenario projected through the 21st century. The global assessment is essentially the same as Knutson et al. (2010) and the assessment of projections in the western North Pacific is essentially unchanged from Ying et al. (2012). The annual frequency of tropical cyclones is generally projected to decrease or remain essentially unchanged in the next century in most regions although as noted above, the confidence in the projections is lower in specified regions than global projections. The decrease in storm frequency is apparently related to a projected decrease of upward deep convective mass flux and increase in the saturation deficit of the middle troposphere in the tropics associated with global warming (Bengtsson et al., 2007; Emanuel et al., 2008; Zhao et al., 2009; Held and Zhao, 2011; Emanuel et al., 2012; Murakami et al., 2012; Sugi et al., 2012; Sugi and Yoshimura, 2012).

A number of experiments that are able to simulate intense tropical cyclones project increases in the frequency of these storms in some regions, although there are presently only limited studies to assess and there is insufficient data to draw from in most regions to make a confident assessment (Figure 14.17). The models generally project an increase in mean lifetime-maximum intensity of simulated storms (Supplementary Material Table 14.SM.3), which is consistent with a projected increase in the frequency in the more intense storms (Elsner et al., 2008). The projected increase in intensity concurrent with a projected decrease in frequency can be argued to result from a difference in scaling between projected changes in surface enthalpy fluxes and the Clausius-Clapeyron relationship associated with the moist static energy of the middle-troposphere (Emanuel et al., 2008). The increase in rainfall rates associated with tropical cyclones is a consistent feature of the numerical models under greenhouse warming as atmospheric moisture content in the tropics and tropical cyclone moisture convergence is projected to increase (Trenberth et al., 2005; Trenberth et al., 2007a; Allan and Soden, 2008; Knutson et al., 2010; Knutson et al., 2013). Although no broad-scale, detectable long-term changes in tropical cyclone rainfall rates have been reported, preliminary evidence for a detectable anthropogenic increase in atmospheric moisture content over ocean regions has been reported by Santer et al. (2007).

A number of studies since the AR4 have attempted to project future changes in tropical cyclone tracks and genesis at inter- or intra-basin scale (Leslie et al., 2007; Vecchi and Soden, 2007b; Emanuel et al., 2008; Yokoi and Takayabu, 2009; Zhao et al., 2009; Li et al., 2010b; Murakami and Wang, 2010; Lavender and Walsh, 2011; Murakami et al., 2011a; Murakami et al., 2013). These studies suggest that projected changes in tropical cyclone activity are strongly correlated with projected changes in the spatial pattern of tropical SST (Sugi et al., 2009; Chauvin and Royer, 2010; Murakami et al., 2011b; Zhao and Held, 2012) and associated weakening of the Pacific Walker circulation (Vecchi and Soden, 2007a), indicating that reliable projections of regional tropical cyclone activity depend critically on the reliability of the projected pattern of SST changes. However, assessing changes in regional tropical cyclone frequency is still limited because confidence in projections critically depend on the performance of control simulations (Murakami and Sugi, 2010), and current climate models still fail to simulate observed temporal and spatial variations in tropical cyclone frequency (Walsh et al., 2012). As noted above, tropical cyclone genesis and track variability is modulated in most regions by known modes of atmosphere/ocean variability. The details of the relationships vary by region (e.g., El Niño events tend to cause track shifts in western North Pacific typhoons and tend to suppress Atlantic storm genesis and development). Similarly, it has been demonstrated that accurate modelling of tropical cyclone activity fundamentally depends on the model's ability to reproduce these modes of variability (e.g., Yokoi and Takayabu, 2009). Reliable projections of future tropical cyclone activity, both global and regional, will then depend critically on reliable projections of the behaviour of these modes of variability (e.g., ENSO) under global warming, as well as an adequate understanding of their physical links with tropical cyclones. Presently there is still uncertainty in their projected behaviours (e.g., Section 14.4).

The reduction in signal-to-noise ratio that accompanies changing focus from global to regional scales also lengthens the emergence time-scale (i.e., the time required for a trend signal to rise above the natural variability in a statistically significant way). Based on changes in tropical cyclone intensity predicted by idealized numerical simulations with CO₂-induced tropical SST warming, Knutson and Tuleya (2004) suggested that clearly detectable increases may not be manifest for decades to come. The more recent high-resolution dynamical downscaling study of Bender et al. (2010) supports this argument and suggests that the predicted increases in the frequency of the strongest Atlantic storms may not emerge as a statistically significant signal until the latter half of the 21st century under the SRES A1B emissions scenario. However, regional forcing by agents other than greenhouse gas, such as anthropogenic aerosols, is known to affect the regional climatic conditions differently (e.g., Zhang and Delworth, 2009), and there is evidence that tropical cyclone activity has changed in some regions because of effects from anthropogenic aerosol pollution. The fidelity of the emergence time-scales projected under A1B warming thus depends on the fidelity of A1B aerosol projections, which are known to be uncertain (Forster et al., 2007; Haerter et al., 2009).

[INSERT FIGURE 14.17 HERE]

Figure 14.17: General consensus assessment of the numerical experiments described in Supplementary Material Tables 14.SM.1–14.SM.4 in the. All values represent expected percent change in the average over period 2081–2100 relative to 2000–2019, under an A1B-like scenario, based on expert judgment after subjective normalisation of the model projections. Four metrics were considered: the percent change in I) the total annual frequency of tropical storms, II) the annual frequency of Category 4 and 5 storms, III) the mean Lifetime Maximum Intensity (LMI; the maximum intensity achieved during a storm's lifetime), and IV) the precipitation rate within 200 km of storm centre at the time of LMI. For each metric plotted, the solid blue line is the best guess of the expected percent change, and the coloured bar provides the 67% (*likely*) confidence interval for this value (note that this interval ranges across –100% to +200% for the annual frequency of Category 4 and 5 storms in the North Atlantic). Where a metric is not plotted, there is insufficient data (denoted "insf. d.") available to complete an assessment. A randomly drawn (and coloured) selection of historical storm tracks are underlain to identify regions of tropical cyclone activity.

14.6.2 Extra-Tropical Cyclones

Some agreement on the response of storm tracks to anthropogenic forcing started to emerge in the climate model projections from CMIP3, with many models projecting a poleward shift of the storm tracks (Yin, 2005) and an expansion of the tropics (Lu et al., 2007). As stated in AR4 (Meehl et al., 2007) this response is particularly clear in the Southern Hemisphere, but less clear in the Northern Hemisphere. Although clearer in zonal mean responses (Yin, 2005), regional responses at different longitudes differ widely from this in many models (Ulbrich et al., 2008). There is a strong two-way coupling between storm tracks and the large-scale circulation (Lorenz and Hartmann, 2003; Robinson, 2006; Gerber and Vallis, 2007), which results in

associated shifts in storm tracks and westerly jet streams (Raible, 2007; Athanasiadis et al., 2010).

14.6.2.1 Process Understanding of Future Changes

Future storm track change is the result of several different competing dynamical influences (Held, 1993; O'Gorman, 2010; Woollings, 2010). It is becoming apparent that the relatively modest storm track response in many models reflects the partial cancelling of opposing tendencies (Son and Lee, 2005; Lim and Simmonds, 2009; Butler et al., 2010).

One of the most important factors is the change in the meridional temperature gradient from which extra-tropical cyclones (ETCs) draw most of their energy. This gradient is projected to increase in the upper troposphere due to tropical amplification and decrease in the lower troposphere due to polar amplification, and it is still unclear whether this will lead to an overall increase or decrease in ETC activity. The projected response can involve an increase in eddy activity at upper levels and a decrease at lower levels (Hernandez-Deckers and von Storch, 2010), although in other models changes in low level eddy activity are more in line with the upper level wind changes (Mizuta et al., 2011; Wu et al., 2011; Mizuta, 2012). The projected warming pattern also changes vertical temperature gradients leading to increased stability at low latitudes and decreased stability at higher latitudes, and there is some modelling evidence that this may be a strong factor in the response (Lu et al., 2008; Kodama and Iwasaki, 2009; Lim and Simmonds, 2009; Lu et al., 2010). Increasing depth of the troposphere might also be important for future changes (Lorenz and DeWeaver, 2007).

Uncertainties in the projections of large-scale warming contribute to uncertainty in the storm track response (Rind, 2008). Several mechanisms have been proposed to explain how the storm tracks respond to the large-scale changes, including changes in eddy phase speed (Chen et al., 2007; Chen et al., 2008; Lu et al., 2008), eddy source regions (Lu et al., 2010) and eddy length scales (Kidston et al., 2011) with a subsequent effect on wave-breaking characteristics (Riviere, 2011). Furthermore, changes in the large-scale warming might also be partly due to changes in the storm tracks due to the two-way coupling between storm tracks and the large-scale flow. However, there is evidence that the amplitude of the tropical and polar warming are largely determined by atmospheric poleward heat fluxes set by local processes (Hwang and Frierson, 2010).

Local processes could prove important for the storm track response in certain regions, for example, sea ice loss (Kvamsto et al., 2004; Seierstad and Bader, 2009; Deser et al., 2010c; Bader et al., 2011) and spatial changes in sea surface temperatures (Graff and LaCase, 2012). Local land-sea contrast in warming also has a local influence on baroclinicity along the eastern continental coastlines (Long et al., 2009; McDonald, 2011). It is not clear how the storm track responds to multiple forcings with some studies suggesting a linear response (Lim and Simmonds, 2009) while others suggest more complex interaction (Butler et al., 2010).

The projected increase in moisture content in a warmer atmosphere is also *likely* to have competing effects. Latent heating has been shown to play a role in invigorating individual ETCs, especially in the downstream development over eastern ocean (Dacre and Gray, 2009; Fink et al., 2009; Fink et al., 2012). However, there is evidence that the overall effect of moistening is to weaken ETCs by improving the efficiency of poleward heat transport and hence reducing the dry baroclinicity (Frierson et al., 2007; O'Gorman and Schneider, 2008; Schneider et al., 2010; Lucarini and Ragone, 2011). Consistent with this, studies have shown that precipitation is projected to increase in ETCs despite no increase in wind speed intensity of ETCs (Bengtsson et al., 2009; Zappa et al., 2013b).

14.6.2.2 Regional Projections

Large-scale projections of ETCs are assessed in Section 12.4.4.3. This section complements this by presenting a more detailed assessment of regional changes.

Individual model projections of regional storm track changes are often comparable with the magnitude of interannual natural variability and so the changes are expected to be relevant for regional climate. However, the magnitude of the response is model-dependent at any given location, especially over land (Harvey et al., 2012). There is also disagreement between different cyclone/storm track identification methods, even when applied to the same data (Raible et al., 2008; Ulbrich et al., 2009), although in the response to anthropogenic

forcing, these differences appear mainly in the statistics of weak cyclones (Ulbrich et al., 2013). Conversely, when the same method is applied to different models the spread between the model responses is often larger than the ensemble mean response, especially in the Northern Hemisphere (Ulbrich et al., 2008; Laine et al., 2009).

The poleward shift of the Southern Hemisphere storm track remains one of the most reproducible projections, yet even here there is considerable quantitative uncertainty. This is partly associated with the varied model biases in jet latitude (Kidston and Gerber, 2010) although factors such as the varied cloud response may play a role (Trenberth and Fasullo, 2010). Many models project a similar poleward shift in the North Pacific (Bengtsson et al., 2006; Ulbrich et al., 2008; Catto et al., 2011), although this is often weaker compared to natural variability and often varies considerably between ensemble members (Pinto et al., 2007; McDonald, 2011). Poleward shifts are generally less clear at the surface than in the upper troposphere (Yin, 2005; McDonald, 2011; Chang et al., 2012), which reduces their relevance for regional impacts. However, a shift in extreme surface winds is still detectable in the zonal mean, especially in the subtropics and the southern high latitudes (Gastineau and Soden, 2009). A weakening of the Mediterranean storm track is a particularly robust response (Pinto et al., 2007; Loeptien et al., 2008; Ulbrich et al., 2009; Donat et al., 2011) for which increasing static stability is important (Raible et al., 2010). In general, the storm track response in summer is weaker than in winter with less consistency between models (Lang and Waugh, 2011).

The response of the North Atlantic storm track is more complex than a poleward shift in many models, with an increase in storm activity and a downstream extension of the storm track into Europe (Bengtsson et al., 2006; Pinto et al., 2007; Ulbrich et al., 2008; Catto et al., 2011; McDonald, 2011). In some models this regional response is important (Ulbrich et al., 2009), with storm activity over Western Europe increasing by 50% (McDonald, 2011) or by an amount comparable to the natural variability (Pinto et al., 2007; Woollings et al., 2012). The return periods of intense cyclones are shortened (Della-Marta and Pinto, 2009) with impact on potential wind damage (Leckebusch et al., 2007; Donat et al., 2011) and economic losses (Pinto et al., 2012). This response is related to the local minimum in warming in the North Atlantic ocean, which serves to increase the meridional temperature gradient on its southern side (Laine et al., 2009; Catto et al., 2011). The minimum in warming arises due to the weakening of northward ocean heat transports by the Atlantic meridional overturning circulation (AMOC), and the varying AMOC responses of the models can account for a large fraction of the variance in the Atlantic storm track projections (Woollings et al., 2012). CMIP5 models show a similar, albeit weaker extension of the storm track towards Europe, flanked by reductions in cyclone activity on both the northern and southern sides (Harvey et al., 2012; Zappa et al., 2013b). Despite large biases in the mean state, the model responses were found to agree with one another within sampling variation caused by natural variability (Sansom et al., 2013). Colle et al. (2013) noted similar reductions but also found that the higher resolution CMIP5 models gave more realistic ETC performance in the historical period. The best 7 models were found to give projections of increased 10–20% increase in cyclone track density over the eastern U.S., including 10–40% more intense (<980 hPa) cyclones.

There is general agreement that there will be a small global reduction in ETC numbers (Ulbrich et al., 2009). In individual regions there can be much larger changes which are comparable to natural variations, but these changes are not reproduced by the majority of the models (e.g., Donat et al., 2011). ETC intensities are particularly sensitive to the method and quantity used to define them, so there is little consensus on changes in intensity (Ulbrich et al., 2009). While there are indications that the absolute values of pressure minima deepen in future scenario simulations (Lambert and Fyfe, 2006), this is often associated with large-scale pressure changes rather than changes in the pressure gradients or winds associated with ETCs (Bengtsson et al., 2009; Ulbrich et al., 2009; McDonald, 2011). The CMIP5 model projections show little evidence of change in the intensity of winds associated with ETCs (Zappa et al., 2013b).

There are systematic storm track biases common to many models, which might have some influence on the projected storm track response to forcing (Chang et al., 2012). Some models with improved representation of the stratosphere have shown a markedly different circulation response in the Northern Hemisphere, with consequences for Atlantic / European storm activity in particular (Scaife et al., 2011a). Concerns over the skill of many models in representing both the stratosphere and the ocean mean that confidence in Northern Hemisphere storm track projections remains low. Higher horizontal resolution can improve ETC representation, yet there are still relatively few high-resolution global models which have been used for storm track projections (Geng and Sugi, 2003; Bengtsson et al., 2009; Catto et al., 2011; Colle et al., 2013;

Zappa et al., 2013a). Several studies have used RCMs to simulate storms at high resolution in particular regions. In multi-model experiments over Europe, the ETC response is more sensitive to the choice of driving GCM than the choice of RCM (Leckebusch et al., 2006; Donat et al., 2011), highlighting the importance of large-scale circulation uncertainties. There has been little work on potential changes to mesoscale storm systems, although it has been suggested that polar lows may reduce in frequency due to an increase in static stability (Zahn and von Storch, 2010). Higher resolution runs of one climate model also suggest an increase in intensity of autumn ETCs due to increased transitioning of Atlantic hurricanes (Haarsma et al., 2013).

14.6.3 Assessment Summary

The influence of past and future climate change on tropical cyclones is *likely* to vary by region, but the specific characteristics of the changes are not yet well understood, and the substantial influence of ENSO and other known climate modes on global and regional tropical cyclone activity emphasizes the need for more reliable assessments of future changes in the characteristics of these modes. Recent advances in understanding and phenomenological evidence for shorter-term effects on tropical cyclones from aerosol forcing are providing increasingly greater confidence that anthropogenic forcing has had a measurable effect on tropical cyclone activity in certain regions. Shorter term increases such as those observed in the Atlantic over the past 30–40 years appear to be robust and have been hypothesised to be related, in part, to regional external forcing by greenhouse gasses and aerosols, but the more steady century-scale trends that may be expected from CO₂ forcing alone are much more difficult to assess given the data uncertainty in the available tropical cyclone records.

While projections under 21st century greenhouse warming indicate that it is *likely* that the global frequency of tropical cyclones will either decrease or remain essentially unchanged, concurrent with a *likely* increase in both global mean tropical cyclone maximum wind speed and rainfall rates, there is lower confidence in region-specific projections of frequency and intensity. Still, based on high-resolution modelling studies, the frequency of the most intense storms, which are associated with particularly extensive physical effects, will *more likely than not* increase substantially in some basins under projected 21st century warming.

There is *high confidence* that the global number of extra-tropical cyclones is *unlikely* to decrease by more than a few percent due to anthropogenic change. There is *high confidence* that a small poleward shift is *likely* in the Southern Hemisphere storm track, but the magnitude is model-dependent. There is *medium confidence* that a poleward shift in the N. Pacific storm track is *more likely than not* and that it is *unlikely* that the response of the N. Atlantic storm track is a simple poleward shift. There is *low confidence* in the magnitude of regional storm track changes, and the impact of such changes on regional surface climate.

14.7 Additional Phenomena of Relevance

14.7.1 Pacific-South American Pattern

The Pacific-South American (PSA) pattern is a teleconnection from the tropics to Southern Hemisphere extratropics through Rossby wave trains (Box 2.5). This pattern induces atmospheric circulation anomalies over South America, affecting extreme precipitation (Drumond and Ambrizzi, 2005; Cunningham and Cavalcanti, 2006; Muza et al., 2009; Vasconcellos and Cavalcanti, 2010). PSA trends for recent decades depend on the choice of indices and are hence uncertain (Section 2.7.8). The PSA pattern is reproduced in many model simulations (Solman and Le Treut, 2006; Vera and Silvestri, 2009; Bates, 2010; Rodrigues et al., 2011; Cavalcanti and Shimizu, 2012).

The intensification and westward displacement of the PSA wave pattern in projections of CMIP3 may be related to the increase in frequency and intensity of positive SST anomalies in the tropical Pacific by the end of the 21st century (2081–2100, Junquas et al., 2011). These perturbations of the PSA characteristics are linked with changes in SACZ dipole precipitation and affect South America precipitation (Section 14.3.1.3). The PSA pattern occurrence and implications for precipitation increase in the southeastern South America have been associated with the zonally–asymmetric part of the global SST change in the equatorial Indian–western Pacific Oceans (Junquas et al., 2013).

Process understanding of the formation of the PSA gives *medium confidence* that future changes in the mean atmospheric circulation for austral summer will project on the PSA pattern thereby influencing the SACZ and precipitation over Southeastern South America. However, the literature is not sufficient to assess more general changes in PSA, and *confidence* is *low* in its future projections.

14.7.2 Pacific-North American Pattern

The Pacific-North American (PNA) pattern, as defined in Box 2.5, Table 1 and portrayed in Box 2.5, Figure 2 is a prominent mode of atmospheric variability over the North Pacific and the North American land mass. This phenomenon exerts notable influences on the temperature and precipitation variability in these regions (e.g., Nigam, 2003). The PNA pattern is related to ENSO events in the tropical Pacific (see Section 14.4), and also serves as a bridge linking ENSO and NAO variability (see Li and Lau, 2012). The data records indicate a significant positive trend in the wintertime PNA index over the past 60 years (see Table 2.12 and Box 2.5, Figure 1).

Stoner et al. (2009) have assessed the capability of 22 CMIP3 GCMs in replicating the essential aspects of the observed PNA pattern. Their results indicate that a majority of the models overestimate the fraction of variance explained by the PNA pattern, and that the spatial characteristics of PNA patterns simulated in 14 of the 22 models are in good agreement with the observations. The model-projected future evolution of the PNA pattern has not yet been fully assessed and therefore *confidence* in its future development is *low*.

14.7.3 Pacific Decadal Oscillation/Inter-Decadal Pacific Oscillation

The Pacific Decadal Oscillation (PDO, Box 2.5) refers to the leading Empirical Orthogonal Function (EOF) of monthly SST anomalies over the North Pacific (north of 20°N) from which the globally-averaged SST anomalies have been subtracted (Mantua et al., 1997). It exhibits anomalies of one sign along the west coast of North America and of opposite sign in the western and central North Pacific (see also Section 9.5.3.6 and Chapter 11). The PDO is closely linked to fluctuations in the strength of the wintertime Aleutian Low Pressure System. The timescale of the PDO is around 20–30 years, with changes of sign between positive and negative polarities in the 1920s, the late 1940s, the late 1970s, and around 2000.

The extension of the PDO to the whole Pacific basin is known as the Inter-decadal Pacific Oscillation (IPO, Power et al., 1999). The inter-decadal Pacific Oscillation (IPO) is nearly identical in form to the PDO in the Northern Hemisphere but is defined globally, as a leading EOF (principal component) of 13-year lowpass-filtered global SST anomalies (Parker et al., 2007) and has substantial amplitude in the tropical and southern Pacific. The time series of the PDO and IPO are highly correlated on an annual basis. The PDO/IPO pattern is considered to be the result of internal climate variability (Schneider and Cornuelle, 2005; Alexander, 2010) and has not been observed to exhibit a long-term trend. The PDO/IPO is associated with ENSO modulations, with more El Niño activity during the positive PDO/IPO and more La Niña activity during the negative PDO/IPO.

At the time of the AR4, little had been published on modelling of the PDO/IPO or of its evolution in future. In a recent study, Furtado et al. (2011) found that the PDO/IPO did not exhibit major changes in spatial or temporal characteristics under greenhouse gas warming in most of the 24 CMIP3 models used, although some models indicated a weak shift toward more occurrences of the negative phase of the PDO/IPO by the end of the 21st century (2081–2100, Lapp et al., 2011). However, given that the models strongly underestimate the PDO/IPO connection with tropical Indo-Pacific SST variations (Furtado et al., 2011; Lienert et al., 2011), the credibility of the projections remains uncertain. Furthermore, internal variability is so high that it is hard to detect any forced changes in the Aleutian Low for the next half a century (Deser et al., 2012; Oshima et al., 2012). Therefore *confidence* is *low* in future changes in PDO/IPO.

14.7.4 Tropospheric Biennial Oscillation

The Tropospheric Biennial Oscillation (TBO, Meehl, 1997) is a proposed mechanism for the biennial tendency in large scale drought and floods of south Asia and Australia. Multiple studies imply that TBO involves the Asian-Australian monsoon, the IOD, and ENSO (Sections 14.2.2, 14.3.3 and 14.4; see also Supplementary Material Section 14.SM.5.2).

The IPO (Section 14.7.3) affects the decade-to-decade strength of the TBO. A major contributor to recent change in the TBO comes from increase of SST in the Indian Ocean that contributes to stronger trade winds in the Pacific, one of the processes previously identified with strengthening the TBO (Meehl and Arblaster, 2012). Thus, prediction of decadal variability assessed in Chapter 11 that can be associated, for example, with the IPO (e.g., Meehl et al., 2010) can influence the accuracy of shorter-term predictions of the TBO across the entire Indo-Pacific region (Turner et al., 2011), but the relevance for longer time scales is uncertain.

Since AR4, little work has been done to document the ability of climate models to simulate the TBO. However, Li et al. (2012b) showed that, there is an overall improvement in the seasonality of monsoons rainfall related to changes in the TBO from CMIP3 to CMIP5, with most CMIP5 models better simulating both the monsoon timing and the very low rainfall rates outside of the monsoon season (see also Section 14.2.2). In addition they concluded that the India-Australia link seems to be robust in all models.

With regard to possible future behaviour of the TBO, no analysis using multiple GCMs has been made since the AR4. In models that more accurately simulate the TBO in the present-day climate, the TBO strengthens in a future warmer climate (Nanjundiah et al., 2005). However, as with ENSO (Section 14.4) and IOD (Section 14.3.3), internally generated decadal variability complicates the interpretation of such future changes. Therefore, it remains unclear how future changes in the TBO will emerge and how this may influence regional climate in the future. Confidence in the projected future changes in TBO remains *low*.

14.7.5 Quasi-Biennial Oscillation

The quasi-biennial oscillation (QBO) is a near-periodic, large-amplitude, downward propagating oscillation in zonal winds in the equatorial stratosphere (Baldwin et al., 2001). It is driven by vertically propagating internal waves that are generated in the tropical troposphere (Plumb, 1977). The QBO has substantial effects on the global stratospheric circulation, in particular the strength of the northern stratospheric polar vortex as well as the extratropical troposphere (Boer, 2009; Marshall and Scaife, 2009; Garfinkel and Hartmann, 2011). These extratropical effects occur primarily in winter when the stratosphere and troposphere are strongly coupled (Anstey and Shepherd, 2008; Garfinkel and Hartmann, 2011).

It has been unclear how the QBO will respond to future climate change related to greenhouse gas increase and recovery of stratospheric ozone. Climate models assessed in the AR4 did not simulate the QBO as they lacked the necessary vertical resolution (Kawatani et al., 2011). Recent model studies without using gravity wave parameterization (Kawatani et al., 2011; Kawatani et al., 2012) showed that the QBO period and amplitude may become longer and weaker, and the downward penetration into the lowermost stratosphere may be more curtailed in a warmer climate. This finding is attributed to the effect of increased equatorial upwelling (stronger Brewer-Dobson circulation; Butchart et al., 2006; Garcia and Randel, 2008; McLandress and Shepherd, 2009; Okamoto et al., 2011) dominating the effect of increased wave forcing (more convective activity). Two studies with gravity wave parameterization, however, gave conflicting results depending on the simulated changes in the intensity of the Brewer-Dobson circulation (Watanabe and Kawatani, 2012).

There are limited published results on the future behaviour of the QBO, using CMIP5 models. On the basis of the recent literature, it is uncertain how the period or amplitude of the QBO may change in future and confidence in the projections remains *low*.

14.7.6 Atlantic Multi-Decadal Oscillation

The Atlantic Multidecadal Oscillation (AMO, Box 2.5, see also Section 9.5.3.3.2) is a fluctuation seen in the instrumental SST record throughout the North Atlantic Ocean and is related to variability in the thermohaline circulation (Knight et al., 2005). Area-mean North Atlantic SST shows variations with a range of about 0.4°C (see Box 2.5) and a warming of a similar magnitude since 1870. The AMO has a quasi-periodicity of about 70 years, although the approximately 150-year instrumental record possesses only a few distinct phases—warm during approximately 1930–1965 and after 1995, and cool between 1900–1930 and 1965–1995. The phenomenon has also been referred to as ‘Atlantic Multidecadal Variability’ to avoid the

implication of temporal regularity. Along with secular trends and Pacific variability, the AMO is one of the principal features of multidecadal variability in the instrumental climate record.

The AR4 highlighted a number of important links between the AMO and regional climates (Chapters 2 and 10). Subsequent research using observational and paleo-climate records, and climate models, has confirmed and expanded upon these connections, such as West African Monsoon and Sahel rainfall (Mohino et al., 2011; Section 14.2.4), summer climate in North America (Seager et al., 2008; Section 14.8.3; Feng et al., 2011) and Europe (Folland et al., 2009; Ionita et al., 2012; Section 14.8.6), the Arctic (Chylek et al., 2009; Mahajan et al., 2011), and Atlantic major hurricane frequency (Chylek and Lesins, 2008; Zhang and Delworth, 2009; Section 14.6.1). Further, the list of AMO influences around the globe has been extended to include decadal variations in many other regions (e.g., Zhang and Delworth, 2006; Kucharski et al., 2009a; Kucharski et al., 2009b; Huss et al., 2010; Marullo et al., 2011; Wang et al., 2011).

Paleo-reconstructions of Atlantic temperatures show AMO-like variability well before the instrumental era, as noted in the AR4 (Chapter 6; see also Section 5.4.2). Recent analyses confirm this, and suggest potential for intermittency in AMO variability (Saenger et al., 2009; Zanchettin et al., 2010; Chylek et al., 2012). Control simulations of climate models run for hundreds or thousands of years also show long-lived Atlantic multidecadal variability (Menary et al., 2012). These lines of evidence suggest that AMO variability will continue into the future. No fundamental changes in the characteristics of North Atlantic multidecadal variability in the 21st century are seen in CMIP3 models (Ting et al., 2011).

Many studies have diagnosed a trend towards a warm North Atlantic in recent decades additional to that implied by global climate forcings (Knight, 2009; Polyakov et al., 2010). It is unclear exactly when the current warm phase of the AMO will terminate, but may occur within the next few decades, leading to a cooling influence in the North Atlantic and offsetting some of the effects characterizing global warming (Keenlyside et al., 2008; see also Section 11.3.3.3).

Some similarity in the shape of the instrumental time series of global and northern hemisphere mean surface temperatures and the AMO has long been noted. By removing an estimate of the effect of interannual variability phenomena like ENSO (Section 14.4), AMO transitions have been shown to have the potential to produce large and abrupt changes in hemispheric temperatures (Thompson et al., 2010). Estimates of the AMO's contribution to recent climate change are uncertain, however, as attribution of the observed AMO requires a model (physical or conceptual) whose assumptions are nearly always difficult to verify (Knight, 2009).

14.7.7 Assessment Summary

Literature is generally insufficient to assess future changes in behaviour of the PNA, PSA, TBO, QBO, and PDO/IPO. Confidence in the projections of changes in these modes is therefore *low*. However, process understanding of the formation of the PSA gives *medium confidence* that future changes in the mean atmospheric circulation for austral summer will project on the PSA pattern thereby influencing the SACZ and precipitation over Southeastern South America.

Paleoclimate reconstructions and long model simulations indicate that the AMO is *unlikely* to change its behaviour in the future as the mean climate changes. However, natural fluctuations in the AMO over the coming few decades are *likely* to influence regional climates at least as strongly as will human-induced changes.

14.8 Future Regional Climate Change

14.8.1 Overview

The following sections assess future climate projections for several regions, and relate them, where possible, to projected changes in the major *climate phenomena* assessed in Sections 14.2–14.7. The regional climate change assessments are mainly of mean surface air temperature and mean precipitation based primarily on multi-model ensemble projections from general circulation models. Reference is made to the appropriate projection maps from CMIP5 (Taylor et al., 2011c) presented in Annex I: Atlas of Global and Regional

Climate Projections. Annex I uses smaller sub-regions similar to those introduced by SREX (Seneviratne et al., 2012). Table 14.1 presents a quantitative summary of the regional area-averages over three projection periods (2016–2035, 2046–2065 and 2081–2100 with respect to the reference period 1986–2005, representing near future, middle century and end of century) for the RCP4.5 scenario. The 26 land regions assessed here are presented in Seneviratne et al., 2012, page 12 and the coordinates can be found from their online Appendix 3.A. Added to this are additional six regions containing the two polar regions, the Caribbean, Indian Ocean and Pacific Island States (see Annex I for further details). Table 14.1 identifies the smaller sub-domains grouped within the somewhat large regions that are discussed in Sections 14.8.2–14.8.15. Tables for RCP2.6, RCP6.0 and RCP8.5 scenarios are presented in Supplementary Material Tables 14.SM.1a–14.SM.1c. For continental-scale regions, projected changes in mean precipitation between (2081–2100) and (1986–2005) are compared in two generations of models forced under two comparable emission scenarios: RCP4.5 in CMIP5 versus A1B in CMIP3. In contrast to the Annex, the seasons here are chosen differently for each region so as to best capture the regional features such as monsoons. Downscaling issues are illustrated in panels showing results from an ensemble of high resolution time slice experiments with the MRI model (Endo et al., 2012; Mizuta et al., 2012). To facilitate a direct comparison across the scenarios, the precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Published results using other downscaling methods are also assessed when found essential to illustrate issues related to regional climate change.

Regional climate projections are generally more uncertain than projections of global mean temperature but the sources of uncertainty are similar (see Chapters 8, 11, and 12) yet differ in relative importance. For example, natural variability (Deser et al., 2012), aerosol forcing (Chapter 7) and land use/cover changes (DeFries et al., 2002; Moss et al., 2010) all become more important sources of uncertainty on a regional scale. Regional climate assessments incur additional uncertainty due to the cascade of uncertainty through the hierarchy of models needed to generate local information (cf. downscaling in Section 9.6). Calibration (bias correction) of model output to match local observations is an additional important source of uncertainty in regional climate projections (e.g., Ho et al., 2012), which should be considered when interpreting the regional projections. Therefore, the model spread shown in Annex 1 should not be interpreted as the final uncertainty in the observable regional climate change response.

Table 14.2 summarises the assessed confidence in the ability of CMIP5 models to represent regional scale present-day climate (temperature and precipitation, based on Chapter 9), the main controlling phenomena for weather and climate in that region and the assessed resulting confidence in the future projections. There is generally less confidence in projections of precipitation than of temperature. For example, in Annex I, the temperature projections for 2081–2100 are almost always above the model estimates of natural variability, whereas the precipitation projections less frequently rise above natural variability. Although some projections are robust for reasons that are well understood (e.g., the projected increase in precipitation at high latitudes), many other regions have precipitation projections that vary in sign and magnitude across the models. These issues are further discussed in Section 12.4.5.2. Details on how the confidence table is constructed are found in the Supplementary Material.

Credibility in regional climate change projections is increased if it is possible to find key drivers of the change that are known to be well-simulated and well-projected by climate models. Table 14.3 summarises the assessment of how major climate phenomena might be relevant for future regional climate change. For each entry in the table, the relevance is based on an assessment of confidence in future change in the phenomenon and the confidence in how the phenomenon influences regional climate. For example, NAO is assigned high relevance (red) for the Arctic region because NAO is known to influence the Arctic and there is high confidence that there will be a positive future change in the NAO index. If there is low confidence in how a phenomenon might change (e.g., ENSO) but high confidence that it has a strong regional impact, then the cell in the table is assigned medium relevance (yellow). It can be seen from the table that there are many cases where major phenomena are assessed to have high (red) or medium (yellow) relevance for future regional climate change. See Supplementary Material Section 14.SM.6.1 for more details on how this relevance table was constructed.

[INSERT TABLE 14.1 HERE]

Table 14.1: Temperature and precipitation projections by the CMIP5 global models. The figures shown are averages over SREX regions (Seneviratne et al., 2012) of the projections by a set of 42 global models for the RCP4.5 scenario.

Added to the SREX regions are a six other regions including the two Polar Regions, the Caribbean, Indian Ocean and Pacific Island States (see Annex I for further details). The 26 SREX regions are: Alaska/NW Canada (ALA), Eastern Canada/Greenland/Iceland (CGI), Western North America (WNA), Central North America (CNA), Eastern North America (ENA), Central America/Mexico (CAM), Amazon (AMZ), NE Brazil (NEB), West Coast South America (WSA), South-Eastern South America (SSA), Northern Europe (NEU), Central Europe (CEU), Southern Europe/the Mediterranean (MED), Sahara (SAH), Western Africa (WAF), Eastern Africa (EAF), Southern Africa (SAF), Northern Asia (NAS), Western Asia (WAS), Central Asia (CAS), Tibetan Plateau (TIB), Eastern Asia (EAS), Southern Asia (SAS), South-Eastern Asia (SEA), Northern Australia (NAS) and Southern Australia/New Zealand (SAU). The area-mean temperature and precipitation responses are first averaged for each model over the 1986–2005 period from the historical simulations and the 2016–2035, 2046–2065 and 2081–2100 periods of the RCP4.5 experiments. Based on the difference between these two periods, the table shows the 25th, 50th and 75th percentiles, and the lowest and highest response among the 42 models, for temperature in degrees Celsius and precipitation as a percent change. Regions in which the middle half (25–75%) of this distribution is all of the same sign in the precipitation response are coloured light brown for decreasing precipitation and light green for increasing precipitation. Information is provided for land areas contained in the boxes unless otherwise indicated. The temperature responses are averaged over the boreal winter and summer seasons; December, January and February (DJF) and June, July and August (JJA) respectively. The precipitation responses are averaged over half year periods, boreal winter; October, November, December, January, February and March (ONDJFM) and summer; April, May, June, July, August and September (AMJJAS).

[INSERT TABLE 14.2 HERE]

Table 14.2: Assessed confidence (*high, medium, low*) in climate projections of regional temperature and precipitation change from the multi-model ensemble of CMIP5 models for the RCP4.5 scenario. Column 1 refers to the SREX regions (cf. Seneviratne et al., 2012, page 12. The region's coordinates can be found from their online Appendix 3.A) and six additional regions including the two polar regions, the Caribbean, Indian Ocean and Pacific Island States (see Annex I for further details). Columns 2 to 4 show confidence in models' ability to simulate present-day mean temperature and precipitation as well as the most important phenomena for that region based on Figures 9.39, 9.40, and 9.45. In column 4, the individual phenomena are listed, with associated confidence levels shown below, in the same order as the phenomena. Note that only phenomena assessed in Figure 9.45 are listed. Column 5 is an interpretation of the relevance of the main climate phenomena for future regional climate change, based on Table 14.3. Note that the SREX regions are smaller than the regions listed in Table 14.3. Columns 6 and 7 express confidence in projected temperature and precipitation changes, based solely on model agreement for 2080–2099 vs. 1985–2005, as listed in Table 14.1 and in the maps shown in Annex I. The confidence is assessed for two periods for temperature (DJF and JJA) and two-half year periods for precipitation (October–March and April–September). When the projections are consistent with no significant change, it is marked by an asterisk (*) and the assigned confidence is *medium*. Further details on how confidence levels have been assigned are provided in the Supplementary Material (Section 14.SM.6.1).

[INSERT TABLE 14.3 HERE]

Table 14.3: Summary of the relevance of projected changes in major phenomena for mean change in future regional climate. The relevance is classified into high (red), medium (yellow), low (cyan), and “no obvious relevance” (grey), based on confidence that there will be a change in the phenomena (“HP” for high, “MP” for medium, “LP” for low), and confidence in the impact of the phenomena on each region (“HI” for high, “MI” for medium, “LI” for low). More information on how these assessments have been constructed is given in the Supplementary Material (Section 14.SM.6.1).

14.8.2 Arctic

This section is concerned with temperature and precipitation dimensions of Arctic climate change, and their links to climate phenomena. The reader is referred elsewhere for information on sea ice loss (Sections 4.2.2, 5.5.2 and Chapter 10), and projections of sea ice change (Sections 9.4.3, 9.8.3 and Chapters 11 and 12).

Arctic climate is affected by three modes of variability: NAO (Section 14.5.1), PDO (Section 14.7.5), and AMO (Section 14.7.6). The NAO index is positively correlated with temperatures in the northeastern Eurasian sector, and negatively correlated with temperatures in the Baffin Bay and Canadian Archipelago, but exhibits little relationship with central Arctic temperatures (Polyakov et al., 2003). The PDO plays a role in temperature variability of Alaska and the Yukon (Hartmann and Wendler, 2005). The AMO is positively associated with SST throughout the Arctic (Chylek et al., 2009; Levitus et al., 2009; Chylek et al., 2010) (Mahajan et al., 2011). Extratropical Cyclones are also mainly responsible for winter precipitation in the region (see Table 14.3).

The surface and lower troposphere in the Arctic and surrounding land areas show regional warming over the past three decades of about 1°C/decade—significantly greater than the global mean trend (Figures 2.22 and

2.25). According to temperature reconstructions, this signal is highly unusual: Temperatures averaged over the Arctic over the past few decades are significantly higher than any seen over the past 2000 years (Kaufman et al., 2009). Temperatures 11,000 years ago were greater than the 20th century mean, but this is likely a strongly-forced signal, since summer solar radiation was 9% greater than present (Miller et al., 2010). Finally, warmer temperatures have been sustained in pan-Arctic land areas where a declining NAO over the past decade ought to have caused cooling (Semenov, 2007; Turner et al., 2007b). Since AR4, evidence has also emerged that precipitation has trended upward in most pan-Arctic land areas over the past few decades (e.g., Pavelsky and Smith, 2006; Rawlins et al., 2010), though the evidence remains mixed (e.g., Dai et al., 2009). Increasing extratropical cyclone activity over the Canadian Arctic has also been observed (Section 2.6.4).

Since AR4, there has been progress in adapting RCMs for polar applications (Wilson et al., 2012). These models have been evaluated with regard to their ability to simulate Arctic clouds, surface heat fluxes, and boundary layer processes (Tjernstrom et al., 2004; Inoue et al., 2006; Rinke et al., 2006). They have been used to improve simulations of Arctic-specific climate processes, such as glacial mass balance (Zhang et al., 2007). A few regional models have been used for Arctic climate change projections (e.g., Zahn and von Storch, 2010; Koenigk et al., 2011; Döscher and Koenigk, 2012). For information on GCM quality in the Arctic, see Chapter 9 and the brief summary of assessed confidence in the CMIP5 models in Table 14.2.

The CMIP5 model simulations exhibit an ensemble-mean polar amplified warming, especially in winter, similar to CMIP3 model simulations (Bracegirdle and Stephenson, 2012; see also Box 5.1). For RCP4.5, ensemble-mean winter warming rises to 4.6°C over pan-Arctic land areas by the end of the 21st century (2081–2100), and about 7.4°C over the Arctic (Table 14.1). Throughout the century, the warming exceeds simulated estimates of internal variability (Figure AI.8). The RCP4.5 ensemble-mean warming is more modest in JJA (Table 14.1), reaching about 2.3°C by century's end over pan-Arctic land areas, and 1.5°C over the Arctic. The summer warming exceeds variability estimates by about mid-century (Figure AI.9). These simulated anthropogenic seasonal warming patterns match qualitatively the observed warming patterns over the past six decades (AMAP, 2011), and the observed warming patterns are *likely* to be at least partly anthropogenic in origin (Section 10.3.1.1.4). Given the magnitude of future projected changes relative to variability, and the presence of anthropogenic signals already, it is likely future Arctic surface temperature changes will continue to be strongly influenced by the anthropogenic forcing over the coming decades.

The CMIP5 models robustly project precipitation increases in the pan-Arctic region over the 21st century, as did their CMIP3 counterparts (Kattsov et al., 2007; Rawlins et al., 2010). Under the RCP4.5 scenario, the cold-season, ensemble-mean precipitation increases about 25% by century's end (Table 14.1), due to enhanced precipitation in Extratropical Cyclones (Table 14.3). However, this signal does not rise consistently above the noise of simulated variability until mid-century (Figure AI.10). During the warm season, precipitation increases are smaller, about 15% (Table 14.1), though these signals also rise above variability by mid-century (Figure AI.11). The inter-model spread in the precipitation increase is generally as large as the ensemble-mean signal itself (similar to CMIP3 model behaviour, Holland and Webster, 2007), so the magnitude of the future increase is uncertain. However, since nearly all models project a large precipitation increase rising above the variability year-round, it is *likely* the pan-Arctic region will experience a statistically-significant increase in precipitation by mid-century (see also Table 14.2). The small projected increase in the NAO is *likely* to affect Arctic precipitation (and temperature) patterns in the coming century (Section 14.5.1; Table 14.3), though the importance of these signals relative to anthropogenic signals described here is unclear.

In summary: It is *likely* Arctic surface temperature changes will be strongly influenced by anthropogenic forcing over the coming decades dominating natural variability such as induced by NAO. It is *likely* the pan-Arctic region will experience a significant increase in precipitation by mid-century due mostly to enhanced precipitation in Extratropical Cyclones.

14.8.3 North America

The climate of North America (NA) is affected by the following phenomena: NAO (Section 14.5.1), ENSO (Section 14.4), PNA (Section 14.7.2), PDO (Section 14.7.3), NAMS (Section 14.2.3), TCs and ETCs (Section 14.6). The NAO affects temperature and precipitation over Eastern NA during winter (Hurrell et al.,

2003). Positive PNA brings warmer temperatures to northern Western NA and Alaska in winter, cooler temperatures to the southern part of Eastern NA, and dry conditions to much of Eastern NA (Nigam, 2003). The PNA can also be excited by ENSO-related SST anomalies (Horel and Wallace, 1981; Nigam, 2003). The PDO is linked to decadal climate anomalies resembling those of the PNA. The NAMS brings excess summer rainfall to Central America and Mexico and the southern portion of Western NA (Gutzler, 2004). TCs also impact the Gulf Coast and Eastern NA (see Box 14.3). The AMM and AMO may affect their frequency and intensity (Landsea et al., 1999; Goldenberg et al., 2001; Cassou et al., 2007; Emanuel, 2007; Vimont and Kossin, 2007; Smirnov and Vimont, 2011). ETCs are also mainly responsible for winter precipitation, especially in the northern half of NA. See Table 14.3 for a summary of this information.

A general surface warming over NA has been documented over the last century (see Section 2.4). It is particularly large over Alaska and northern Western NA during winter and spring and the northern part of Eastern NA during summer (Zhang et al., 2011b). There is also a cooling tendency over Central and Eastern NA (i.e., the “warming hole” discussed in Section 2.6.1) during spring, though it is absent in lower tropospheric temperature (cf. Figure 2.32). The warming has coincided with a general decline in NA snow extent and depth (Brown and Mote, 2009; McCabe and Wolock, 2010; Kapnick and Hall, 2012). Consistent with surface temperature trends, temperature extremes also exhibit secular changes. Cold days and nights have decreased in the last half century, while warm days and nights have increased (see Chapter 2). These changes are especially apparent for nightly extremes (Vincent et al., 2007). It is unclear whether there have been mean precipitation trends over the last 50 years (Section 2.5.1; Zhang et al., 2011b). However, precipitation extremes increased, especially over Central and Eastern NA (see Section 2.6.2 and Seneviratne et al., 2012).

Table 14.2 provides an assessment of GCM quality for simulations of temperature, precipitation, and main phenomena in NA’s regions. Regarding regional modelling experiments since AR4, biases have decreased somewhat as resolutions increase. The North American Regional Climate Change Assessment Program created a simulation suite for NA at 50-km resolution. When forced by reanalyses, this suite generally reproduces climate variability within observational error (Leung and Qian, 2009; Wang et al., 2009b; Gutowski, 2010; Mearns et al., 2012). Other regional modelling experiments covering parts or all of NA have shown improvements as resolution increases (Liang et al., 2008a; Lim et al., 2011; Yeung et al., 2011), including for extremes (Kawazoe and Gutowski, 2013). Bias reductions are large for snowpack in topographically complex Western NA, as revealed by 2- to 20-km resolution regional simulations (Qian et al., 2010b; Salathe Jr et al., 2010; Pavelsky et al., 2011; Rasmussen et al., 2011). Thus there has been substantial progress since AR4 in understanding the value of regional modelling in simulating NA climate. The added value of using regional models to simulate climate change is discussed in Section 9.6.6.

NA warming patterns in RCP4.5 CMIP5 projections are generally similar to those of CMIP3 (Figures AI.4 and AI.5, Table 14.1). In winter, warming is greatest in Alaska, Canada, and Greenland (Figures AI.12 and AI.16), while in summer, maximum warming shifts south, to Western, Central, and Eastern NA. Examining near-term (2016–2035) CMIP5 projections of the less sensitive models (25th percentile, i.e., upper left maps in Figures AI.12, AI.13, AI.16, AI.17, AI.20, AI.21, AI.24, and AI.25), the warming generally exceeds natural variability estimates. Exceptions are Alaska, parts of Western, Central, and Eastern NA, and Canada and Greenland during winter, when natural variability linked to wintertime storms is particularly large. By 2046–2065, warming in all regions exceeds the natural variability estimate for all models. Thus it is *very likely* the warming signal will be large compared to natural variability in all NA regions throughout the year by mid-century. This warming generally leads to a 2- to 4-fold increase in simulated heat wave frequency over the 21st century (e.g., Lau and Nath, 2012).

Anthropogenic climate change may also bring systematic cold-season precipitation changes. As with previous models, CMIP5 projections generally agree in projecting a winter precipitation increase over the northern half of NA (Figure 14.18 and AI.19). This is associated with increased atmospheric moisture, increased moisture convergence, and a poleward shift in ETC activity (Section 14.6.2 and Table 14.3). The change is consistent with CMIP3 model projections of positive NAO trends (Table 14.3; Hori et al., 2007; Karpechko, 2010; Zhu and Wang, 2010). Winter precipitation increases extend southward into the USA (northern portions of SREX regions 3–5; Neelin et al., 2013) but with decreasing strength relative to natural variability. This behaviour is qualitatively reproduced in higher resolution simulations (Figure 14.18).

Warm-season precipitation also exhibits significant increases in Alaska, northern Canada, and Eastern NA by century's end (Figures 14.18, AI.19, AI.22). However, CMIP5 models disagree on the sign of the precipitation change over the rest of NA (Figures AI.26 and AI.27), consistent with CMIP3 results (Figure 14.18; Neelin et al., 2006; Rauscher et al., 2008; Seth et al., 2010). Higher resolution simulations show a tendency towards more precipitation than either CMIP3 or CMIP5 models (Figure 14.18), suggesting the simulated warm-season precipitation change in the region may be resolution-dependent. Future precipitation changes associated with the NAMS are likewise uncertain, though there is medium confidence the phenomenon will move to later in the annual cycle (Section 14.2.3, Table 14.3). As there is medium confidence tropical cyclones will be associated with greater rainfall rates, the Gulf and East coasts of NA may be impacted by greater precipitation when tropical cyclones occur (Table 14.3).

[INSERT FIGURES 14.18 HERE]

Figure 14.18: Maps of precipitation changes for North America in 2080–2099 with respect to 1986–2005 in June–August (above) and December–February (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

CMIP3 models showed a 21st century precipitation decrease across much of south-western NA, accompanied by a robust evaporation increase characteristic of mid-latitude continental warming (Seager et al., 2007; Seager and Vecchi, 2010) and an increase in drought frequency (Sheffield and Wood, 2008; Gutzler and Robbins, 2011). When downscaled, CMIP3 models showed less drying in the region (Gao et al., 2012c) and an extreme precipitation increase, despite overall drying (Dominguez et al., 2012). CMIP5 models do not consistently show such a precipitation decrease in this region (Neelin et al., 2013). This is one of the few emerging differences between the two ensembles in climate projections over NA. However, the CMIP5 models still show a strong decrease in soil moisture here (Dai, 2013), due to increasing evaporation.

In summary, it is *very likely* that by mid-century the anthropogenic warming signal will be large compared to natural variability such as that stemming from the NAO, ENSO, PNA, PDO, and the NAMS in all NA regions throughout the year. It is *likely* that the northern half of NA will experience an increase in precipitation over the 21st century, due in large part to a precipitation increase within ETCs.

14.8.4 Central America and Caribbean

The Central America and the Caribbean (CAC) region is affected by several phenomena, including the ITCZ (Section 14.3.1.1), NAMS (Section 14.2.3.1), ENSO (Section 14.4), and TCs (Section 14.6.1; Table 14.3; also Gamble and Curtis, 2008). The annual cycle results from air–sea interactions over the Western Hemisphere warm pool in the tropical eastern north Pacific and the Intra Americas Seas (Amador et al., 2006; Wang et al., 2007). The Caribbean Low Level Jet is a key element of the region's summer climate (Cook and Vizy, 2010) and is controlled by the size and intensity of the Western Hemisphere warm pool (Wang et al., 2008b). It is also modulated by SST gradients between the eastern equatorial Pacific and tropical Atlantic (Taylor et al., 2011d). ENSO is the main driver of climate variability, with El Niño being associated with dry conditions, and La Niña with wet conditions (Karmalkar et al., 2011). Other teleconnection patterns, such as the NAO (Section 14.5.1) and the strength of boreal winter convection over the Amazon, influence trade winds over the Tropical North Atlantic and can combine with ENSO to modulate the summer Western Hemisphere warm pool (e.g., Enfield et al., 2006). Table 14.3 summarizes the main phenomena and their relevance to climate change over the CAC.

Because interdecadal climate variations can be large in the CAC region, precipitation trends must be interpreted carefully. From 1950 to 2003, negative trends were seen in several data sets in the Caribbean region and parts of Central America (Neelin et al., 2006). However, regarding secular trends (1901–2005), this signal was identified only in the Caribbean region (Trenberth et al., 2007b). Prolonged dry or wet periods are related to decadal variability of the adjacent Pacific and Atlantic (Mendoza et al., 2007; Seager et al., 2009; Mendez and Magana, 2010), and the intensity of easterlies over the region. For instance, increased easterly surface winds over Puerto Rico from 1950 to 2000 disrupted a pattern of inland moisture

convergence, leading to a dramatic precipitation decrease (Comarazamy and Gonzalez, 2011).

Table 14.2 provides an overall assessment of GCM quality for simulations of temperature, precipitation, and main phenomena in the CAC subregions. Annual cycles of temperature and precipitation are well simulated by CMIP5 models, though precipitation from June to October is underestimated (Figure 9.38). Regional models also simulate temperature and precipitation climatologies, and the magnitude and annual cycle of the Caribbean Low Level Jet reasonably well (Campbell et al., 2010; Taylor et al., 2013).

CMIP3 models generally projected a precipitation reduction over much of the Caribbean region, consistent with the observed negative trend since 1950 (Neelin et al., 2006; Rauscher et al., 2008). The subtropics are generally expected to dry as global climate warms (Held and Soden, 2006), but in both CMIP3 and CMIP5 models the CAC region shows the greatest drying. Future drying may also be related to strengthening of the Caribbean Low Level Jet (Taylor et al., 2013) and subsidence over the Caribbean region associated with warmer SSTs in the tropical Pacific than Atlantic (Taylor et al., 2011d). A high resolution regional Ocean GCM using a CMIP3 ensemble for boundary conditions confirms that the Intra American Seas circulation weakens by similar rate as the reduction in Atlantic Meridional Overturning (Liu et al., 2012c). This weakening causes the Gulf of Mexico to warm less than other oceans.

Downscaling experiments for the region have shown a mid-21st century warming between 2°C and 3°C (Vergara et al., 2007; Rauscher et al., 2008; Karmalkar et al., 2011). Precipitation decreases over most of the CAC region, similar to the signal in driving global models (Campbell et al., 2010; Hall et al., 2012). However, only a few downscaling studies took into account key elements of the region's climate, such as easterly wave activity, TCs, or interannual variability mechanisms linked to ENSO (Karmalkar et al., 2011).

By century's end, CMIP5 models project greatest warming in the CAC region in JJA. Warming is projected to be larger over Central America than the Caribbean in summer and winter (Figures AI.24, AI.2, Table 14.1). From October to March, ensemble-mean projections indicate precipitation decrease in northern Central America, including Mexico. In the Caribbean precipitation is projected to decrease in the south (consistent with the observed trends) but to increase in the north (Figure AI.26). From April to September, the projected zone of precipitation reduction expands over the entire CAC region, and this signal is generally larger than the models' estimates of natural variability (Figure AI.27). Precipitation changes projected by CMIP3, CMIP5 and a high resolution model show a similar reduction in parts of Mexico and the southern Caribbean in DJFM, and in Central America and the Caribbean in JJAS (Figure 14.19). The CMIP5 ensemble shows greater agreement in the DJFM precipitation increase in the northern Caribbean sector than CMIP3. These projected changes are also reflected in Table 14.1. Figures AI.26, AI.27 and Figure 14.19 suggest an intensification and southward displacement of the East Pacific ITCZ, which can contribute to drying in southern Central America (Karmalkar et al., 2011).

ENSO will continue to influence CAC climate, but changes in ENSO frequency or intensity remain uncertain (Section 14.4). Projected drier conditions may also be related to decreased frequency of TCs, though the associated rainfall rate of these systems are higher in future projections (Section 14.6.1).

In summary, due to model agreement on projections and the degree of consistency with observed trends, it is *likely* warm-season precipitation will decrease in the Caribbean region, over the coming century. However, there is only *medium confidence* that Central America will experience a decrease in precipitation.

[INSERT FIGURES 14.19 HERE]

Figure 14.19: Maps of precipitation changes for Central America and Caribbean in 2080–2099 with respect to 1986–2005 in June–September (above) and December–March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

14.8.5 South America

South America (SA) is affected by several climate phenomena. ENSO (Section 14.4) and Atlantic Ocean modes (Section 14.3.4) have a role in interannual variability of many regions. The SAMS (Section 14.2.3.2) is responsible for rainfall over large areas, while the SACZ (Section 14.3.1.3) and Atlantic ITCZ (Section 14.3.1.1) also affect precipitation. Teleconnections such as the PSA (Section 14.7.2), the SAM (Section 14.5.2) with related ETCs (Section 14.6.2), and the IOD (Section 14.3.3) also influence climate variability. Table 14.3 summarizes the main phenomena and their assessed relevance to climate change over SA.

Positive minimum temperature trends have been observed in SA (Alexander et al., 2006; Marengo and Camargo, 2008; Rusticucci and Renom, 2008; Marengo et al., 2009; Skansi et al., 2013; SREX Chapter 3). Glacial retreat in the tropical Andes was observed in the last three decades (Vuille et al., 2008; Rabatel et al., 2013). In contrast to the warming over the continental interior, a prominent but localized coastal cooling was detected during the past 30–50 years, extending from central Peru (Gutiérrez et al., 2011) to northern (Schulz et al., 2012) and central Chile (Falvey and Garreaud, 2009). Observed precipitation changes include a significant increase in precipitation over the 20th century over the southern sector of southeastern SA, a negative trend in SACZ continental area (Section 2.5.1; Barros et al., 2008), a negative trend in mean precipitation and precipitation extremes in central-southern Chile, and a positive trend in southern Chile (Haylock et al., 2006; Quintana and Aceituno, 2012). Other detected changes include positive extreme precipitation trends in southeastern SA, central-northern Argentina, and northwestern Peru and Ecuador (Section 2.6.2; Haylock et al., 2006; Dufek et al., 2008; Marengo et al., 2009; Re and Barros, 2009; Skansi et al., 2013).

Table 14.2 provides an overall assessment of GCM quality for simulations of temperature, precipitation, and main phenomena in the sub-regions of SA. In general, GCM results are consistent with observed temperature tendencies (e.g., Haylock et al., 2006). Trends toward warmer nights in CMIP3 models (Marengo et al., 2010b; Rusticucci et al., 2010) are consistent with observed trends. CMIP3 models, however, fail to reproduce the cooling ocean and warming land trends observed in the last 30 years along subtropical western SA noted above. The number of warm nights in SA is well represented in CMIP5 simulations (Sillmann et al., 2013). CMIP5 models reproduce the annual cycle of precipitation over SA, though the multi-model mean underestimates rainfall over some areas (Figure 9.38). In tropical SA, rainy season precipitation is better reproduced in the CMIP5 ensemble than CMIP3 (Figure 9.39). CMIP3 models were able to simulate extreme precipitation indices over SA (Rusticucci et al., 2010), but CMIP5 models improved them globally (Sillmann et al., 2013). CMIP5 also improved simulations of precipitation indices in the SAMS region (Kitoh et al., 2013; Section 14.2.3.2). The main precipitation features are well represented by regional models in several areas of SA (Solman et al., 2008; Alves and Marengo, 2010; Chou et al., 2012; Solman et al., 2013). However, regional models underestimate daily precipitation intensity in the La Plata Basin and in eastern Northeastern SA in DJF and almost over the whole continent in JJA (Carril et al., 2012).

Regarding future projections, CMIP5 models indicate higher temperatures over all of SA, with the largest changes in Southeastern Amazonia by century's end. (Figures AI.28, AI.29, Table 14.1). Temperature changes projected by RCMs forced by a suite of CMIP3 models agree that the largest warming occurs over the southern Amazon during austral winter. Regional models project greater frequency of warm nights over SA, except in parts of Argentina, and a reduction of cold nights over the whole continent (Marengo et al., 2009). CMIP5 projections confirm the results of CMIP3 in AR4 and SREX (see Section 12.4.9).

CMIP5 results confirm precipitation changes projected by CMIP3 models in the majority of SA regions, with increased confidence, as more models agree in the changes (AI.30, AI.34, AI31, AI35). Inter-model spread in precipitation also decreased in some SA regions from CMIP3 to CMIP5 (Blázquez and Nuñez, 2012). CMIP5 precipitation projections for end of century (2081–2100) show a precipitation increase from October to March over the southern part of Southeast Brazil and the La Plata Basin, the extreme south of Chile, the northwest coast of SA, and the Atlantic ITCZ, extending to a small area of the northeastern Brazil coast (Figures AI.30, AI.34). Reduced October to March rainfall is projected in the extreme northern region of SA, eastern Brazil, and Central Chile. In eastern Amazonia and Northeastern Brazil, CMIP5 models show both drying and moistening. This uncertainty can also be seen in Table 14.1.

Figure 14.20 confirms that changes in Northwestern, Southwestern, and Southeastern SA are consistent among CMIP3 and CMIP5 ensembles and a high resolution model ensemble, which gives more confidence in these results. However, in eastern Amazonia and northeast and eastern Brazil, there is less agreement.

Results from high resolution or regional models forced by CMIP3 models provides further indication the projected changes are robust. A high resolution regional model ensemble projects precipitation increases during austral summer over the La Plata Basin region, northwestern SA, and southernmost Chile, and a decrease over northern SA, eastern Amazonia, eastern Brazil, central Chile, and the Altiplano (Figure 14.21). Other regional models also project a precipitation increase over the Peruvian coast and Ecuador and a reduction in the Amazon Basin (Marengo et al., 2010b; Marengo et al., 2012).

From April to September, the CMIP5 ensemble projects precipitation increases over the La Plata Basin and northwestern SA near the coast (Figures AI31, AI35). In contrast, a reduction is projected for Northeast Brazil and eastern Amazonia. Precipitation is projected to decrease in Central Chile, but to increase over extreme southern areas. In CMIP3 models, a precipitation reduction in the central Andes resulted from a moisture transport decrease from the continental interior to the Altiplano (Minvielle and Garreaud, 2011). CMIP3 and CMIP5 models are consistent in projecting drier conditions in eastern Amazonia during the dry season and wetter conditions in western Amazonia (Malhi et al., 2008; Cook et al., 2011). The Amazon forest's future is discussed in Section 12.5.5.6.1. Areas of maximum change in CMIP5 are consistent with those of CMIP3 in JJA, agreeing also with a high resolution model ensemble (Figure 14.20). Increased precipitation in southeastern SA is projected by a high-resolution model ensemble in all four seasons (Blázquez et al., 2012). The austral winter precipitation increase over the La Plata Basin and southern Chile, and the reduction in eastern Amazonia and Northeast Brazil, are also projected by RCMs (Figure 14.21) as in CMIP5 models. A relevant result from a RCM is the precipitation decrease over most of SA north of 20°S in austral spring, suggesting a longer dry season (Sörensson et al., 2010; see also Section 14.2.3.2). Note that average CMIP5 spatial values in Table 14.1 are consistent with changes seen in the maps, unless for the west coast of SA, where there are spatial variations within the area and the values don't reflect the changes.

Regional model projections and a high-resolution model ensemble indicate an increase in the number of consecutive dry days in northeastern SA (Marengo et al., 2009; Kitoh et al., 2011). An increase in heavy precipitation events over almost the entire continent, especially Amazonia, southern Brazil, and northern Argentina, is projected by a high-resolution model ensemble (Kitoh et al., 2011) and in subtropical areas of South America by regional models (Marengo et al., 2009). The SREX report indicated low to medium confidence in CMIP5 SA precipitation trends. However, the increased ability of CMIP5 models to represent extremes (Kitoh et al., 2013) provides higher confidence in the signals discussed above (Section 14.2.3.2), consistent with global changes in land areas (Section 12.4.5).

Precipitation changes projected over SA are consistent with El Niño influences, e.g., rainfall increase over southeastern and northwestern SA and decrease over eastern Amazonia. However, CMIP3 models could not represent features of Canonical and Modoki ENSO well (Roxy et al., 2013) and there is no consensus about future ENSO behaviour (Coelho and Goddard, 2009; Collins et al., 2010) even with CMIP5 results (Section 14.4). As the various types of ENSO produce different impacts on SA (Ashok et al., 2007; Hill et al., 2011; Tedeschi et al., 2013), future ENSO effects remain uncertain. It is *very likely* that ENSO remains the dominant mode of interannual variability in the future (Section 14.4.6). Therefore, regions in SA currently influenced by Pacific SST will continue to experience ENSO effects on precipitation and temperature.

Projected precipitation increases in the southern sector of southeastern SA are consistent with changes in the SACZ dipole (Section 14.3.1.3) and PSA (Section 14.7.2). Increased precipitation in this region may also have a contribution from a more frequent and intense Low Level Jet (Nuñez et al., 2009; Soares and Marengo, 2009). CMIP3 model analyses show little impact on extreme precipitation from SAM changes toward century's end, except in Patagonia (Menendez and Carril, 2010). However, the southward shift of stormtracks associated with the SAM's projected positive trend (Reboita et al., 2009; Section 14.5.2) impacts zones of cyclogenesis off the Southeast SA coast (Kruger et al., 2011; Section 12.4.4).

In summary, it is *very likely* temperatures will increase over the whole continent, with greatest warming projected in southern Amazonia. It is *likely* there will be an increase (reduction) in frequency of warm (cold) nights in most regions. It is *very likely* precipitation will increase in the southern sector of Southeastern and Northwestern SA, and decrease in Central Chile and extreme north of the continent. It is *very likely* that less rainfall will occur in eastern Amazonia, Northeast and Eastern Brazil during the dry season. However, in the rainy season there is medium confidence in the precipitation changes over these regions. There is high confidence in an increase of precipitation extremes.

Figure 14.21: (a) DJF and (b) JJA relative precipitation change in 2071–2100 with respect to 1961–1990 in the A1B scenario from an ensemble of 10 RCMs participating in the CLARIS-LPB Project. Hatching denotes areas where 8 out of 10 RCMs agree in the sign of the relative change. (c) DJF and (d) JJA dispersion among regional model projections of precipitation changes averaged over land grid points in South Eastern South America, SESA (35°S–25°S, 60°W–50°W), South Atlantic Convergence Zone, SACZ (25°S–15°S, 45°W–40°W) and Southern Amazonia (15°S–10°S, 65°W–55°W), indicated by the boxes in (a).

14.8.6 Europe and Mediterranean

This section assesses regional climate change in Europe and the North African and West Asian rims of the Mediterranean basin. Area-average summaries are presented for the three sub-regions of Northern Europe (NEU), Central Europe (CEU) and Mediterranean (MED) (cf. Tables 14.1–14.2).

The most relevant climate phenomena for this region are NAO (Section 14.5.1), extra-tropical cyclones (Section 14.6.2), and blocking (Box 14.2, Folland et al., 2009; Feliks et al., 2010; Dole et al., 2011; Mariotti and Dell'Aquila, 2012). These phenomena also interact with longer time-scale North Atlantic ocean-atmosphere phenomena such as the AMO (Section 14.7.6, Mariotti and Dell'Aquila, 2012; Sutton and Dong, 2012). Other phenomena have minor influence in limited sectors of the region (see Supplementary Material Section 14.SM.6.3).

Recent 1979–2010 trends in annual mean temperature in each subregion have all exceeded the global mean land trend of 0.27°C per decade (Table 2.4): [NEU: 0.48°C per decade; CEU: 0.44°C per decade; MED: 0.34°C per decade] Consistent with previous AR4 conclusions (Section 11.3), recent studies of extreme events (Section 2.6.1) point to a *very likely* increase of the number of warm days and nights, and decrease of the number of cold days and nights, since 1950 in Europe. Heat waves can be amplified by drier soil conditions resulting from warming (Vautard et al., 2007; Seneviratne et al., 2010; Hirschi et al., 2011). Several studies (Section 2.6.2.1) also indicate general increases in the intensity and frequency of extreme precipitation especially in winter during the last four decades however there are inconsistencies between studies, regions and seasons.

The ability of climate models to simulate the climate in this region has improved in many important aspects since AR4 (see Figure 9.38). Particularly relevant for this region are increased model resolution and a better representation of the land surface processes in many of the models that participated in the recent CMIP5 experiment. Table 14.2 provides an assessment of the CMIP5 quality for simulations of temperature, precipitation, and main phenomena in the region. The CMIP5 projections reveal warming in all seasons for the three sub-regions, while precipitation projections are more variable across sub-regions and seasons. In the winter half year (October to March), NEU and CEU are projected to have increased mean precipitation associated with increased atmospheric moisture, increased moisture convergence, and intensification in extratropical cyclone activity (Section 14.6.2 and Table 14.3) and no change or a moderate reduction in the MED. In the summer half year (April to September), NEU and CEU mean precipitation are projected to have only small changes whereas there is a notable reduction in MED (see Table 14.1, Figures AI.36-AI.37 and AI.42-AI.43). Figure 14.22 illustrates that the precipitation changes are broadly consistent with the findings CMIP3.

High resolution projections from the Japanese high resolution model ensemble also agree with these findings and are consistent with downscaling results from coordinated multi-model GCM/RCM experiments (e.g.,

ENSEMBLES, Déqué et al., 2012). In general, regional climate change amplitudes for temperature and precipitation follow the global warming amplitude although modulated both by changes in the large-scale circulation and by regional feedback processes (Kjellstrom et al., 2011), which confirms findings in AR4 (Chapter 11).

Some new investigations have focused on the uncertainties associated with model projections. A large ensemble of RCM-GCM shows that the temperature response is robust in spite of a considerable uncertainty related to choice of model combination (GCM/RCM) and sampling (natural variability), even for the 2021–2050 time frame (Déqué et al., 2012). Other studies based on CMIP3 projections suggest that GHG-forced changes in the MED are *likely* to become distinguishable from the “noise” created by internal decadal variations in decades beyond 2020–2030 (Giorgi and Bi, 2009). It has been also shown using an ensemble of RCM simulations that the removal of NAO-related variability leads to an earlier emergence of change in seasonal mean temperatures for some regions in Europe (Kjellström et al., 2013). Hence, in the near-term, decadal predictability is *likely* to be critically dependent on the regional impacts of modes of variability “internal” to the climate system. However it has been shown that NAO trends do not account for a large fraction of the long-term future change in mean temperature or precipitation (Stephenson et al., 2006) and that large-scale atmospheric circulation changes in CMIP5 models are not the main driver of the warming projected in Europe by the end of the century (2081–2100, Cattiaux et al., 2013). Therefore, changes in climate phenomena contribute to the uncertainty in the near-term projections rather than long-term changes in this region (Table 14.3), further supporting the credibility in model projection (Table 14.2).

Recent studies have clearly identified a possible amplification of temperature extremes by changes in soil moisture (Jaeger and Seneviratne, 2010; Hirschi et al., 2011), acting as a mechanism that further magnify the intensity and frequency of heat waves given the projected enhance of summer drying conditions. This is in line with the assessed results presented in SREX (Seneviratne et al., 2012). At the other end of the spectrum, studies indicate that European winter variability may be related to sea-ice reductions in the Barents-Kara Sea (Petoukhov and Semenov, 2010) and CMIP5 models in projections for the future in general exhibit a similar relation until the summer sea-ice has almost disappeared (Yang and Christensen, 2012). Although the mechanism behind this relation remains unclear this suggests that cold winters in Europe will continue to occur in coming decades, despite an overall warming.

Climate models have improved fidelity in simulating of aspects regional climates over Europe and the Mediterranean, the spread in projections is still substantial, partly due to large amounts of natural variability in this region (particularly NAO and AMO), besides the inherent model deficiencies .

In summary, there is *high confidence* in model projections of mean temperature in this region. It is *very likely* that temperatures will continue to increase throughout the 21st century over all of Europe and the Mediterranean region. It is *likely* that winter mean temperature will rise more in NEU than in CEU or MED, whereas summer warming will *likely* be more intense in MED and CEU than in NEU. The length, frequency, and/or intensity of warm spells or heat waves are assessed to be *very likely* to increase throughout the whole region. There is *medium confidence* in an annual mean precipitation increase in NEU and CEU, while a decrease is *likely* in MED summer mean precipitation.

[INSERT FIGURE 14.22 HERE]

Figure 14.22: Maps of precipitation changes for Europe and Mediterranean in 2080–2099 with respect to 1986–2005 in June to August (above) and December to February (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

14.8.7 Africa

The African continent encompasses a variety of climatic zones. Here the continent is divided into four major sub-regions as Sahara (SAH), Western Africa (WAF), Eastern Africa (EAF) and Southern Africa (SAF). A fifth Mediterranean region to the north of Sahara is discussed in Section 14.8.6. In tropical latitudes, rainfall

follows insolation (this simplified picture is modified by the presence of orography, especially in the Great Horn of Africa, the geography of the coastline, and by the oceans). The most relevant phenomena affecting climate variability are the monsoons (Section 14.2.4), ENSO (Section 14.4), Indian and Atlantic Ocean SSTs (IOD, Section 14.3.3; AMM Section 14.3.4; AMO Section 14.7.6) and the atmospheric Walker circulation (Section 2.7.5). Tropical cyclones impact East African and Madagascan coastal regions (Section 14.6.1) and extra-tropical cyclones clearly impact southern Africa (Section 14.6.2).

Sub-Saharan Sahelian climate is dominated by the monsoonal system that brings rainfall to the region during only one season (Polcher et al., 2011). Most of the rain between May/June and September comes from mesoscale 'squall line' systems that travel short distances in their lifetime (~1000–2000 km), and whose distribution is somewhat modified by the synoptic scale African Easterly Wave (Ruti and Dell'Aquila, 2010). The onset of the rainy season in West Africa is a key parameter triggering changes in the vegetation and surface properties, that implies feedbacks to the local atmospheric heat and moisture cycle. The length and frequency of dry spells as well as the length or cumulated rainfall of the season also affect this. All are affected by a large inter-annual variability (Janicot et al., 2011). When evaluating models their ability to reproduce such characteristics of the African Monsoon is essential. A large effect of natural multi-decadal SST and warming of the oceans on Sahel rainfall is *very likely* (Hoerling et al., 2006; Ting et al., 2009; Mohino et al., 2011; Rodriguez-Fonseca et al., 2011; Ting et al., 2011).

East Africa experiences a semi-annual rainfall cycle, driven by the ITCZ movement across the equator. Direct links between the region's rainfall and ENSO have been demonstrated (Giannini et al., 2008) and references therein), but variations in Indian Ocean SST (phases of the IOD) are recognised as the dominant driver of east African rainfall variability (Marchant et al., 2007). This feature acts to enhance rainfall through either anomalous low-level easterly flow of moist air into the continent (Shongwe et al., 2011), or a weakening of the low-level westerly flow over the northern Indian Ocean that transports moisture away from the continent (Black et al., 2003). While the effect of the IOD is evident in the short rainy season, Shongwe et al. (2011) do not find a similar relationship for the long rains. Williams and Funk (2011), however, argue for a reduction in the long rains over Kenya and Ethiopia in response to warmer Indian Ocean SSTs.

Variability in Southern Africa's climate is strongly influenced by its adjacent oceans (Rouault et al., 2003; Hansingo and Reason, 2008, 2009; Hermes and Reason, 2009) as well as by ENSO (Vigaud et al., 2009; Pohl et al., 2010). Although it is generally observed that El Niño events correspond to conditions of below-average rainfall over much of southern Africa (Mason, 2001; Giannini et al., 2008; Manatsa et al., 2008) the ENSO teleconnection is not linear, but rather has complex influence in which a number of regimes of local rainfall response can be identified (Fauchereau et al., 2009). The extreme south-western parts of southern Africa receive rainfall in austral winter brought by mid-latitude frontal systems mostly associated with passing extra tropical cyclones, but the majority of the region experiences a single summer rainfall season occurring between November and April. A semi-permanent zone of sub-tropical convergence, is a major contributor to summer rainfall in sub-tropical southern Africa (Fauchereau et al., 2009; Vigaud et al., 2012).

Because of its exceptional magnitude and its clear link to global SST, 20th century decadal rainfall variability in the Sahel is a test of GCMs ability to produce realistic long-term changes in tropical precipitation. Despite biases in the region (Cook and Vizy, 2006) the CMIP3 coupled models overall can capture the observed correlation between Sahel rainfall and basin-wide area averaged SST variability (Biasutti et al., 2008) even though individual models may fail, especially at interannual time-scales (Lau et al., 2006; Joly et al., 2007). Recently, Ackerley et al. (2011) used a perturbed physics ensemble and reached a similar result for the role of atmospheric sulphate, confirming previous results (Rotstayn and Lohmann, 2002; Held et al., 2005). Since AR4, only limited information about improved performance has been documented and only in WAF has major efforts been focusing on relating model behaviour with ability to simulate local climate processes in such details. However, in a comparative study of the ability of CMIP3 and CMIP5 to simulate multiple SST-Africa teleconnections, Rowell (2013) found varying degrees of success in simulating these. In particular, no clear indication of an improvement in the CMIP5 models vs. the CMIP3 models was identified.

In projections of the 21st century, the CMIP3 models produced both significant drying and significant moistening (Held et al., 2005; Biasutti and Giannini, 2006; Cook and Vizy, 2006; Lau et al., 2006), and the mechanisms by which a model dries or wets the Sahel are not fully understood (Cook, 2008). At least

qualitatively, the CMIP3 ensemble simulates a more robust response during the pre-onset and the demise portion of the rainy season (Biasutti and Sobel, 2009; Seth et al., 2011). Rainfall is projected to decrease in the early phase of the seasons—implying a small delay in the main rainy season; but is projected to increase at the end of the season—implying an intensification of late-season rains (d'Orgeval et al., 2006). Projections of a change in the timing of the rains is common to other monsoon regions (Li et al., 2006; Biasutti and Sobel, 2009; Seth et al., 2011), including Southern Africa.

The relevance of a local effect is supported by several lines of evidence. There is observational evidence that local soil moisture gradients can trigger convective systems and that these surface contrasts are as important as topography for generating these systems, which bring most of the rain to the region (Taylor et al., 2011a; Taylor et al., 2011b). Additional evidence comes from simulations of future rainfall changes in West Africa by RCMs subject to coupled model-derived boundary conditions (Patricola and Cook, 2010), documenting a wetting response of the Sahel to increased GHG in the absence of other forcings. But the relative importance of this effect versus the response to SST trends is not well quantified, mostly due to the limitation of using a single RCM.

An evaluation of six GCMs over East Africa by Conway et al. (2007) reveals no clear multi-model trend in mean annual rainfall by the 2080s, but some indications of increased SON and decreased MAM rainfall are noted. They found inconsistency in how the models represent changes in the IOB and consequent changes in rainfall over East Africa. Shongwe et al. (2011) analysed an ensemble of 12 CMIP3 GCMs (forced with A1B emissions). They found widespread increases in short season (OND) rainfall including extreme precipitation across the region, with statistically significant ensemble mean increases. For the long rains (MAM), similar changes in the sign and magnitude of mean and extreme seasonal rainfall were seen, but model skill in simulating the MAM season is relatively poor. The changes shown for the short rains are consistent with a differential warming of 21st century Indian Ocean SSTs, which leads to a positive IOD-like state (see Section 14.3.3). The atmospheric consequence of this is a weakening of the descending branch of the East African Walker cell and enhancement of low-level moisture convergence over east Africa (Vecchi and Soden, 2007a; Shongwe et al., 2011).

In an assessment of 19 CMIP3 models run with the A1B emissions forcing, Giannini et al. (2008) note a tendency toward a persistent El Niño-like pattern (see Section 14.4) in the equatorial Pacific along with a decrease in rainfall over southern Africa. Dynamical downscaling of a single GCM by Engelbrecht et al. (2011) shows—for the austral winter—an intensification of the southern edge of the sub-tropical high pressure belt resulting in southward displacement of the mid-latitude systems that bring frontal rain to the south western parts of the continent, thus resulting in decrease in rainfall. The decrease in summer rainfall is consistent with high-resolution (18 km) RCM simulations done by Haensler et al. (2011) which indicate widespread reductions in rainfall over southern Africa under the A1B scenario.

Shongwe et al. (2009) identified reduction in spring (SON) rainfall throughout the eastern parts of southern Africa. There is good consensus amongst the models used, with the spring anomalies indicating a trend toward later onset of the summer rainy season. Autumn (MAM) reductions are shown for most of southern Africa while eastern South Africa experiences no change and eastern parts of southern Africa show a small increase.

Table 14.2 provides an overall assessment of CMIP5 quality for simulations of temperature, precipitation, and main phenomena in the different sub-regions of Africa. Overall, confidence in the projected precipitation changes is at best *medium*. This is owing to the overall modest ability of models to capture the most important phenomena having a strong control on African climates (Table 14.3).

The ability of climate models to simulate historical climate, its change, and its variability, has improved in many aspects since the AR4 (see Section 9.6.1). But for Africa there is no clear evidence that the modest increase in resolution and a better representation of the land surface processes in many CMIP5 models have resulted in marked improvements (e.g., Figure 9.39). The CMIP5 models projection for this century is further warming in all seasons in the considered four sub-regions, while precipitation show some distinct sub-regional and seasonally dependent changes. In the October to March half year all four regions are projected to receive practically unaltered precipitation amounts by 2081–2100, although somewhat elevated in RCP8.5. In the April to September half year SAH, WAF and EAF will experience little change but a quite

notable reduction in SAF is projected (see Table 14.1, Figures AI.40–AI.51). This is consistent with the results from CMIP3 as depicted in Figure 14.23 in the West African monsoon wet season and austral summer. High resolution information provided by the Japanese high resolution model ensemble also matches this finding.

In summary, due to the physical understanding of the processes involved and models (in)ability to capture large scale climate evolution and represent local processes, it is *very likely* that all of Africa will continue to warm during the 21st century. The overall quality of the CMIP5 models imply, that SAH already very dry is *very likely* to remain very dry. Due to the inability of GCMs to capture the convective systems adequately, there is *low confidence* in projection statements about drying or wetting of WAF. But due to models ability to capture the overall monsoonal behaviour, there is *medium confidence* in projections of a small delay in the rainy season with an increase at the end of the season. There is *medium confidence* in projections showing little change in mean precipitation in EAF and reduced precipitation in the Austral winter in SAF, since models tend to represent Indian Ocean SST developments with credibility. Likewise, increasing rainfall in EAF is *likely* for the short rainy season, but *low confidence* exists in projections regarding drying or wetting in the long rainy season.

Figure 14.23: Maps of precipitation changes for Africa in 2080–2099 with respect to 1986–2005 in June to September (above) and December to March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

14.8.8 Central and North Asia

This area mostly covering the interior of a large continent extending from the Tibetan plateau to the Arctic is mainly influenced by weather systems coming from the west or south, giving some dependency on the AAM (Section 14.2.2) on the one hand and NAO/NAM (Section 14.5.1) on the other, with associated atmospheric blocking as an additional phenomenon of influence related to the latter (Box 14.2). In particular, the variability and long-term change of the climate system in central Asia and northern Asia are closely related to variations of the NAO and NAM (Takaya and Nakamura, 2005; Knutson et al., 2006; Popova and Shmakin, 2010; Sung et al., 2010; Table 14.3). Hence model simulations that do not take the natural variability of the AO/NAO/NAM into account are not expected to replicate the full extent of the observed warming in northern Asia.

As a part of the polar amplification, large warming trends ($>2^{\circ}\text{C}$ per 50 years) in the second half of the 20th century are observed in the northern Asian sector (Chapter 2 and Chapter 4). The warming trend was particularly strong in the cold season (November to March), with an increase of 2.4°C in the mid-latitude semi-arid area of Asia, where the annual rainfall is within the range of 200–600 mm over the period of 1901–2009 (Huang et al., 2012). The observations indicate some increasing trends of heavy precipitation events in northern Asia, but no spatially coherent trends in central Asia (Seneviratne et al., 2012).

The CMIP5 models, generally have difficulties in representing the mean climate expressed as the climatological means of both temperature and precipitation (Table 14.2) for the sub-regions represented in this area, which is partly related to the poor resolution unable to resolve the complex mountainous terrain dominating this region. But the scarceness of observational data and issues related to how these best can be compared with coarse resolution models adds to the uncertainty regarding model quality.

The model projections presented in AR4 (Section 11.4) indicated strong warming in northern Asia during winter and in central Asia during summer. Precipitation was projected to increase throughout the year in northern Asia with largest fractional increase during winter. For central Asia, a majority of the CMIP3 models projected decreasing precipitation during spring and summer. Seneviratne et al. (2012) indicate increases in all precipitation extreme indices for northern Asia, and in the 20-year return value of annual maximum daily precipitation for central Asia. These projections are supported by output from CMIP5

models subject to various RCP scenarios (see Annex I). CMIP5 projected temperature increase in Central Asia of comparable magnitude in both JJA and in DJF. In North Asia, temperatures rise more in DJF than in JJA, while less annual variation is found over Central Asia and the Tibetan Plateau (Table 14.1, Figures AI.12–AI.13, AI.52–AI.55 and AI.56–AI.57). The sensitivity of the climate response to enhanced greenhouse gas forcing is high in northwestern China and Mongolia (Xu et al., 2009).

With a RCM Sato et al. (2007) projected precipitation decreases over northern Mongolia and increases over southern Mongolia in July. Soil moisture over Mongolia decreases in July as a result of the combined effect of decreased precipitation and increased potential evaporation due to rising surface temperature. In North Asia, all CMIP5 models projects an increase in precipitation in the winter half year, and summer half year precipitation is also projected to increase (Table 14.1, Figures AI.14–AI.15). In Central Asia and the Tibetan Plateau, model agreement is lower on changes both for winter and summer precipitation (Figure 14.24, Table 14.1, and Figures AI.54–AI.55 and AI.58–AI.59). The ability of these CMIP5 models to simulate precipitation over this region varies, but as an exact dependence on climate phenomena is not well constrained and therefore presumably weak (Table 14.3). The reasonable level of agreement in projections of precipitation to be positive and significantly above the 20 year natural variability (Table 14.2), therefore suggests that confidence in the sign of the projected change in future precipitation is *medium*.

In summary, all the areas are projected to warm, a stronger than global mean warming trend is projected for northern Asia during winter. For central Asia, warming magnitude is similar between winter and summer. Precipitation in northern Asia will *very likely* increase, whereas the precipitation trend over central Asia is *likely* to increase. Extreme precipitation events will *likely* increase in both regions.

[INSERT FIGURE 14.24 HERE:]

Figure 14.24: Maps of precipitation changes for Central, North, East and South Asia in 2080–2099 with respect to 1986–2005 in June to September (above) and December to March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

14.8.9 East Asia

Summer is the rainy season for East Asia. The Meiyu-Changma-Baiu rain band is the defining feature of East Asian summer climate, extending from eastern China through central Japan (Ding and Chan, 2005; Zhou et al., 2009b). The summer rain band is anchored by the subtropical westerly jet (Sampe and Xie, 2010), and located on the northwestern flank of the western North Pacific subtropical high (Zhou and Yu, 2005). The wintertime circulation is characterized by monsoonal northerlies between the Siberian High and the Aleutian Low.

[INSERT FIGURE 14.25 HERE]

Figure 14.25: Linear trend for local summer (a) total precipitation (b) R95 (summer total precipitation when PR>95th percentile) during 1961–2006. The unit is % per 50-year. The trends statistically significant at 5% level are dotted. The daily precipitation data over Australia and China are produced by the Australian Water Availability Project (AWAP, Jones et al., 2009a) and National Climate Centre China of China Meteorological Administration (Wu and Gao, 2013), respectively, while that over the other area is compiled by the Highly Resolved Observational Data Integration Towards the Evaluation of Water Resources (APHRODITE) project (Yatagai et al., 2012). The resolution of precipitation dataset is $0.5^\circ \times 0.5^\circ$. Local summer is defined as June-July-August in the Northern Hemisphere, and December-January-February in the Southern Hemisphere.

Both the East Asian summer and winter monsoon circulations have experienced an interdecadal scale weakening after the 1970s due to natural variability of the coupled climate system, leading to enhanced mean and extreme precipitation along the Yangtze River valley (30°N) but deficient mean precipitation in North China in summer (Figure 14.25), and a warmer climate in winter. The observed monsoon circulation changes are partly reproduced by GCMs driven by PDO-related SST patterns but the quality of precipitation simulation is poor (Zhou et al., 2008a; Li et al., 2010a; Zhou and Zou, 2010).

In AR4, the regional warming is projected to be above the global mean in East Asia (Section 11.4). It is *very likely* that heat waves/hot spells in summer will be of longer duration, more intense and more frequent, but very cold days are *very likely* to decrease in frequency. The precipitation is *likely* to increase in both boreal winter and summer, while the frequency of intense precipitation events is *very likely* to increase. Extreme rainfall and winds associated with tropical cyclones are *likely* to increase (Christensen et al., 2007). CMIP5 results support many of these assessments.

More recent analysis suggested that CMIP3 models projected increased summer precipitation in amount and intensity over East Asia (Figure 14.24 for SRES A1B scenario) due to enhanced moisture convergence in a warmer climate (Ding et al., 2007; Sun and Ding, 2010; Chen et al., 2011; Kusunoki and Arakawa, 2012), along with an increase in interannual variability (Lu and Fu, 2010). CMIP5 projections for RCP4.5 support those from AR4 for summer (Figure 14.24), with 90% of the models projecting a precipitation increase in the winter half year (see Table 14.1 and Figures AI.56–AI.59). CMIP3 models projections indicated a decrease of winter precipitation extending northeastward from South China Sea to south of Japan under SRES A1B scenario, changes seen in CMIP5 projections but with smaller spatial coverage (Figure 14.24).

An increase of extreme precipitation is projected over East Asia in a warmer climate (Jiang et al., 2011; Lee et al., 2011; Li et al., 2011b, 2011a). A high-resolution model projects an increase of Meiyu precipitation in May through July, Changma precipitation over Korean peninsula in May, and Baiu precipitation over Japan in July (Kusunoki and Mizuta, 2008), and an increase of heavy precipitation over East Asia under SRES A1B scenario (Kusunoki and Mizuta, 2008; Endo, 2012). CMIP3 models project a late withdrawal of Baiu (Kitoh and Uchiyama, 2006), as what has been observed in eastern and western Japan (Endo, 2010). There is a significant increase in mean, daily-maximum and minimum temperatures in southeastern China, associated with a decrease in the number of frost days and an increase in the heat wave duration under SRES A2 scenario (Chen et al., 2011). The CMIP5 model projections also indicate an increase of temperature in both boreal winter and summer over East Asia for RCP4.5 (Table 14.8.a). A decrease of the annual and seasonal maximum wind speeds is found under SRES A2 scenario due to both the reduced intensity of cold waves and the reduced intensity of the winter monsoons (Jiang and Zhao, 2013).

The future warming patterns simulated by RCMs essentially follow those of the driving GCMs (e.g., Dairaku et al., 2008). For summer precipitation, however, RCM downscaling usually shows different regional details due to more realistic topographic forcing than in GCMs (Gao et al., 2008; Gao et al., 2012a). The uncertainty of precipitation projection in eastern China is larger than that in western China (Gao et al., 2012b). RCM downscaling indicate that both the seasonal mean summer rainfall and extreme precipitation around Japan Islands are projected to increase (Im et al., 2008; Iizumi et al., 2012).

Projections with a 5-km RCM show that the heaviest hourly precipitation is projected to increase even in the near future (2030s) when temperature increase is modest (Kitoh et al., 2009). A southwest expansion of the subtropical anticyclone over the northwestern Pacific Ocean associated with El Niño-like mean state changes in the Pacific and a dry air intrusion in the mid-troposphere from the Asian continent gives a favourable condition for intense precipitation in the Baiu season in Japan (Kanada et al., 2010). Increased water vapour supply from the south of the Baiu front and an intensified frontal zone with intense mean updrafts contribute to the increased occurrence of intense daily precipitation during the late Baiu season (Kanada et al., 2012).

In summary, based on CMIP5 model projections, there is *medium confidence* that with an intensified East Asian summer monsoon, summer precipitation over East Asia will increase (Table 14.3). Under RCP4.5 scenario, precipitation increase is *likely* over East Asia during the Meiyu-Changma-Baiu season in May to July, and precipitation extremes are *very likely* to increase over the eastern Asian continent in all seasons and over Japan in summer. But the level of confidence in the projected changes is *low* due to the limited skill of CMIP5 models in simulating the East Asian summer monsoon rainband (Table 14.2).

14.8.10 West Asia

This region extends from the Mediterranean to the western fringes of South Asia, covering the Middle East and the Arabian Peninsula and includes large areas of barren desert. The climate over this region varies from arid to semi-arid and precipitation is primarily received in the cold season.

The western part of the region is on the margin of Atlantic and Mediterranean influences, primarily the NAO (Section 14.2.9) during winter months, and indirectly the monsoon heat low (Section 14.2.2.1) in the summer months. Precipitation in this region comes largely from passing extra-tropical cyclones (Section 14.6.2). Land-falling TCs (Section 14.6.1) that occasionally influence the eastern part of the Arabian Peninsula are notable extreme events. Pacific Ocean variability, associated with ENSO (Section 14.2.4), and the ITCZ (Section 14.3.1) are also known to impact weather and climate in different parts of West Asia.

In recent decades, there appears to be a weak but non-significant downward trend in mean precipitation (Zhang et al., 2005; Alpert et al., 2008; AlSarmi and Washington, 2011; Tanarhte et al., 2012), although intense weather events appear to be increasing (Alpert et al., 2002; Yosef et al., 2009). In contrast, upward temperature trends are notable and robust (Alpert et al., 2008; AlSarmi and Washington, 2011; Tanarhte et al., 2012).

The ability of climate models to simulate historical climate, its change and its variability, has improved in many important aspects since the AR4 (see Figure 9.39 in Chapter 9). CMIP5 models tend to be able to reproduce the basic climate state of the region as well as the main phenomena affecting it with some fidelity (Table 14.2), but the region is at the fringes of the influence of different drivers of European, Asian and African climates and remains poorly analysed in the peer reviewed literature with respect to climate model performances.

The CMIP5 models projections for this century is for further warming in all seasons, while precipitation shows some distinct sub-regional and seasonally dependent changes, characterized by model scatter. In both winter (October to March) and summer (April to September) precipitation in general is projected to decrease, (see Table 14.1, Figures AI.52–AI.55). However, the various interacting dynamical influences on precipitation of the region (that models have varying success in capturing in the current climate) results in uncertainty in both the patterns and magnitude of future precipitation change. Indeed, while the overall pattern of change has remained the same between CMIP3 and CMIP5, the confidence has decreased somewhat and the boundary between the Mediterranean decreases and the general mid-latitude increase to the north has shifted closer to the region (Figure 14.26 and AI.54–AI.55). So, while the Mediterranean side still appears *likely* to become drier, the *likely* precipitation changes for the interior land masses are less clear and the intensified and northward shifting ITCZ may imply an increase in precipitation in the most southern part of the Arabian Peninsula. Overall, the projections by the end of the century (2081–2100) indicates little overall change, although with a tendency for reduced precipitation, particular in the high end scenarios (Figures AI.5–AI.55). However, regardless of the sign of precipitation change in the high mountain regions of the interior, the influence of warming on the snow pack will *very likely* cause important changes in the timing and amount of the spring melt (Diffenbaugh et al., 2013).

Recent downscaling results (Lionello et al., 2008; Evans, 2009; Jin et al., 2010; Dai, 2011) suggest that Eastern Mediterranean will experience a decrease in precipitation during the rainy season due to a northward displacement of the storm tracks (Section 14.6.2). A northward shift in the ITCZ results in more precipitation in the southern part, not previously being seriously affected by it. A moderate change in the annual cycle of precipitation has also been simulated by some models. Precipitation and temperature statistics in RCMs for an area consisting of the western part of the Arab Peninsula was assessed by Black (2009) and Onol and Semazzi (2009) confirming GCM-based findings. Increased drought duration has been projected (Kim and Byun, 2009). Inland from the Mediterranean coastal areas, resolution of the terrain becomes more important and, while downscaled results (Evans, 2008; Marcella and Eltahir, 2011; Lelieveld et al., 2012) broadly agree with GCM projections, higher resolution results in some differences associated with mountain barrier jets (Evans, 2008; see also Figure 14.26).

In summary, since AR4 climate models appear to have only modestly improved fidelity in simulating aspects of large-scale climate phenomena influencing regional climates over West Asia. Model agreement, however, indicates that it is *very likely* that temperatures will continue to increase. But at the same time, model agreement on projected precipitation changes have reduced, resulting in *medium confidence* in projections showing an overall reduction in precipitation.

[INSERT FIGURE 14.26 HERE]:

Figure 14.26: Maps of precipitation changes for West Asia in 2080-2099 with respect to 1986-2005 in June-August

(above) and December–February (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

14.8.11 South Asia

From June through September, the Indian summer monsoon (Section 14.2.2.1) dominates South Asia, while the northeast winter monsoon contributes substantially to annual rainfall over southeastern India and Sri Lanka. The winter weather systems are also important in northern parts of South Asia, i.e., the western Himalayas.

Seasonal mean rainfall shows interdecadal variability, noticeably a declining trend with more frequent deficit monsoons (Kulkarni, 2012). There are regional inhomogeneities: precipitation decreased over central India along the monsoon trough (Figure 14.25) due to a number of factors (Section 14.2.2) including black carbon, sulphate aerosols (Chung and Ramanathan, 2007; Bollasina et al., 2011), land-use changes (Niyogi et al., 2010) and SST rise over the Indo-Pacific warm pool (Annamalai et al., 2013). The increase in the number of monsoon break days over India (Dash et al., 2009), and the decline in the number of monsoon depressions (Krishnamurthy and Ajayamohan, 2010) are consistent with the overall decrease in seasonal mean rainfall. The frequency of heavy precipitation events is increasing (Rajeevan et al., 2008; Krishnamurthy et al., 2009; Sen Roy, 2009; Pattanaik and Rajeevan, 2010), while light rain events are decreasing (Goswami et al., 2006; also reflected in Figure 14.25 right panel).

CMIP models reasonably simulate the annual cycle of precipitation and temperature over South Asia (Table 14.2; Figure 9.38) but are limited in simulating fine structures of rainfall variability on sub-seasonal and sub-regional scales (Turner and Annamalai, 2012). CMIP5 models show improved skill in simulating monsoon variability compared to CMIP3 (Sperber et al., 2012).

Summer precipitation changes in South Asia are consistent overall between CMIP3 and CMIP5 (Figure 14.24), but model scatter is large in winter precipitation change (Figure 14.24; Figure AI.62). Changes in the summer monsoon dominate annual rainfall (see Section 14.2.2). The CMIP3 multi-model ensemble shows an increase in summer precipitation (Kumar et al., 2011a; May, 2011; Sabade et al., 2011), although there are wide variations among model projections (Annamalai et al., 2007; Kripalani et al., 2007b). Spatially, the rainfall increase is stronger over northern parts of South Asia, Bangladesh, and Sri Lanka with a weak decrease over Pakistan (Turner and Annamalai, 2012). In RCP6.0 and RCP8.5 scenarios, frequency of extreme precipitation days shows consistent increasing trends in 2060 and beyond (Chaturvedi et al., 2012; Figure AI.63). In six CMIP3 models, precipitation anomalies during Indian summer monsoon breaks strengthen in a warmer climate, but changes in the timing and duration of active/break spells are variable among models (Mandke et al., 2007). Note that the active/break spells of the monsoon are related to the MJO (see Section 14.3.2), a phenomenon that models simulate poorly (refer to Chapter 9; Lin et al., 2008a; Sperber and Annamalai, 2008).

High-resolution RCM and GCM projections showed an overall increase of precipitation over a large area of peninsular India (Rupa Kumar et al., 2006; Stowasser et al., 2009; Kumar et al., 2011a), but a significant reduction in orographic rainfall in both seasonal mean and extreme events on west coasts of India (Rajendran and Kitoh, 2008; Ashfaq et al., 2009; Kumar et al., 2013). Such spatial variations in projected precipitation near orography are noticeable in Figure 14.24 on the background of the overall increase.

CMIP5 models project a clear increase in temperature over India especially in winter (Figures AI.60–AI.61), with enhanced warming during night than day (Kumar et al., 2011a) and over northern India (Kulkarni, 2012). In summer, extremely hot days and nights are projected to increase. Table 14.2 summarizes the projected temperature and precipitation changes for SAS in the RCP4.5 scenario based on CMIP5.

In summary, there is high confidence in projected rise in temperature. There is medium confidence in summer monsoon precipitation increase in the future over South Asia. Model projections diverge on smaller regional scales.

14.8.12 Southeast Asia

Southeast Asia features a complex range of terrains and land-sea contrasts. Across the region, temperature has been increasing at a rate of 0.14°C to 0.20°C per decade since the 1960s (Tangang et al., 2007), coupled with a rising number of hot days and warm nights, and a decline in cooler weather (Manton et al., 2001; Caesar et al., 2011). A positive trend in the occurrence of heavy (top 10% by rain amount) and light (bottom 5%) rain events and a negative trend in moderate (25–75%) rain events has been observed (Lau and Wu, 2007). Annual total wet-day rainfall has increased by 22 mm per decade, while rainfall from extreme rain days has increased by 10 mm per decade (Alexander et al., 2006; Caesar et al., 2011).

Several large-scale phenomena influence the climate of this region. While ENSO (Section 14.4) influence is predominant in East Malaysia and areas east of it, Maritime continent monsoon (Section 14.2.3) influences the climate in Peninsular Malaya. The impact of IOD (Section 14.3.3) is more prominent in eastern Indonesia. Thus climate variability and trends differ vastly across the region and between seasons. Between 1955 and 2005 the ratio of rainfall in the wet to the dry seasons increased (Aldrian and Djamil, 2008). This appears to be at least in part consistent with an upward trend of the IOD. While an increasing frequency of extreme events has been reported in the northern parts of South East Asia, decreasing trends in such events are reported in Myanmar (Chang, 2011), see also Figure 14.25.

For a given region, strong seasonality in change is observed. In Peninsular Malaya during the southwest monsoon season, total rainfall and the frequency of wet days decreased, but rainfall intensity increased in much of the region (Deni et al., 2010). During the northeast monsoon, total rainfall, the frequency of extreme rainfall events, and rainfall intensity all increased over the peninsula (Suhaila et al., 2010).

High resolution model simulations are necessary to resolve complex terrain such as in South East Asia (Nguyen et al., 2012); Section 14.2.2.4). In a RCM downscaling simulation using the A1B emission scenario (Chotamonsak et al., 2011), regional average rainfall was projected to increase, consistent with a combination of the “warmer getting wetter” mechanism (Section 14.3.1), an increase in summer monsoon, though there is a lack of consensus on future ENSO changes. The spatial pattern of change is similar to that projected in the AR4 (Section 11.4).

The median increase in temperature over land ranges from 0.8°C in RCP2.8 to 3.2°C in RCP8.5 by the end of this century (2081–2100). A moderate increase in precipitation is projected for the region: 1% in RCP2.8 increasing to 8% in RCP8.5 by 2100 (Table 14.1, Supplementary Material Table 14.SM.1a–14.SM.1c, Figure 14.27, Figures AI.64–AI.65). On islands neighbouring the Southeast tropical Indian Ocean, rainfall is projected to decrease during July to November (the IOD prevalent season), consistent with a slower oceanic warming in the east than in the west tropical Indian Ocean, despite little change projected in the IOD (Section 14.3.3).

In summary, warming is *very likely* to continue with substantial sub-regional variations. There is *medium confidence* in a moderate increase in rainfall, except on Indonesian islands neighbouring the Southeast Indian Ocean. Strong regional variations are expected because of terrain.

[INSERT FIGURE 14.27 HERE]

Figure 14.27: Maps of precipitation changes for Southeast Asia, Australia and New Zealand in 2080–2099 with respect to 1986–2005 in June–September (above) and December–March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

14.8.13 Australia and New Zealand

The climate of Australia is a mix of tropical and extra-tropical influences. Northern Australia lies in the tropics and is strongly affected by the Australian monsoon circulation (Section 14.2.2) and ENSO (Section 14.4). Southern Australia extends into the extra-tropical westerly circulation and is also affected by the middle latitude storm track (Section 14.6.2), the SAM (Section 14.5.2), mid-latitude transient wave propagation, and remotely by the IOD (Section 14.3.3) and ENSO.

Eastern-northeastern Australian rainfall is strongly influenced by the ENSO cycle, with La Niña years typically associated with wet conditions and more frequent and intense tropical cyclones in summer, and El Niño years with drier than normal conditions, most notably in spring. The SAM plays a significant role in modulating southern Australian rainfall, the positive SAM being associated with generally above-normal rainfall during summer (Hendon et al., 2007; Thompson et al., 2011), but in winter with reduced rainfall, particularly in Southwest Western Australia (Hendon et al., 2007; Meneghini et al., 2007; Pezza et al., 2008; Risbey et al., 2009; Cai et al., 2011c). Rossby wavetrains induced by tropical convective anomalies associated with the IOD (Cai et al., 2009), and associated with ENSO through its coherence with the IOD (Cai et al., 2011b) also have a strong impact, leading to lower winter and spring rainfall particularly over Southeastern Australia during positive IOD and El Niño events. Along the eastern seaboard, extra-tropical cyclones (Section 14.6.2) exert a strong influence on the regional climate, while ENSO and other teleconnections play a lesser role (Risbey et al., 2009; Dowdy et al., 2012).

Significant trends have been observed in Australian rainfall over recent decades (Figure 14.25), varying vastly by region and season. Increasing summer rainfall and decreasing temperature trends over Northwest Australia have raised the question of whether aerosols originating in the northern hemisphere play a role (Rotstayn et al., 2007; Shi et al., 2008b; Smith et al., 2008; Rotstayn et al., 2009; Cai et al., 2011d), but there is no consensus at present. By contrast, a prominent rainfall decline has been experienced in austral winter over Southwest Western Australia (Cai and Cowan, 2006; Bates et al., 2008) and in mid-to-late autumn over Southeastern Australia (Murphy and Timbal, 2008). Over Southwest Western Australia, the decrease in winter rainfall since the late 1960s of about 20% have led to an even bigger (~50%) drop in inflow into dams. The rainfall decline has been linked to changes in large-scale mean sea level pressure (Bates et al., 2008), shifts in synoptic systems (Hope et al., 2006), changes in baroclinicity (Frederiksen and Frederiksen, 2007), the SAM (Cai and Cowan, 2006; Meneghini et al., 2007), land cover changes (Timbal and Arblaster, 2006), anthropogenic forcing (Timbal et al., 2006), Indian Ocean warming (England et al., 2006), and teleconnection to Antarctic precipitation (van Ommen and Morgan, 2010).

Over Southeastern Australia, the decreasing rainfall trend is largest in autumn with sustained declines during the drought of 1997-2009, especially in May (Cai and Cowan, 2008; Murphy and Timbal, 2008; Cai et al., 2012a). The exact causes remain contentious, and for the decrease in May, may include ENSO variability and long-term Indian Ocean warming (Cai and Cowan, 2008; Ummenhofer et al., 2009b), a weakening of the subtropical storm track due to decreasing baroclinic instability of the subtropical jet (Frederiksen et al., 2010; Frederiksen et al., 2011b; Frederiksen et al., 2011a), and a poleward shift the ocean-atmosphere circulation (Smith and Timbal, 2012; Cai and Cowan, 2013). The well-documented poleward expansion of the subtropical dry zone (Seidel et al., 2008; Johanson and Fu, 2009; Lucas et al., 2012), particularly in April and May, is shown to account for much of the April-May reduction (Cai et al., 2012a). Rainfall trends over Southeastern Australia in spring, far weaker but with a signature in the subtropical ridge (Cai et al., 2011a; Timbal and Drosowsky, 2012), have been shown to be linked with trends and variability in the IOD (Cai et al., 2009; Ummenhofer et al., 2009b). Antarctic proxy data which captures both Eastern Australian rainfall and ENSO variability (Vance et al., 2012) shows a predominance of El Niño/drier conditions in the 20th century than was the average over the last millennium.

On seasonal to decadal timescales, New Zealand precipitation is modulated by the SAM (Kidston et al., 2009; Thompson et al., 2011), ENSO (Kidson and Renwick, 2002; Ummenhofer and England, 2007), and the IPO (Griffiths, 2007). Increased westerly flow across New Zealand, associated with negative SAM and with El Niño events, leads to increased rainfall and generally lower than normal temperatures in western regions. The positive SAM and La Niña conditions are generally associated with increased rainfall in the north and east of the country, and warmer than normal conditions. On longer time scales, a drying trend since 1979 across much of New Zealand during austral summer is consistent with recent trends in the SAM and to a lesser extent ENSO and the IPO (Griffiths, 2007; Ummenhofer et al., 2009a). In western regions,

however, the drying is accompanied by a trend towards increased heavy rainfall (Griffiths, 2007). Temperatures over New Zealand have risen by just under 1°C over the past century (Dean and Stott, 2009). The upward trend has been modulated by an increase in the frequency of cool southerly wind flows over the country since the 1950s, without which the observed warming is consistent with large-scale anthropogenic forcing (Dean and Stott, 2009).

A recent analysis (Irving et al., 2012; their Figure 9) shows that climate projections over Australia using CMIP5 models, which generally simulate the climate of Australia well (Watterson et al., 2013), are highly consistent with existing CMIP3-derived projections. The projected changes include a further 1.0 to 5.0°C temperature rise by the year 2070 (relative to 1990, Table 14.1); a long-term drying over southern areas during winter, particularly in the south-west (Figure 14.27), that is consistent with an upward trend of the SAM (Pitman and Perkins, 2008; Shi et al., 2008a; Cai et al., 2011c); a long-term rainfall decline over southern and eastern areas during spring, in part consistent with an upward trend of the IOD index (Smith and Chandler, 2010; Zheng et al., 2010; Weller and Cai, 2013; Zheng et al., 2013). Precipitation change in northeast Australia remains uncertain (Moise et al., 2012), related to the lack of consensus over how ENSO may change (Collins et al., 2010). In terms of climate extremes, more frequent hot days and nights and less frequent cold days and nights are projected (Alexander and Arblaster, 2009). Changes in the intensity and frequency of extreme rainfall events generally follow the mean rainfall change (Kharin et al., 2007), although there is an increase in most regions in the intensity of short duration extremes (e.g., Alexander and Arblaster, 2009).

For New Zealand, future climate projections suggest further increases in the westerlies in winter and spring, though model biases in jet latitude in the present climate reduce confidence in the detail of future projections (Barnes et al., 2010). The influence of poleward expansion of the subtropical high pressure belt is projected to lead to drier conditions in parts of the country (Figure 14.27, Table 14.1), and a decrease in westerly wind strength in northern regions. Such projections imply increased seasonality of rainfall in many regions of New Zealand (Reisinger et al., 2010). Both flood and drought occurrence is projected to approximately double over New Zealand during the 21st century, under the SRES A1B scenario. Temperatures are projected to rise at about 70% of the global rate, because of the buffering effect of the oceans around New Zealand. Temperature rises are projected to be smallest in spring (SON) while the season of greatest warming varies by region around the country. Continued decreases in frost frequency, and increases in the frequency of high temperature extremes, are expected, but have not been quantified (Reisinger et al., 2010).

In summary, based on understanding of recent trends and on CMIP5 results, it is *likely* that cool season precipitation will decrease over southern Australia associated in part with trends in the SAM, the IOD, and a poleward shift and expansion of the subtropical dry-zone. It is *very likely* that Australia will continue to warm through the 21st century, at a rate similar to the global land-surface mean. The frequency of very warm days is *virtually certain* to increase through this century, across the whole country.

It is *very likely* that temperatures will continue to rise over New Zealand. Precipitation is *likely* to increase in western regions in winter and spring, but the magnitude of change is *likely* to remain comparable to that of natural climate variability through the rest of the century. In summer and autumn, it is *as likely as not* that precipitation amounts will change.

14.8.14 Pacific Islands Region

The Pacific Islands region includes the northwest tropical Pacific, and the tropical southwest Pacific. North of the Equator, the wet season occurs from May to November. In the south, the wet seasons occurs from November to April.

The phenomena mainly responsible for climate variations in the Pacific Islands are ENSO (Section 14.4), the SPCZ (Section 14.3.1.2), the ITCZ (Section 14.3.1.1), and the Western North Pacific Monsoon (Section 14.2.2.5). During El Niño events, the ITCZ and SPCZ move closer to the Equator, rainfall decreases in western regions and increases in the central Pacific, and tropical cyclone numbers tend to increase and to occur farther east than normal (Diamond et al., 2012). During La Niña, the western tropical Pacific tends to experience above-average numbers of tropical cyclones (Nicholls et al., 1998; Lavender and Walsh, 2011).

The seasonal evolution of the SPCZ has a strong influence on the seasonality of the climate of the southern tropical Pacific, particularly during the wet season. The SPCZ moves northward during moderate El Niño events and southward during La Niña events (Folland et al., 2002; Vincent et al., 2011). During El Niño events, southwest Pacific Island nations experience an increased occurrence of forest fires and droughts (Salinger et al., 2001; Kumar et al., 2006b), and an increased probability of tropical cyclone damage, as tropical cyclogenesis tends to reside within 6°–10° south of the SPCZ (Vincent et al., 2011). Nauru experiences drought during La Niña as the SPCZ and ITCZ move to the west (Brown et al., 2012c). During strong El Niño events (e.g., 1982/1983, 1997/1998) the SPCZ undergoes an extreme swing of up to 10 degrees towards the equator and collapses to a more zonally-oriented structure (Vincent et al., 2011; Section 14.3.2). The impacts from these zonal SPCZ events are much more severe than those from moderate El Niño events (Vincent et al., 2011; Cai et al., 2012b), and can induce massive droughts and food shortages (Barnett, 2011).

Temperatures have increased at a rate between 0.1°C and 0.2°C per decade throughout the Pacific Islands during the 20th century (Folland et al., 2003). Changes in temperature extremes have followed those of mean temperatures, (Manton et al., 2001; Griffiths et al., 2005). During 1961–2000, locations to the north-east of the SPCZ became wetter, with the largest trends occurring in the eastern Pacific Ocean (east of 160°W), while locations to the south-west of the SPCZ became drier (Griffiths et al., 2003), indicative of a northeastward shift of the SPCZ. Trends in the frequency of rain days were generally similar to those of total annual rainfall (Manton et al., 2001; Griffiths et al., 2003). Since 1980, Western Pacific monsoon- and ITCZ-related rain during June to August has decreased (Hennessy et al., 2011).

Future projections for tropical Pacific Island nations are based on direct outputs from a suite of CMIP3 models, updated using CMIP5 wherever available (Brown et al., 2011; Hennessy et al., 2011; Irving et al., 2011; Moise and Delage, 2011; Perkins, 2011; Perkins et al., 2012). These projections carry a large uncertainty, even in the sign of change, as discussed below and as evident in Table 14.1.

Annual average air and sea surface temperature are projected to continue to increase for all tropical Pacific countries. By 2055, under the high A2 emissions scenario, the increase is projected to be 1°C–2°C. A rise in the number of hot days and warm nights is also projected, and a decline in cooler weather, as already observed (Manton et al., 2001). For a low emission scenario, the lower range decreases about 0.5°C while the upper range reduces by between 0.2°C and 0.5°C.

To a large extent, the response of the ITCZ, the SPCZ, and the WNPSM to greenhouse warming will determine how rainfall patterns will change in tropical Pacific. In northwestern and near-equatorial regions, rainfall during all seasons is projected to increase in the 21st century. Wet season increases are consistent with the expected intensification of the WNPSM and the ITCZ (Smith et al., 2012a). For the southwestern tropical Pacific, the CMIP3 and CMIP5 ensemble mean change in summer rainfall is far smaller than the inter-model range (Brown et al., 2012b; Widlansky et al., 2013). There is a projected intensification in the western part of the SPCZ and near the equator with little mean change in SPCZ position (Brown et al., 2012a; Brown et al., 2012b). For the southern group of the Cook Islands, the Solomon Islands, and Tuvalu, average rainfall during the wet season is projected to increase; and for Vanuatu, Tonga, Samoa, Niue, Fiji, a decrease in dry season rainfall is accompanied by an increase in the wet season, indicating an intensified seasonal cycle.

Extreme rainfall days are *likely* to occur more often in all regions (Perkins, 2011), based on an intensification of the ITCZ and the SPCZ. Although the intensification appears to be reproduced in CMIP5 models (Brown et al., 2012a), it has recently been questioned (Widlansky et al., 2013; see Section 14.3.1). There are two competing mechanisms, the “wet regions getting wetter” and the “warmest getting wetter, or coldest getting dryer” paradigms. These two mechanisms compete within much of the SPCZ region. Based on a multi-model ensemble of 55 greenhouse warming experiments, in which model biases were corrected, tropical SST changes between 2°C–3°C resulted in a 5% decrease of austral summer moisture convergence in the current SPCZ region (Widlansky et al., 2013). This projects a diminished rainy season for most Southwest Pacific island nations. In Samoa and neighbouring islands, summer rainfall may decrease on average by 10–20% during the 21st century as simulated by the hierarchy of bias-corrected atmospheric model experiments. Less rainfall, combined with increasing surface temperatures and enhanced potential evaporation, could increase

the chance for longer-term droughts in the region. Such projections are completely opposite to those based on direct model outputs (Figure 14.27).

Recent downscaling experiments support the above conclusion regarding the impact of biases on the SPCZ change, and suggest that the projected intensification of the ITCZ may have uncertainties of a similar nature (Chapter 7 of Hennessy et al., 2011). In these experiments a bias correction is applied to average sea surface temperatures, and the atmosphere is forced with the “correct” climatological seasonal cycle together with warming derived from large-scale model outputs. The results show opposite changes in much of the SPCZ and some of the ITCZ regions, resulting in much lower confidence in rainfall projections.

Despite the uncertainty, there is general agreement in model projections regarding an increase in rainfall along the equator (Tables 14.1 and 14.2), and regarding a faster warming rate in the equatorial Pacific than the off-equatorial regions (Xie et al., 2010b). A potential consequence is an increase in the frequency of the zonal SPCZ events (Cai et al., 2012b).

In summary, based on CMIP3 and CMIP5 model projections and recently-observed trends, it is *very likely* that temperatures, including the frequency and magnitude of extreme high temperatures, will continue to increase through the 21st century. In equatorial regions, the consistency across model projections suggests that rainfall is *likely* to increase. However, given new model results and physical insights since the AR4, the rainfall outlook is uncertain in regions directly affected by the SPCZ and western portion of the ITCZ.

14.8.15 Antarctica

Much of the climate variability of Antarctica is modulated by the Southern Annular Mode (SAM, Section 14.5.2), the high-latitude atmospheric response to ENSO (Section 14.4), and interactions between the two (Stammerjohn et al., 2008; Fogt et al., 2011; see also Sections 2.7 and 10.3.3). Signatures of the SAM and ENSO in Antarctic temperature, snow accumulation, and sea ice have been documented by many observational and modelling studies (Bromwich et al., 2004; Guo et al., 2004; Kaspari et al., 2004; van den Broeke and van Lipzig, 2004; Marshall, 2007).

The positive SAM is associated on average with warmer conditions over the Peninsula and colder conditions over East Antarctica, with a mixed and generally non-significant impact over West Antarctica (Kwok and Comiso, 2002; Thompson and Solomon, 2002; van den Broeke and van Lipzig, 2004). ENSO is associated with circulation anomalies over the southeast Pacific that primarily affect West Antarctica (Bromwich et al., 2004; Guo et al., 2004; Turner, 2004). ENSO variability tends to produce out-of-phase variations between the western and eastern sectors of West Antarctica (Bromwich et al., 2004; Kaspari et al., 2004), in association with the PSA pattern (Section 14.7.1).

The positive summer/autumn trend in the SAM index in recent decades (Section 14.5.2) has been related to the contrasting temperature trend patterns observed in these two seasons, with warming in the east and north of the Antarctic Peninsula and cooling (or no significant temperature change) over much of East Antarctica (Turner et al., 2005; Thompson et al., 2011). The high polarity of the SAM is also consistent with the significant increase in snow accumulation observed in the southern part of the Peninsula (Thomas et al., 2008).

Unlike the eastern Antarctic Peninsula, its western coast shows maximum warming in austral winter (when the SAM does not exhibit any significant trend), which has been attributed to reduced sea-ice concentrations in the Bellingshausen Sea. Recent studies have emphasized the role of tropical SST forcing not directly linked to ENSO to explain the prominent spring- and wintertime atmospheric warming in West Antarctica (Ding et al., 2011; Schneider et al., 2012). There is further evidence of tropical SST influence on Antarctic temperatures and precipitation on decadal to inter-decadal time scales (Monaghan and Bromwich, 2008; Okumura et al., 2012).

Modelling of Antarctic climate remains challenging, in part because of the nature of the high-elevation ice sheet in the east Antarctic and its effects on regional climate (Section 9.4.1.1). Moreover, modelling ice properties themselves, for both land ice and sea ice, is an area that is still developing despite improvements in recent years (Vancoppenolle et al., 2009; Picard et al., 2012; Section 9.1.3.2.4). Modelling the role of the

stratosphere and of ozone recovery is critical for Antarctic climate, as stratospheric change is intimately linked to trends in the SAM (Section 14.5.2).

The projected easing of the positive SAM trend in austral summer (Section 14.5.2) may act to delay future loss of Antarctic sea ice (Bitz and Polvani, 2012; Smith et al., 2012b). It is unclear what effect ENSO will have on future Antarctic climate change as the ENSO response to climate change remains uncertain (Section 14.4). Seasonally, changes in the strength of the circumpolar westerlies are also expected during the twenty-first century as a result of changes in the semi-annual oscillation caused by alterations in the mid- to high-latitude temperature gradient in the Southern Hemisphere. Bracegirdle et al. (2008) considered modelled circulation changes over the Southern Ocean and found a more pronounced strengthening of the autumn peak of the semi-annual oscillation compared with the spring peak.

Future changes in surface temperature over Antarctica are *likely* to be smaller than the global mean, and much smaller than those projected for the Arctic, because of the buffering effect of the southern oceans, and the thermal mass of the east Antarctic ice sheet (Section 12.4.6). Warming is *likely* to bring increased precipitation on average across Antarctica (Bracegirdle et al., 2008), but the spatial pattern of precipitation change remains uncertain.

In summary, consistency across CMIP5 projections suggests it is *very likely* that Antarctic temperatures will increase through the rest of the century, but more slowly than the global mean rate of increase (Table 14.1). Sea surface temperatures over the oceans around Antarctica are *likely* to rise more slowly than those over the Antarctic land mass. As temperatures rise, it is also *likely* that precipitation will increase (Table 14.1), up to 20% or more over the east Antarctic. However, given known difficulties associated with correctly modelling Antarctic climate, and uncertainties associated with future SAM and ENSO trends and the extent of Antarctic sea ice, precipitation projections have only *moderate confidence*.

FAQ 14.1: How are Future Projections in Regional Climate Related to Projections of Global Means?

The relationship between regional climate change and global mean change is complex. Regional climates vary strongly with location and so respond differently to changes in global-scale influences. The global mean change is, in effect, a convenient summary of many diverse regional climate responses.

Heat and moisture, and changes in them, are not evenly distributed across the globe for several reasons:

- external forcings vary spatially (e.g., solar radiation depends on latitude, aerosol emissions have local sources, land use changes regionally, etc.);
- surface conditions vary spatially e.g., land/sea contrast, topography, sea surface temperatures, soil moisture content;
- weather systems and ocean currents redistribute heat and moisture from one region to another.

Weather systems are associated with regionally important climate phenomena such as monsoons, tropical convergence zones, storm tracks, and important modes of climate variability (e.g., ENSO, NAO, SAM, etc.). In addition to modulating regional warming, some climate phenomena are also projected to change in the future, which can lead to further impacts on regional climates (see Table 14.3).

Projections of change in surface temperature and precipitation show large regional variations (FAQ14.1, Figure 1). Enhanced surface warming is projected to occur over the high-latitude continental regions and the Arctic ocean, while over other oceans and lower latitudes changes are closer to the global mean (FAQ14.1, Figure 1a). For example, warming near the Great Lakes area of N. America is projected to be about 50% greater than that of the global mean warming. Similar large regional variations are also seen in the projected changes of more extreme temperatures (Figure 1b). Projected changes in precipitation are even more regionally variable than changes in temperature (Figure 1c-d), caused by modulation from climate phenomena such as the monsoons and tropical convergence zones. Near-equatorial latitudes are projected to have increased mean precipitation, while regions on the poleward edges of the subtropics are projected to have reduced mean precipitation. Higher latitude regions are projected to have increased mean precipitation and in particular more extreme precipitation from extra-tropical cyclones.

Polar regions illustrate the complexity of processes involved in regional climate change. Arctic warming is projected to increase more than the global mean, mostly because the melting of ice and snow produces a regional feedback by allowing more heat from the sun to be absorbed. This gives rise to further warming, which encourages more melting of ice and snow. However, the projected warming over the Antarctic continent and surrounding oceans is less marked in part due to a stronger positive trend in the Southern Annular Mode. Westerly winds over the mid-latitude southern oceans have increased over recent decades, driven by the combined effect of loss of stratospheric ozone over Antarctica, and changes in the atmosphere's temperature structure related to increased greenhouse gas concentrations. This change in the Southern Annular Mode is well captured by climate models and has the effect of reducing atmospheric heat transport to the Antarctic continent. Nevertheless, the Antarctic Peninsula is still warming rapidly, because it extends far enough northwards to be influenced by the warm air masses of the westerly wind belt.

FAQ 14.1, Figure 1: Projected 21st century changes in annual mean and annual extremes (over land) of surface air temperature and precipitation: a) mean surface temperature per °C of global mean change, b) 90th percentile of daily maximum temperature per °C of global average maximum temperature, c) mean precipitation (in % per °C of global mean temperature change), and d) fraction of days with precipitation exceeding the 95th percentile. Sources: Panels a) and c) projected changes in means between 1986–2005 and 2081–2100 from CMIP5 simulations under RCP4.5 scenario (see Chapter 12, Figure 12.40); Panels b) and d) projected changes in extremes over land between 1980–1999 and 2081–2100 (from Orłowsky and Seneviratne, 2012).

[END FAQ 14.1 HERE]

[START FAQ 14.2 HERE]

FAQ 14.2: How is Climate Change Affecting Monsoons?

Monsoons are the most important mode of seasonal climate variation in the tropics, and are responsible for a large fraction of the annual rainfall in many regions. Their strength and timing is related to atmospheric moisture content, land-sea temperature contrast, land cover and use, atmospheric aerosol loadings, and other factors. Overall, monsoonal rainfall is projected to become more intense in future, and to affect larger areas, because atmospheric moisture content increases with temperature. However, the localised effects of climate change on regional monsoon strength and variability are complex and more uncertain.

Monsoon rains fall over all tropical continents: Asia, Australia, the Americas, and Africa. The monsoon circulation is driven by the difference in temperature between land and sea, which varies seasonally with the distribution of solar heating. The duration and amount of rainfall depends on the moisture content of the air, and on the configuration and strength of the atmospheric circulation. The regional distribution of land and ocean also plays a role, as does topography. For example, the Tibetan Plateau—through variations in its snow cover and surface heating—modulates the strength of the complex Asian monsoon systems. Where moist on-shore winds rise over mountains, as they do in southwest India, monsoon rainfall is intensified. On the lee side of such mountains, it lessens.

Since the late 1970s, the East Asian summer monsoon has been weakening and not extending as far north as it used to in earlier times, as a result of changes in the atmospheric circulation. That in turn has led to increasing drought in northern China, but floods in the Yangtze river valley farther south. In contrast, the Indo-Australian and Western Pacific monsoon systems show no coherent trends since the mid-20th century, but are strongly modulated by the El Niño-Southern Oscillation (ENSO). Similarly, changes observed in the South American monsoon system over the last few decades are strongly related to ENSO variability, rather than to longer-term human influences on the climate. Evidence of trends in the North American monsoon system is limited, but a tendency towards heavier rainfalls on the northern side of the main monsoon region has been observed. No systematic long-term trends have been observed in the behaviour of the Indian or the African monsoons.

The land surface warms more rapidly than the ocean surface, so that surface temperature contrast is increasing in most regions. The tropical atmospheric overturning circulation, however, slows down on average as the climate warms due to energy balance constraints in the tropical atmosphere. These changes in

the atmospheric circulation lead to regional changes in monsoon intensity, area, and timing. There are a number of other effects as to how climate change can influence monsoons. Surface heating varies with the intensity of solar radiation absorption, which is itself affected by any land use changes that alter the reflectivity (albedo) of the land surface. Also, changing atmospheric aerosol loadings, such as air pollution, affect how much solar radiation reaches the ground, which can change the monsoon circulation by altering summer solar heating of the land surface. Absorption of solar radiation by aerosols, on the other hand, warms the atmosphere, changing the atmospheric heating distribution.

The strongest effect of climate change upon the monsoons is the increase in atmospheric moisture associated with warming of the atmosphere, resulting in an increase in total monsoon rainfall even if the strength of the monsoon circulation weakens or does not change .

[INSERT FAQ 14.2, FIGURE 1 HERE]

FAQ 14.2, Figure 1: Schematic diagram illustrating the main ways that human activity influences monsoon rainfall. As the climate warms, increasing water vapour transport from the ocean into land increases because warmer air contains more water vapour. This also increases the potential for heavy rainfalls. Warming-related changes in large-scale circulation influence the strength and extent of the overall monsoon circulation. Land use change and atmospheric aerosol loading can also affect the amount of solar radiation that is absorbed in the atmosphere and land, potentially moderating the land-sea temperature difference.

Climate model projections through the 21st century show an increase in total monsoon rainfall, largely due to increasing atmospheric moisture content. The total surface area affected by the monsoons is projected to increase, along with the general poleward expansion of the tropical regions. Climate models project from 5% to ~15% increase of global monsoon rainfall depending on scenarios. Though total tropical monsoon rainfall increases, some areas will receive less monsoon rainfall, due to weakening tropical wind circulations. Monsoon onset dates are *likely* to be early or not to change much and the monsoon retreat dates are *very likely* to delay, resulting in lengthening of the monsoon season.

Future regional trends in monsoon intensity and timing remain uncertain in many parts of the world. Year-to-year variations in the monsoons in many tropical regions are affected by ENSO. How ENSO will change in future—and how its effects on monsoon will change—also remain uncertain. However, the projected overall increase in monsoon rainfall indicates a corresponding increase in the risk of extreme rain events in most regions.

Tables**Box 14.1, Table 1:** Regional climate impacts of fundamental modes of variability

Mode	Regional Climate Impacts
ENSO	Global impact on interannual variability in global mean temperature. Influences severe weather and tropical cyclone activity worldwide. The diverse El Niño flavours present different teleconnection patterns that induce large impacts in numerous regions from polar to tropical latitudes (Section 14.4).
PDO	Influences surface air temperature and precipitation over the entire North American continent and extratropical North Pacific. Modulates ENSO rainfall teleconnections e.g., Australian climate (Section 14.7.3)
IPO	Modulates decadal variability in Australian rainfall, and ENSO teleconnections to rainfall, surface temperature, river flow and flood risk over Australia, New Zealand and the SPCZ (Section 14.7.3).
NAO	Influences the N. Atlantic jet stream, storm tracks and blocking and thereby affects winter climate in over the N. Atlantic and surrounding landmasses. The summer NAO (SNAO) influences Western Europe and Mediterranean basin climates in the season (Section 14.5.1).
NAM	Modulates the intensity of mid-latitude storms throughout the Northern Hemisphere and thereby influences North America and Eurasia climates as well as sea ice distribution across the Arctic sea (Section 14.5.1).
NPO	Influences winter air temperature and precipitation over much of western North America as well as Arctic sea ice in the Pacific sector (Section 14.5.1).
SAM	Influences temperature over Antarctica, Australia, Argentina, Tasmania and the south of New Zealand and precipitation over southern South America, New Zealand, Tasmania, Australia and South Africa (Section 14.5.2).
PNA	Influences the jet stream and storm tracks over the Pacific and North American sectors, exerting notable influences on the temperature and precipitation in these regions on intraseasonal and interannual time scales (Section 14.7.2).
PSA	Influences atmospheric circulation over South America and thereby has impacts on precipitation over the continent (Section 14.7.1).
AMO	Influences air temperatures and rainfall over much of the Northern Hemisphere, in particular, North America and Europe. It is associated with multidecadal variations in Indian, East-Asian and West-African monsoons, the North-African Sahel and North-east Brazil rainfall, the frequency of North American droughts and Atlantic hurricanes (Section 14.7.6).
AMM	Influences seasonal hurricane activity in the tropical Atlantic on both decadal and interannual time scales. Its variability is influenced by other modes, particularly ENSO and NAO (Section 14.3.4).
AN	Affects the West African Monsoon, the oceanic forcing of Sahel rainfall on both decadal and interannual time-scales and the spatial extension of drought in South Africa (Section 14.3.4).
IOB	Associated with the intensity of Northwest Pacific monsoon, the tropical cyclone activity over the Northwest Pacific and anomalous rainfall over East Asia (Section 14.3.3).
IOD	Associated with droughts in Indonesia, reduced rainfall over Australia, intensified Indian summer monsoon, floods in East Africa, hot summers over Japan, and anomalous climate in the extratropical Southern Hemisphere (Section 14.3.3).
TBO	Modulates the strength of the Indian and West Pacific monsoons. Affects droughts and floods over large areas of south Asia and Australia (Section 14.7.4).
MJO	Modulates the intensity of monsoon systems around the globe and tropical cyclone activity in the Indian, Pacific and Atlantic Oceans. Associated with enhanced rainfall in Western North America, Northeast Brazil, Southeast Africa and Indonesia during boreal winter and Central America/Mexico and Southeast Asia during boreal summer (Section 14.3.2).
QBO	Strongly affects the strength of the northern stratospheric polar vortex as well as the extratropical troposphere circulation, occurring preferentially in boreal winter (Section 14.7.5).
BLC	Associated with cold air outbreaks, heat-waves, floods and droughts in middle and high latitudes of both hemispheres (Box 14.2)

1 Notes:

2 AMM: Atlantic Meridional Mode

- 1 AMO: Atlantic Multi-decadal Oscillation
- 2 AN: Atlantic Niño pattern
- 3 BLC: Blocking events
- 4 ENSO: El Niño-Southern Oscillation
- 5 IOB: Indian Ocean Basin pattern
- 6 IOD: Indian Ocean Dipole pattern
- 7 IPO: Interdecadal Pacific Oscillation
- 8 MJO: Madden-Julian Oscillation
- 9 NAM: Northern Annular Mode
- 10 NAO: North Atlantic Oscillation
- 11 NPO: North Pacific Oscillation
- 12 PDO: Pacific Decadal Oscillation
- 13 PNA: Pacific North America pattern
- 14 PSA: Pacific South America pattern
- 15 QBO: Quasi-Biennial Oscillation
- 16 SAM: Southern Annular Mode
- 17 TBO: Tropospheric Biennial Oscillation
- 18
- 19

Table 14.1: Temperature and precipitation projections by the CMIP5 global models. The figures shown are averages over SREX regions (Seneviratne et al., 2012) of the projections by a set of 42 global models for the RCP4.5 scenario. Added to the SREX regions are a six other regions including the two Polar Regions, the Caribbean, Indian Ocean and Pacific Island States (see Annex I for further details). The 26 SREX regions are: Alaska/NW Canada (ALA), Eastern Canada/Greenland/Iceland (CGI), Western North America (WNA), Central North America (CNA), Eastern North America (ENA), Central America/Mexico (CAM), Amazon (AMZ), NE Brazil (NEB), West Coast South America (WSA), South-Eastern South America (SSA), Northern Europe (NEU), Central Europe (CEU), Southern Europe/the Mediterranean (MED), Sahara (SAH), Western Africa (WAF), Eastern Africa (EAF), Southern Africa (SAF), Northern Asia (NAS), Western Asia (WAS), Central Asia (CAS), Tibetan Plateau (TIB), Eastern Asia (EAS), Southern Asia (SAS), South-Eastern Asia (SEA), Northern Australia (NAS) and Southern Australia/New Zealand (SAU). The area-mean temperature and precipitation responses are first averaged for each model over the 1986–2005 period from the historical simulations and the 2016–2035, 2046–2065 and 2081–2100 periods of the RCP4.5 experiments. Based on the difference between these two periods, the table shows the 25th, 50th and 75th percentiles, and the lowest and highest response among the 42 models, for temperature in degrees Celsius and precipitation as a percent change. Regions in which the middle half (25–75%) of this distribution is all of the same sign in the precipitation response are coloured light brown for decreasing precipitation and light green for increasing precipitation. Information is provided for land areas contained in the boxes unless otherwise indicated. The temperature responses are averaged over the boreal winter and summer seasons; December, January and February (DJF) and June, July and August (JJA) respectively. The precipitation responses are averaged over half year periods, boreal winter; October, November, December, January, February and March (ONDJFM) and summer; April, May, June, July, August and September (AMJJAS).

1 **Table 14.2:** Assessed confidence (*high, medium, low*) in climate projections of regional temperature and precipitation
 2 change from the multi-model ensemble of CMIP5 models for the RCP4.5 scenario. Column 1 refers to the SREX
 3 regions (cf. Seneviratne et al., 2012, page 12. The region's coordinates can be found from their online Appendix 3.A)
 4 and six additional regions including the two polar regions, the Caribbean, Indian Ocean and Pacific Island States (see
 5 Annex I for further details). Columns 2 to 4 show confidence in models' ability to simulate present-day mean
 6 temperature and precipitation as well as the most important phenomena for that region based on Figures 9.39, 9.40, and
 7 9.45. In column 4, the individual phenomena are listed, with associated confidence levels shown below, in the same
 8 order as the phenomena. Note that only phenomena assessed in Figure 9.45 are listed. Column 5 is an interpretation of
 9 the relevance of the main climate phenomena for future regional climate change, based on Table 14.3. Note that the
 10 SREX regions are smaller than the regions listed in Table 14.3. Columns 6 and 7 express confidence in projected
 11 temperature and precipitation changes, based solely on model agreement for 2080–2099 vs. 1985–2005, as listed in
 12 Table 14.1 and in the maps shown in Annex I. The confidence is assessed for two periods for temperature (DJF and
 13 JJA) and two-half year periods for precipitation (October–March and April–September). When the projections are
 14 consistent with no significant change, it is marked by an asterisk (*) and the assigned confidence is *medium*. Further
 15 details on how confidence levels have been assigned are provided in the Supplementary Material (Section 14.SM.6.1).

1 **Table 14.3:** Summary of the relevance of projected changes in major phenomena for mean change in future regional climate. The relevance is classified into high (red), medium
 2 (yellow), low (cyan), and “no obvious relevance” (grey), based on confidence that there will be a change in the phenomena (“HP” for high, “MP” for medium, “LP” for low), and
 3 confidence in the impact of the phenomena on each region (“HI” for high, “MI” for medium, “LI” for low). More information on how these assessments have been constructed is
 4 given in the Supplementary Material (Section 14.SM.6.1).
 5

Phenomena		Monsoon Systems	Tropical Phenomena ^a	ENSO	Annular and Dipolar Modes	Tropical Cyclones	Extra-Tropical Cyclones ^b
Regions	Section	MP – see Section 14.2	HP/MP/LP/LP – see Section 14.3	LP – see Section 14.4	HP – see Section 14.5	MP – See Section 14.6.1	MP/HP – See Section 14.6.2
Arctic	14.8.2				HP/HI The small projected increase in NAO is likely to contribute to wintertime changes in temperature and precipitation.		MP/HI Projected increase in precipitation in extra-tropical cyclones is likely to enhance mean precipitation.
North America	14.8.3	MP/HI It is likely the number of consecutive dry days will increase, and overall water availability will be reduced.	HP/LI Projected ITCZ shifts unrelated to ENSO changes will impact temperature and precipitation, especially in winter.	LP/HI Likely changes in N. American precipitation if ENSO changes.	HP/MI The small projected increase in the NAO index is likely to contribute to wintertime temperature and precipitation changes in NE America.	MP/HI Projected increases in extreme precipitation near the centres of tropical cyclones making landfall along the western coast of US and Mexico, the Gulf Mexico, and the eastern coast of US and Canada.	MP/HI Projected increases in precipitation in extra-tropical cyclones will lead to large increases in wintertime precipitation over the northern third of the continent.
Central America and Caribbean	14.8.4	MP/HI Projected reduction in mean precipitation .	HP/HI Reduced mean precipitation in southern Central America if there is a southward displacement of the East Pacific ITCZ.	LP/HI Reduced mean precipitation if El Niño events become more frequent and/or intense.		MP/HI More extreme precipitation near the centres of tropical cyclones making landfall along the eastern and western coasts.	
South America	14.8.5	MP/HI Projected increase in extreme precipitation and in the extension of	HP/HI Projected increase in the mean precipitation in the southeast due to the	LP/HI Reduced mean precipitation in eastern Amazonia and increased	HP/HI Poleward shift of storm tracks due to projected positive trend in SAMS		HP/HI Southward displacement of cyclogenesis activity increases the

		monsoon area.	projected southward displacement of the SACZ.	precipitation in the La Plata basin.	phase leads to less precipitation in central Chile and increased precipitation in the southern tip of S. America.		precipitation in the extreme south.
Europe and Mediterranean	14.8.6				<i>HP/HI</i> Projected increase in the NAO will lead to enhanced winter warming and precipitation over NW Europe.		<i>MP/HI</i> Enhanced extremes of storm-related precipitation and decreased frequency of storm-related precipitation over the E. Mediterranean.
Africa	14.8.7	<i>MP/HI</i> Projected enhancement of summer precipitation in West Africa.	<i>HP/LI</i> Enhanced precipitation in parts of East Africa due to projected shifts in ITCZ. Modified precipitation in West or East Africa according to variations in Atlantic or Indian Ocean SSTs.	<i>LP/HI</i> Increased precipitation in E. Africa and decreased precipitation and enhanced warming in S. Africa if El Niño events become more frequent and/or intense.	<i>HP/HI</i> Enhanced winter warming over Southern Africa due to projected increase in SAM.	<i>MP/HI</i> Projected increase in extreme precipitation near the centres of tropical cyclones making landfall along the eastern coast (including Madagascar).	<i>HP/HI</i> Enhanced extremes of storm-related precipitation and decreased frequency of storm-related precipitation over southwestern Africa.
Central and North Asia	14.8.8	<i>MP/MI</i> Projected enhancement in summer mean precipitation.			<i>HP/LI</i> Projected enhancement in winter warming over N. Asia.		
East Asia	14.8.9	<i>MP/MI</i> Enhanced summer precipitation due to intensification of East Asian summer monsoon circulation.		<i>LP/HI</i> Enhanced warming if El Niño events become more frequent and/or intense.		<i>MP/HI</i> Projected increase in extreme precipitation near the centres of tropical cyclones making landfall in Japan, along coasts of east China Sea and Sea of Japan.	<i>MP/MI</i> Projected reduction in midwinter precipitation.
West Asia	14.8.10		<i>HP/LI</i> Enhanced precipitation in southern parts of			<i>MP/HI</i> Projected increase in extreme precipitation	<i>MP/LI</i> Projected decrease in mean precipitation due

			West Asia due to projected northward shift in ITCZ.			near the centres of tropical cyclones making landfall on the Arabian Peninsula.	to northward shift of storm tracks.
South Asia	14.8.11	<i>MP/MI</i> Enhanced summer precipitation associated with Indian Monsoon.	<i>LP/MI</i> Strengthened break monsoon precipitation anomalies associated with MJO.	<i>LP/MI</i> Enhanced warming and increased summer season rainfall variability due to ENSO.		<i>MP/MI</i> Projected increase in extreme precipitation near the centres of tropical cyclones making landfall along coasts of Bay of Bengal and Arabian Sea.	
Southeast Asia	14.8.12	<i>LP/MI</i> Decrease in precipitation over Maritime continent.	<i>HP/MI</i> Projected changes in IOD-like warming pattern will reduce mean precipitation in Indonesia during Jul-Oct.	<i>LP/MI</i> Reduction in mean precipitation and enhanced warming if El Niño events become more frequent and/or intense.		<i>MP/MI</i> Projected increase in extreme precipitation near the centres of tropical cyclones making landfall along coasts of South China Sea, Gulf of Thailand, and Andaman Sea.	
Australia and New Zealand	14.8.13	<i>MP/LI</i> Mean monsoon precipitation may increase over northern Australia.	<i>HP/LI</i> More frequent zonal SPCZ episodes may reduce precipitation in NE Australia.	<i>LP/MI</i> Reduced precipitation in N. and E. Aust. and NZ if El Niño events become more frequent and/or intense.	<i>HP/MI</i> Increased warming and reduced precipitation in NZ and S. Aust. due to projected positive trend in SAM.	<i>MP/MI</i> More extreme precipitation near the centres of tropical cyclones making landfall along the eastern, western, and northern coasts of Australia.	<i>HP/MI</i> Projected increase in extremes of storm-related precipitation.
Pacific Islands Region	14.8.14		<i>HP/LI</i> Increased mean precipitation along equator with ITCZ intensification. More frequent zonal SPCZ episodes leading to reduced precipitation in	<i>HP/LI</i> Increased mean precipitation in central/east Pacific if El Niño events become more frequent and/or intense.		<i>HP/MI</i> More extreme precipitation near the centres of tropical cyclones passing over or near Pacific islands.	

			southwest and increases in east.				
Antarctica	<i>14.8.15</i>			<i>LP/MI</i> Increased warming over Antarctic Peninsula and reduced across central Pacific if El Niño events become more frequent and/or intense.	<i>HP/HI</i> Increased warming over Antarctic Peninsula and west Antarctic related to positive trend projected in SAM.		<i>HP/MI</i> Increased precipitation in coastal areas due to projected poleward shift of storm track.

Figures

Box 14.1, Figure 1: Global distribution of average annual rainfall (in cm/year) from 1979–2010 GPCP data base, monsoon precipitation domain (white contours) as defined in Section 14.2.1, and winter storm-tracks in both hemispheres (black arrows). In left (right) column seasonal correlation maps of NAO, SOI (the atmospheric component of ENSO) and SAM mode indexes vs. monthly temperature (precipitation) anomalies in boreal winter (DJF), austral winter (JJA) and austral spring (SON). Black contours indicate a 99% significance level. The mode indexes were taken from NOAA (<http://www.esrl.noaa.gov/psd/data/climateindices/list/>), global temperatures from NASA GISTEMP (<http://data.giss.nasa.gov/gistemp/>) and global precipitations from GPCP (<http://www.esrl.noaa.gov/psd/data/gridded/data.gpcp.html>).

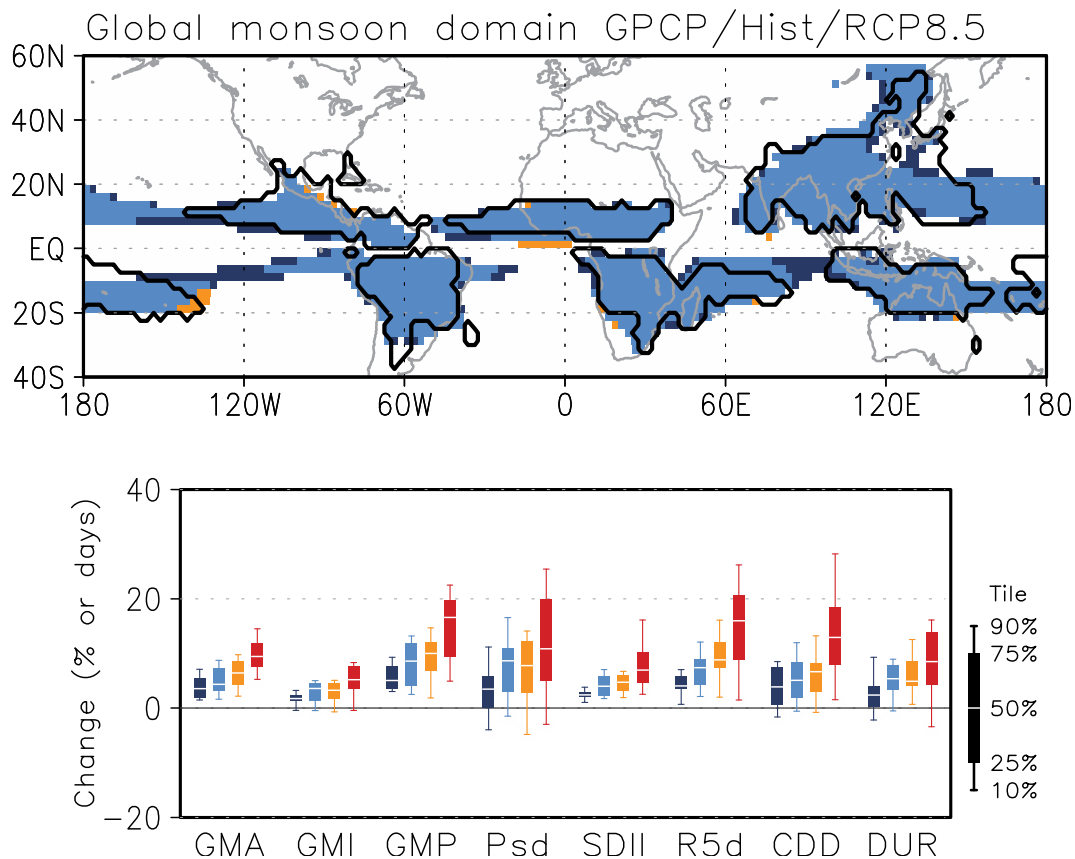

Figure 14.1: (upper) Observed (thick contour) and simulated (shading) global monsoon domain, based on the definition of Wang et al. (2011). The observations are based on GPCP v2.2 data (Huffman et al., 2009), and the simulations are based on 26 CMIP5 multi-model mean precipitation with a common 2.5 by 2.5 degree grid in the present-day (1986–2005) and the future (2080–2099; RCP8.5 scenario). Orange (dark blue) shading shows monsoon domain only in the present-day (future). Light blue shading shows monsoon domain in both periods. (lower) Projected changes for the future (2080–2099) relative to the present-day (1986–2005) in the global monsoon area (GMA) and global monsoon intensity (GMI), global monsoon total precipitation (GMP), standard deviation of inter-annual variability in seasonal average precipitation (Psd), simple daily precipitation intensity index (SDII), seasonal maximum 5-day precipitation total (R5d), seasonal maximum consecutive dry days (CDD), and monsoon season duration (DUR), under the RCP2.6 (dark blue; 18 models), RCP4.5 (light blue; 24 models), RCP6.0 (orange; 14 models), and RCP8.5 scenarios (red; 26 models). Units are % except for DUR (days). Box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles. All of the indices are calculated for the summer season (May to September in the Northern Hemisphere; November to March in the Southern Hemisphere). The indices of Psd, SDII, R5d, and CDD calculated for each model's original grid, and then averaged over the monsoon domains determined by each model at the present-day. The indices of DUR are calculated for 7 regional monsoon domains based on the criteria proposed by Wang and LinHo (2002) using regionally averaged climatological cycles of precipitation, and then their changes are averaged with weighting based on their area at the present-day.

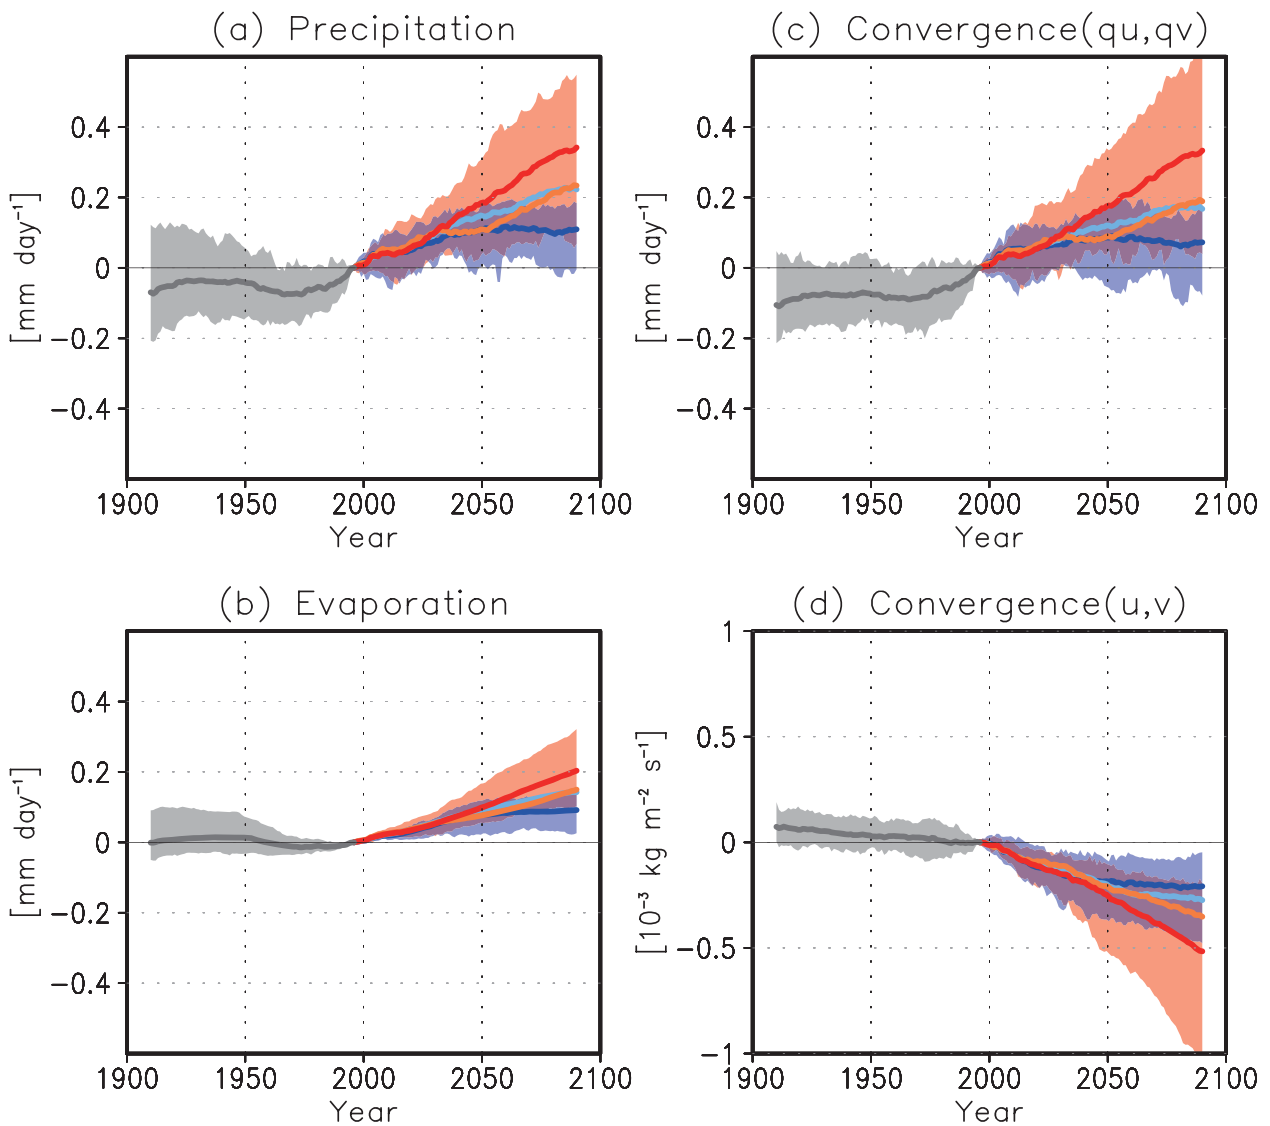

Figure 14.2: Time series of simulated anomalies over the global land monsoon domain for (a) precipitation (mm day^{-1}), (b) evaporation (mm day^{-1}), (c) water vapour flux convergence in the lower (below 500 hPa) troposphere (mm day^{-1}), and (d) wind convergence in the lower troposphere ($10^{-3} \text{ kg m}^{-2} \text{ s}^{-1}$), relative to the present-day (1986–2005), based on CMIP5 multi-model monthly outputs. Historical (grey; 29 models), RCP2.6 (dark blue; 20 models), RCP4.5 (light blue; 24 models), RCP6.0 (orange; 16 models), and RCP8.5 (red; 24 models) simulations are shown in the 10th and 90th percentile (shading), and in all model averages (thick lines).

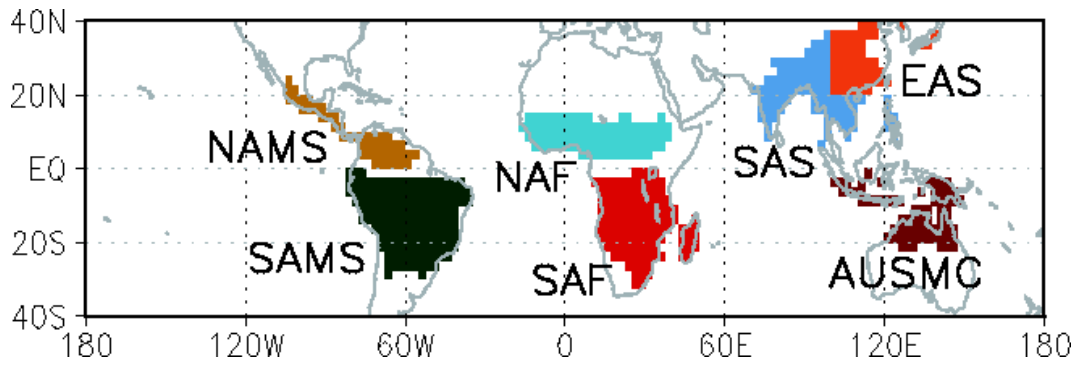

Figure 14.3: Regional land monsoon domain based on 26 CMIP5 multi-model mean precipitation with a common 2.5 by 2.5 degree grid in the present-day (1986–2005). For regional divisions, the equator separates the northern monsoon domains (NAMS, NAF, SAS, and EAS) from the southern monsoon domains (SAMS, SAF, and AUSMC), 60°E separates NAF from SAS, and 20°N and 100°E separates SAS from EAS. All the regional domains are within 40°S to 40°N.

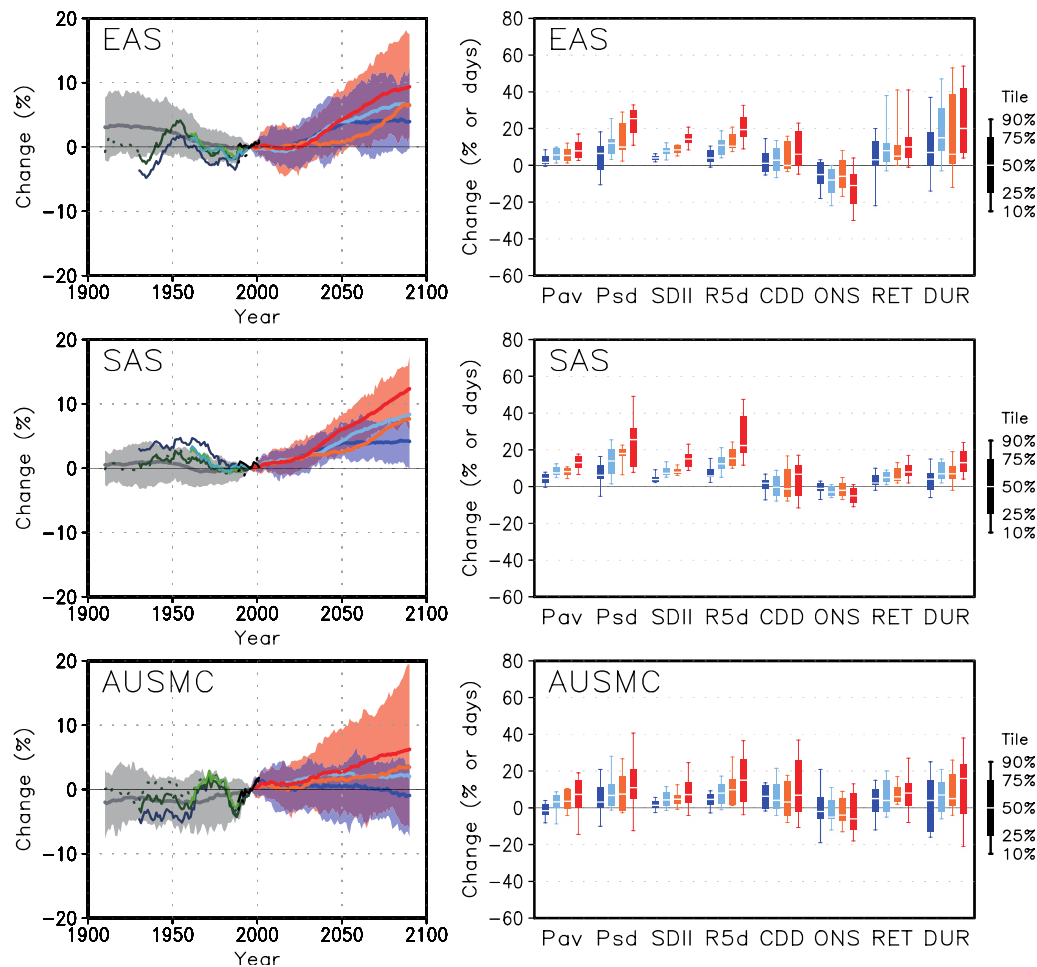

Figure 14.4: Changes in precipitation indices over the regional land monsoon domains of (upper) EAS, (middle) SAS, and (lower) AUSMC based on CMIP5 multi-models. (left) Time series of observed and model-simulated summer precipitation anomalies (%) relative to the present-day average. All the time series are smoothed with a 20-year running mean. For the time series of simulations, all model averages are shown by thick lines for the historical (grey; 40 models), RCP2.6 (dark blue; 24 models), RCP4.5 (light blue; 34 models), RCP6.0 (orange; 20 models), and RCP8.5 scenarios (red; 32 models). Their intervals between 10th and 90th percentiles are shown by shading for RCP2.6 and RCP8.5 scenarios. For the time series of observations, CRU TS3.2 (update from Mitchell and Jones, 2005; dark blue), GPCP v6 (Becker et al., 2013; deep green), (Beck et al., 2005; light green), APHRODITE v1101 (Yatagai et al., 2012; only for EAS and SAS regions; light blue), GPCP v2.2 (updated from Huffman et al., 2009; black), and CMAP v1201 (updated from Xie and Arkin, 1997; black with dots) are shown. GPCP v6 with dot line, GPCP VASCLimO, GPCP v2.2 and CMAP v1201 are calculated using all grids for the period of 1901–2010, 1951–2000, 1979–2010, 1979–2010, respectively. CRU TS3.2, GPCP v6 with solid line, and APHRODITE v1101, are calculated using only grid boxes (2.5 degree in longitude/latitude) where at least one observation site exists for more than 80% of the period of 1921–2005, 1921–2005, and 1951–2005, respectively. (right) Projected changes for the future (2080–2099) relative to the present-day average in averaged precipitation (Pav), standard deviation of inter-annual variability in seasonal average precipitation (Psd), simple precipitation daily intensity index (SDII), seasonal maximum 5-day precipitation total (R5d), seasonal maximum consecutive dry days (CDD), monsoon onset date (ONS), retreat date (RET), and duration (DUR), under the RCP2.6 (18 models), RCP4.5 (24 models), RCP6.0 (14 models), and RCP8.5 scenarios (26 models). Units are % in Pav, Psd, SDII, R5d, and CDD; days in ONS, RET, and DUR. Box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles. All of the indices are calculated for the summer season (May to September in the Northern Hemisphere; November to March in the Southern Hemisphere). The indices of Pav, Psd, SDII, R5d, and CDD calculated for each model's original grid, and then averaged over the monsoon domains determined by each model at the present-day. The indices of ONS, RET, and DUR are calculated for 7 regional monsoon domains based on the criteria proposed by Wang and LinHo (2002) using regionally averaged climatological cycles of precipitation.

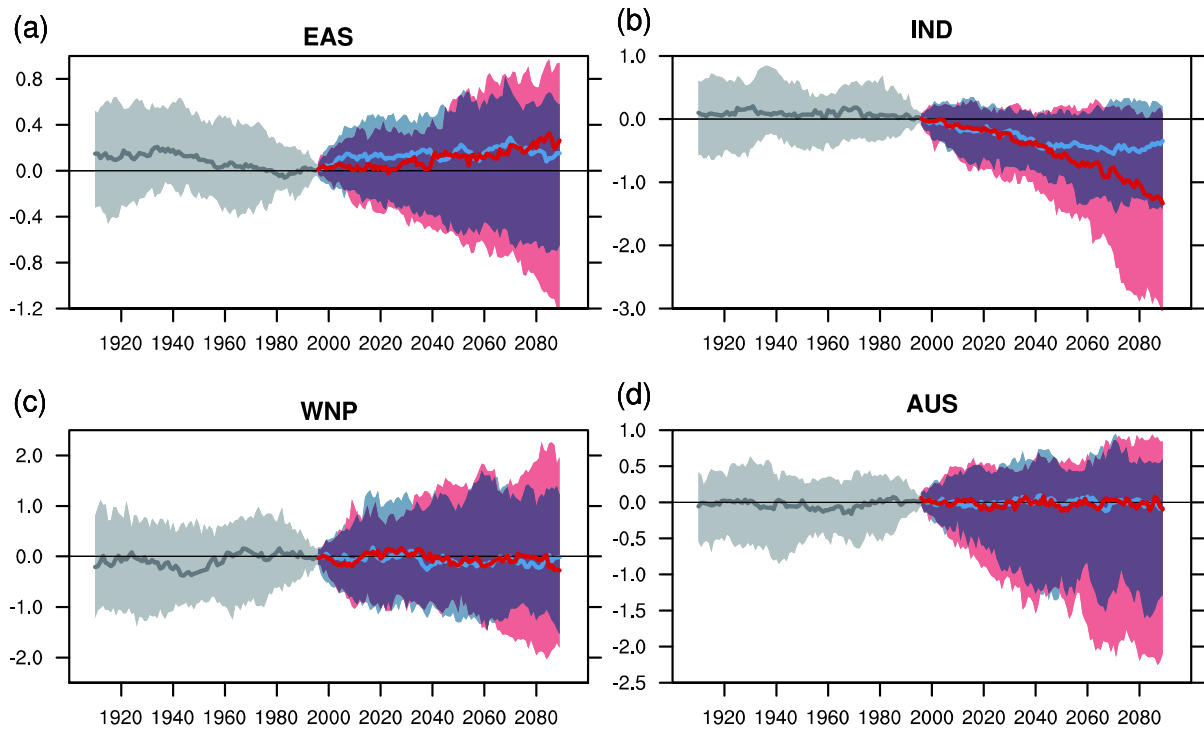

Figure 14.5: Time series of summer monsoon indices (21-year running mean) relative to the base period average (1986–2005). Historical (gray), RCP4.5 (light blue) and RCP8.5 (red) simulations by 39 CMIP5 model ensembles are shown in 10th and 90th (shading), and 50th (thick line) percentile. (a) East Asian summer monsoon (Defined as June–July–August sea level pressure difference between 160°E and 110°E from 10°N to 50°N), (b) Indian summer monsoon (defined as meridional differences of the June–July–August 850 hPa zonal winds averaged over 5°N–15°N, 40°E–80°E and 20°N–30°N, 60°E–90°E), (c) western North Pacific summer monsoon (defined as meridional differences of the June–July–August 850 hPa zonal winds averaged over 5°N–15°N, 100°E–130°E and 20°N–30°N, 110°E–140°E), (d) Australian summer monsoon (defined as December–January–February 850 hPa zonal wind anomalies averaged over 10°S–0°, 120°E–150°E). (See Wang et al. (2004) and Zhou et al. (2009c) for indices definitions).

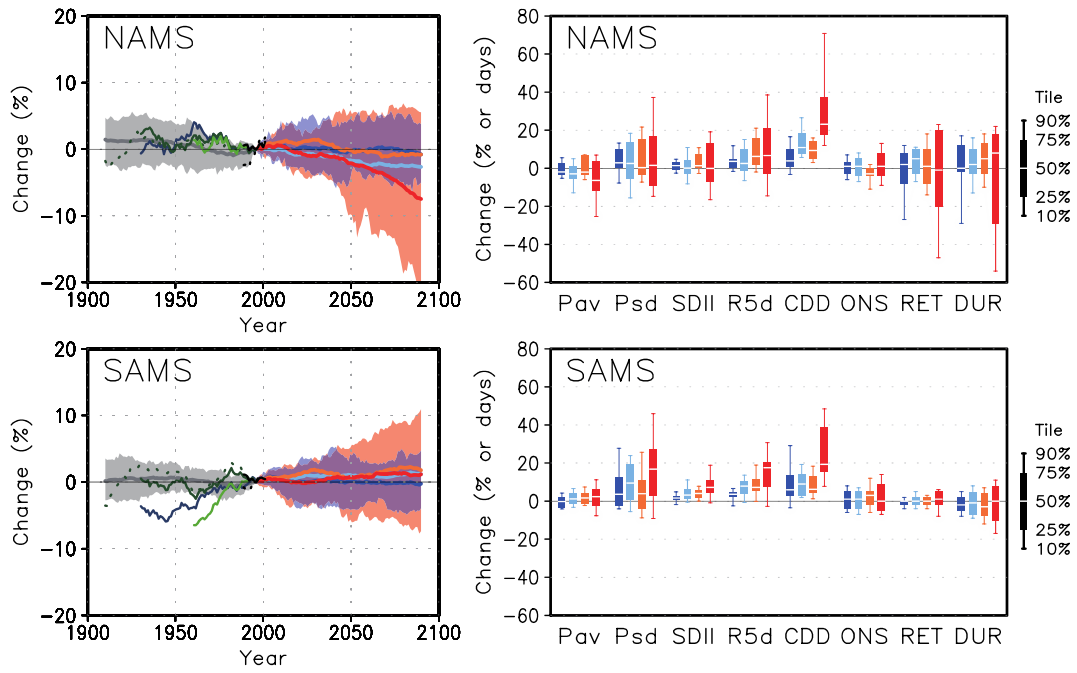

Figure 14.6: As in Figure 14.4, except for (upper) NAMS and (lower) SAMS.

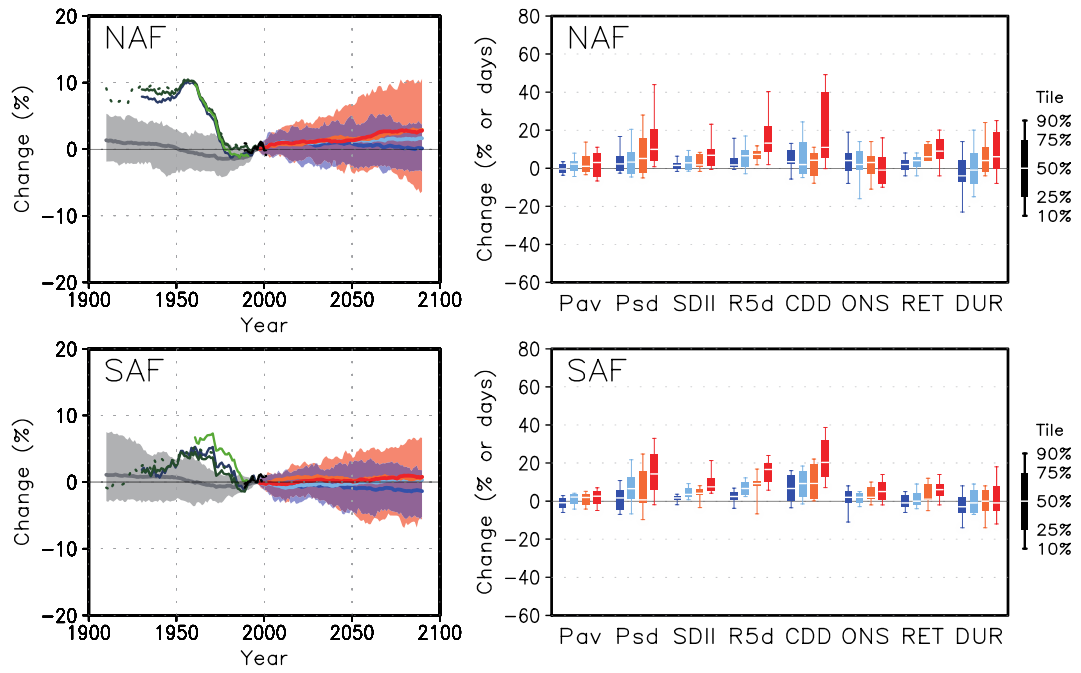

Figure 14.7: As in Figure 14.4, except for (upper) NAF and (lower) SAF.

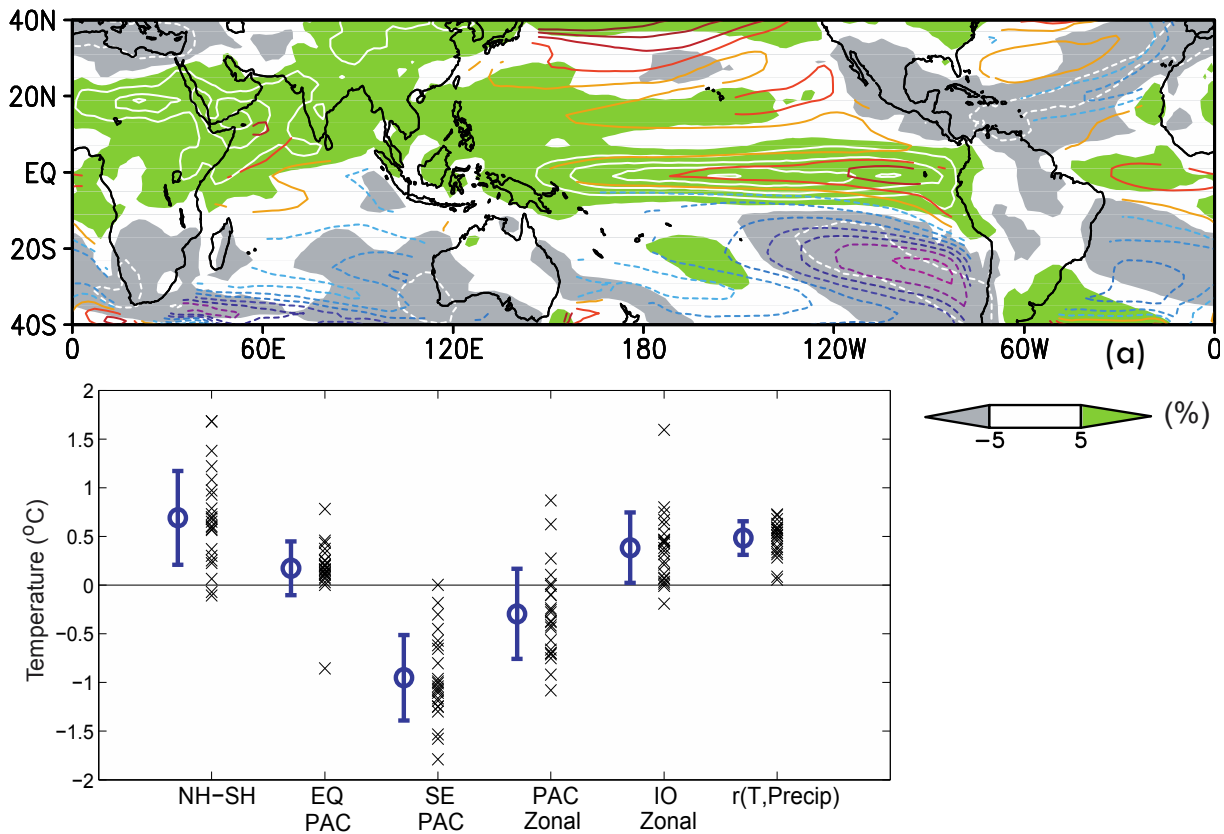

Figure 14.8: Upper panel: Annual-mean precipitation percentage change ($\square P/P$ in green/gray shade and white contours at 20% intervals), and relative SST change (colour contours at intervals of 0.2°C; negative shaded) to the tropical (20°S–20°N) mean warming in RCP8.5 projections, shown as 23 CMIP5 model ensemble mean. Lower panel: SST warming pattern indices in the 23-model RCP8.5 ensemble, shown as the 2081–2100 minus 1986–2005 difference. From left: Northern (EQ–60°N) minus Southern (60°S–EQ) Hemisphere; equatorial (120°E–60°W, 5°S–5°N) and Southeast (130°W–70°W, 30°S–15°S) Pacific relative to the tropical mean warming; zonal SST gradient in the equatorial Pacific (120°E–180°E minus 150°W–90°W, 5°S–5°N) and Indian (50°E–70°E, 10°S–10°N minus 90°E–110°S, 10°S–EQ) Oceans. Rightmost: spatial correlation (r) between relative SST change and precipitation percentage change ($\square P/P$) in the tropics (20°S–20°N) in each model. (The spatial correlation for the multi-model ensemble mean fields in the upper panel is 0.63). The circle and error bar indicate the ensemble mean and ± 1 standard deviation, respectively. The upper panel is a CMIP5 update of Ma and Xie (2013), and see text for indices in the lower panel.

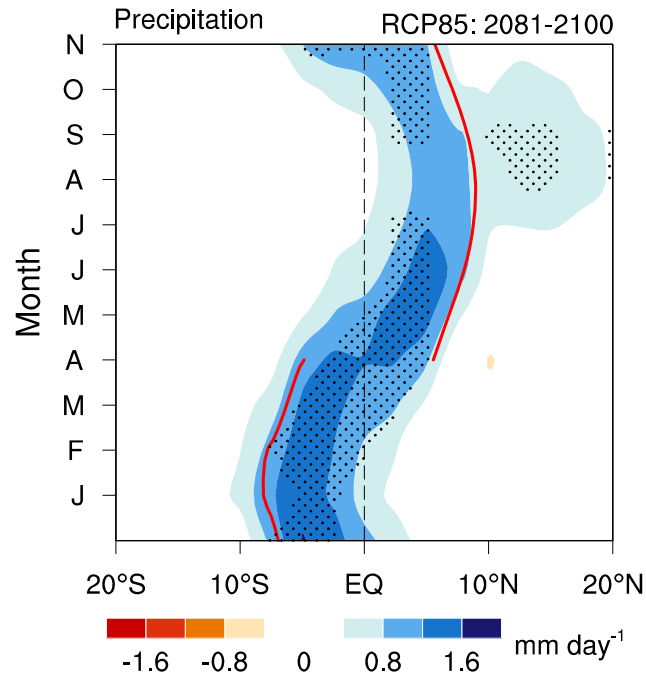

Figure 14.9: Seasonal cycle of zonal-mean tropical precipitation change (2081–2100 in RCP8.5 minus 1986–2005) in CMIP5 multimodel ensemble (MME) mean. Eighteen CMIP5 models were used. Stippling indicates that more than 90% models agree on the sign of MME change. The red curve represents the meridional maximum of the climatological rainfall. Adapted from Huang et al. (2013).

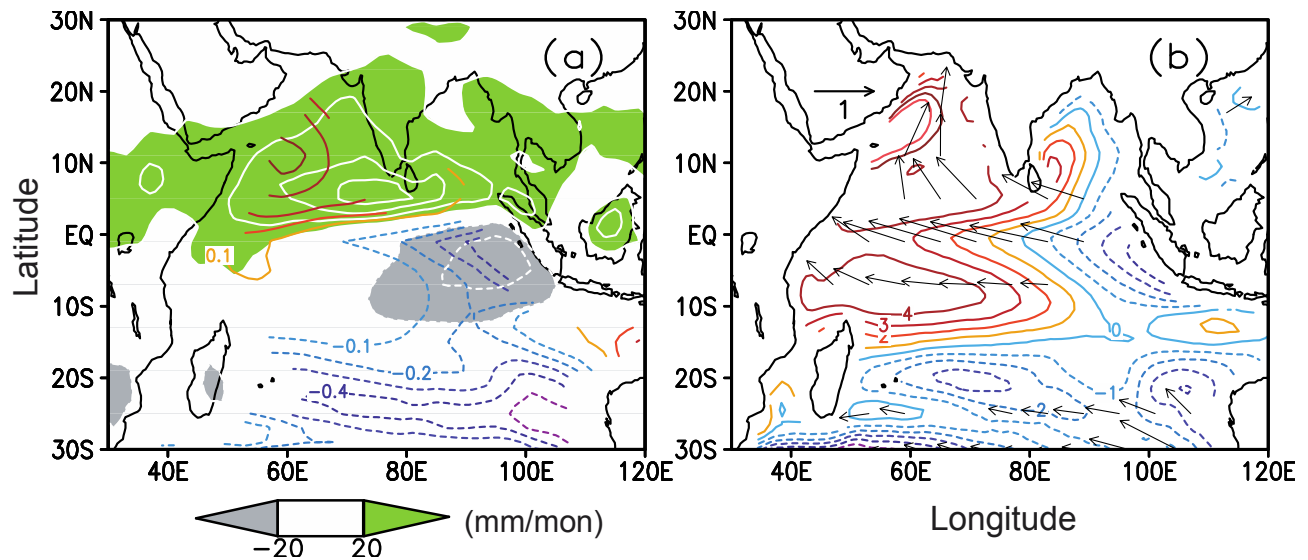

Figure 14.10: September to November changes in a 22-model CMIP5 ensemble (2081–2100 in RCP8.5 minus 1986–2005 in historical run). (a) SST (colour contours at 0.1°C intervals) relative to the tropical mean (20°S–20°N), and precipitation (shading and white contours at 20 mm per month intervals). (b) Surface wind velocity (m s^{-1}), and sea surface height deviation from the global mean (contours, cm). Over the equatorial Indian Ocean, ocean-atmospheric changes form Bjerknes feedback, with the reduced SST warming and suppressed convection in the east. Updated with CMIP5 from Xie et al. (2010b).

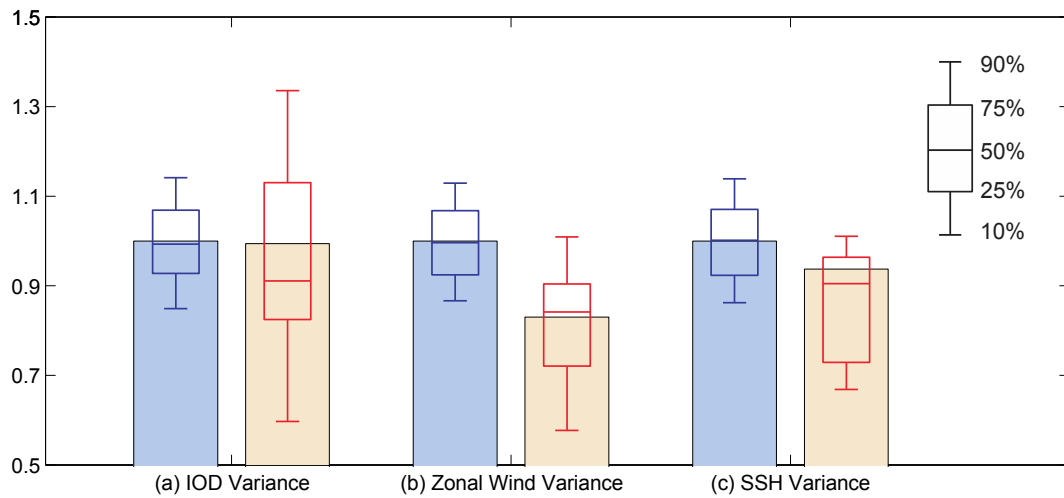

Figure 14.11: CMIP5 multi-model ensemble mean standard deviations of interannual variability for September to November in pre-industrial (PiControl; blue bars) and RCP8.5 (red) runs: (a) the Indian Ocean dipole index defined as the western (50°E–70°E, 10°S–10°N) minus eastern (90°E–110°E, 10°S–0°) SST difference; (b) zonal wind in the central equatorial Indian Ocean (70°E–90°E, 5°S–5°N); and (c) sea surface height in the eastern equatorial Indian Ocean (90°E–110°E, 10°S–0°). The standard deviation is normalized by the pre-industrial (PiControl) value for each model before ensemble average. Blue box-whisker plots show the 10th, 25th, 50th, 75th, and 90th percentiles of 51-year windows for PiControl, representing natural variability. Red box-whisker plots represent inter-model variability for RCP8.5 (red), based on the nearest rank. Adapted from Zheng et al. (2013).

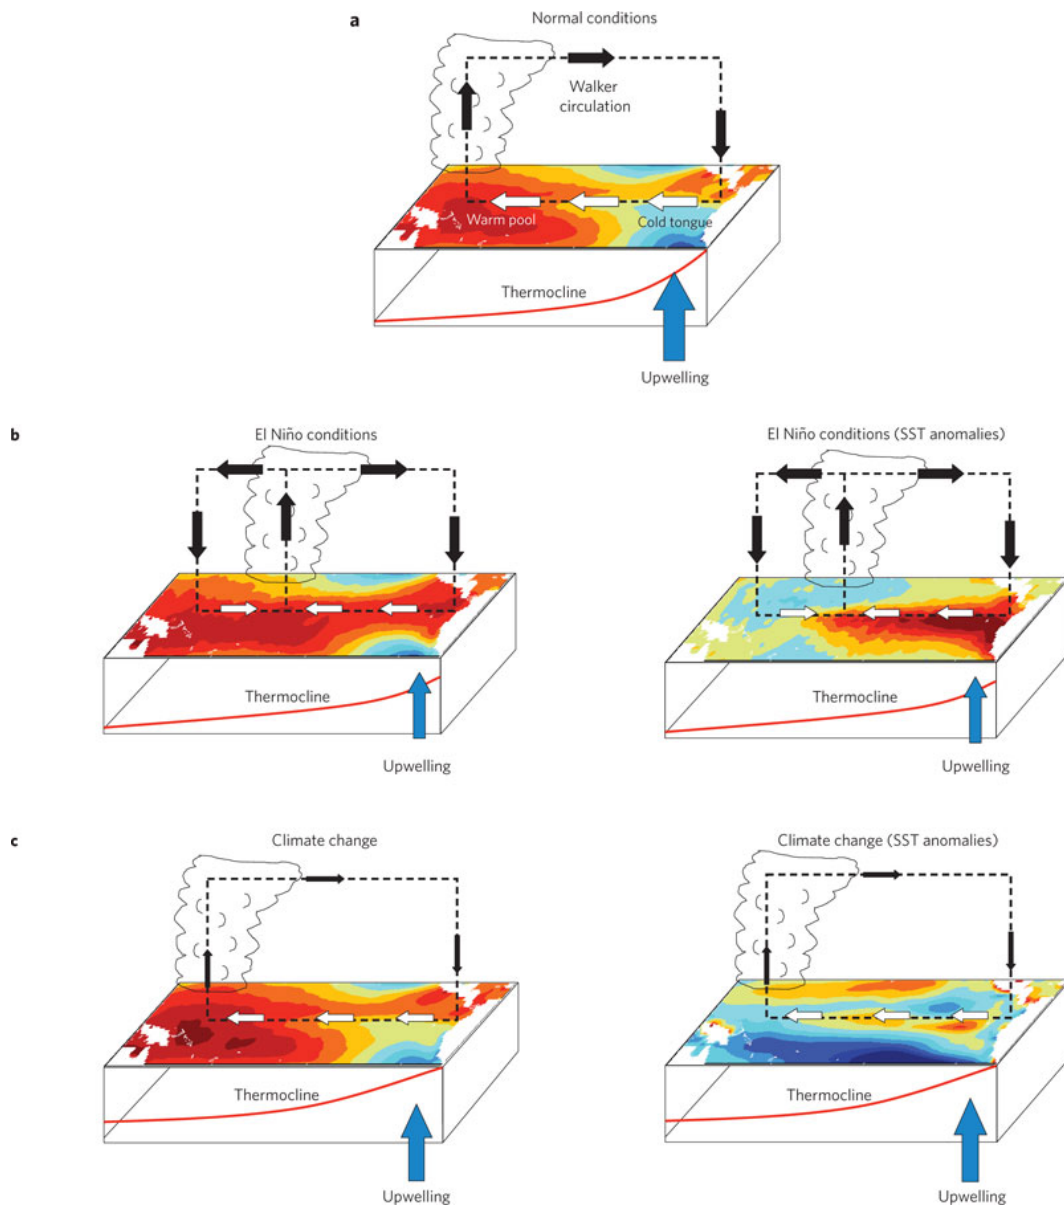

Figure 14.12: Idealized schematic showing atmospheric and oceanic conditions of the tropical Pacific region and their interactions during normal conditions, El Niño conditions, and in a warmer world. (a) Mean climate conditions in the tropical Pacific, indicating SSTs, surface wind stress and associated Walker circulation, the mean position of convection, and the mean upwelling and position of the thermocline. (b) Typical conditions during an El Niño event. SSTs are anomalously warm in the east; convection moves into the central Pacific; the trade winds weaken in the east and the Walker circulation is disrupted; the thermocline flattens and the upwelling is reduced. (c) The likely mean conditions under climate change derived from observations, theory and coupled GCMs. The trade winds weaken; the thermocline flattens and shoals; the upwelling is reduced although the mean vertical temperature gradient is increased; and SSTs (shown as anomalies with respect to the mean tropical-wide warming) increase more on the equator than off. Diagrams with absolute SST fields are shown on the left, diagrams with SST anomalies are shown on the right. For the climate change fields, anomalies are expressed with respect to the basin average temperature change so that blue colours indicate a warming smaller than the basin mean, not a cooling (Collins et al., 2010).

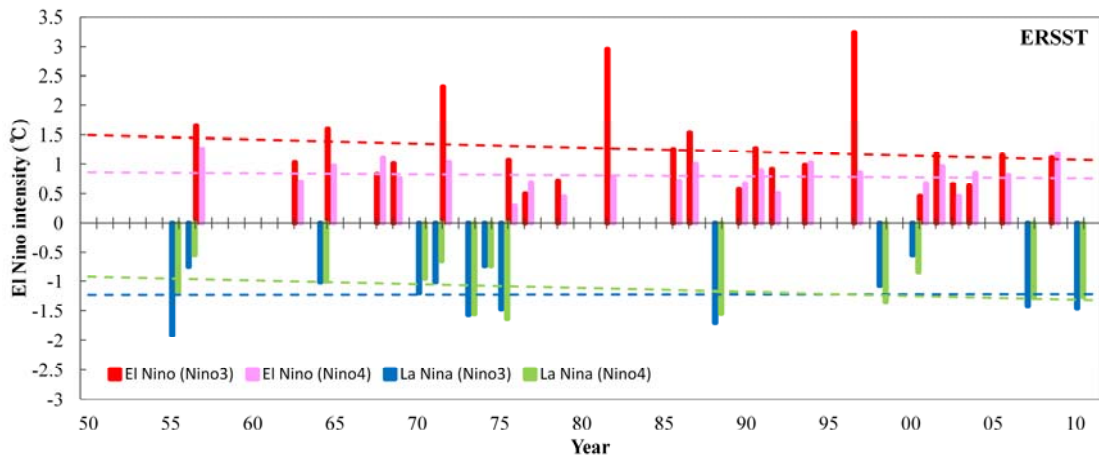

Figure 14.13: Intensities of El Niño and La Niña events for the last 60 years in the eastern equatorial Pacific (Niño3 region) and in the central equatorial Pacific (Niño4 region), and the estimated linear trends, obtained from ERSSTv3.

Figure 14.14: Standard deviation of Niño3 SST anomalies from CMIP5 model experiments. PI, 20C, RCP4.5, RCP8.5 indicate pre-industrial control experiments, 20th century experiments, and 21st century experiment from the RCP4.5 and RCP8.5. Open dot and solid black line indicate multi-model ensemble mean and median, respectively, and the cross mark is 20th observation, respectively. Thick bar and thin outer bar indicate 50% and 75% percentile ranges, respectively.

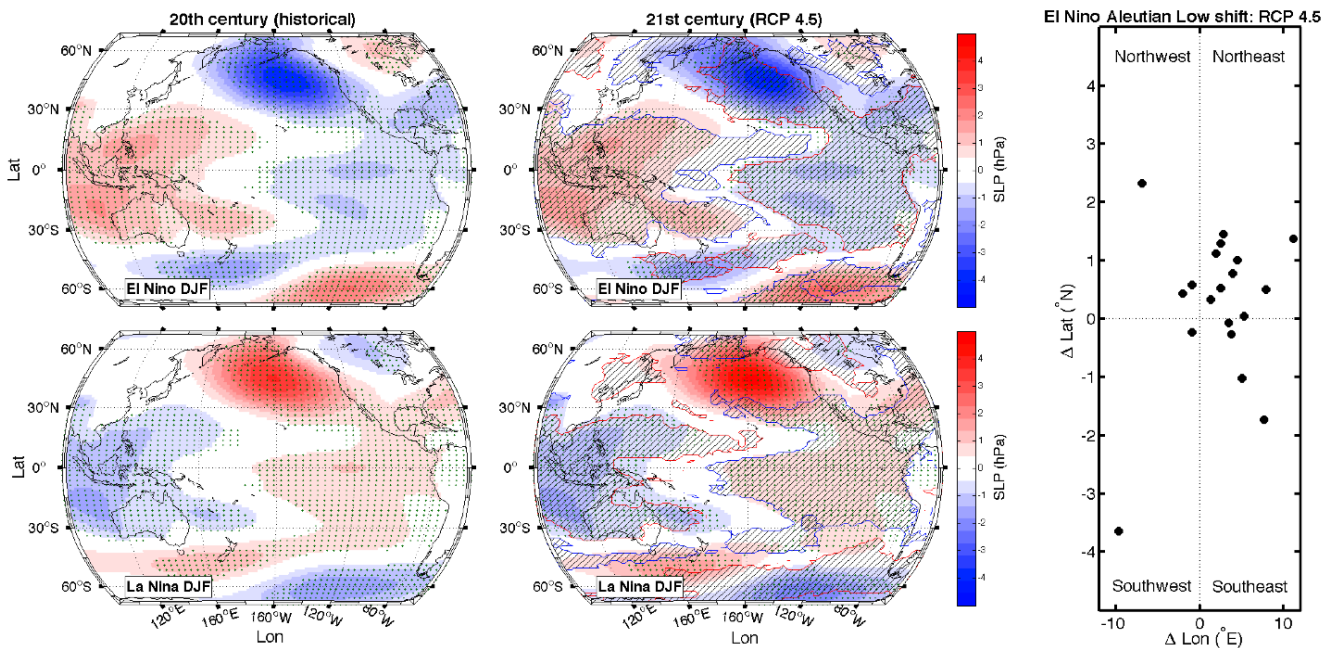

Figure 14.15: Changes to sea level pressure teleconnections during DJF in the CMIP5 models. (a) SLP anomalies for El Niño during the 20th century. (b) SLP anomalies for La Niña during the 20th century. (c) SLP anomalies for El Niño during RCP4.5. (d) SLP anomalies for La Niña during RCP4.5. Maps in (a)-(d) are stippled where more than 2/3 of models agree on the sign of the SLP anomaly ((a),(b): 18 models; (c),(d): 12 models), and hatched where differences between the RCP4.5 multi-model mean SLP anomaly exceeded the 60th percentile (red-bordered regions) or are less than the 40th percentile (blue-bordered regions) of the distribution of 20th century ensemble means. In all panels, El Niño (La Niña) periods are defined as years having DJF NINO3.4 SST above (below) one standard deviation relative to the mean of the detrended time series. For ensemble-mean calculations, all SLP anomalies have been normalized to the standard deviation of the ensemble-member detrended NINO3.4 SST. (e) Change in the "centre of mass" of the Aleutian Low SLP anomaly, RCP4.5 - 20th century. The Aleutian Low SLP centre of mass is a vector with two elements (lat, lon), and is defined as the sum of (lat, lon) weighted by the SLP anomaly, over all points in the region 180°E–120°E, 40°N–60°N having a negative SLP anomaly during El Niño.

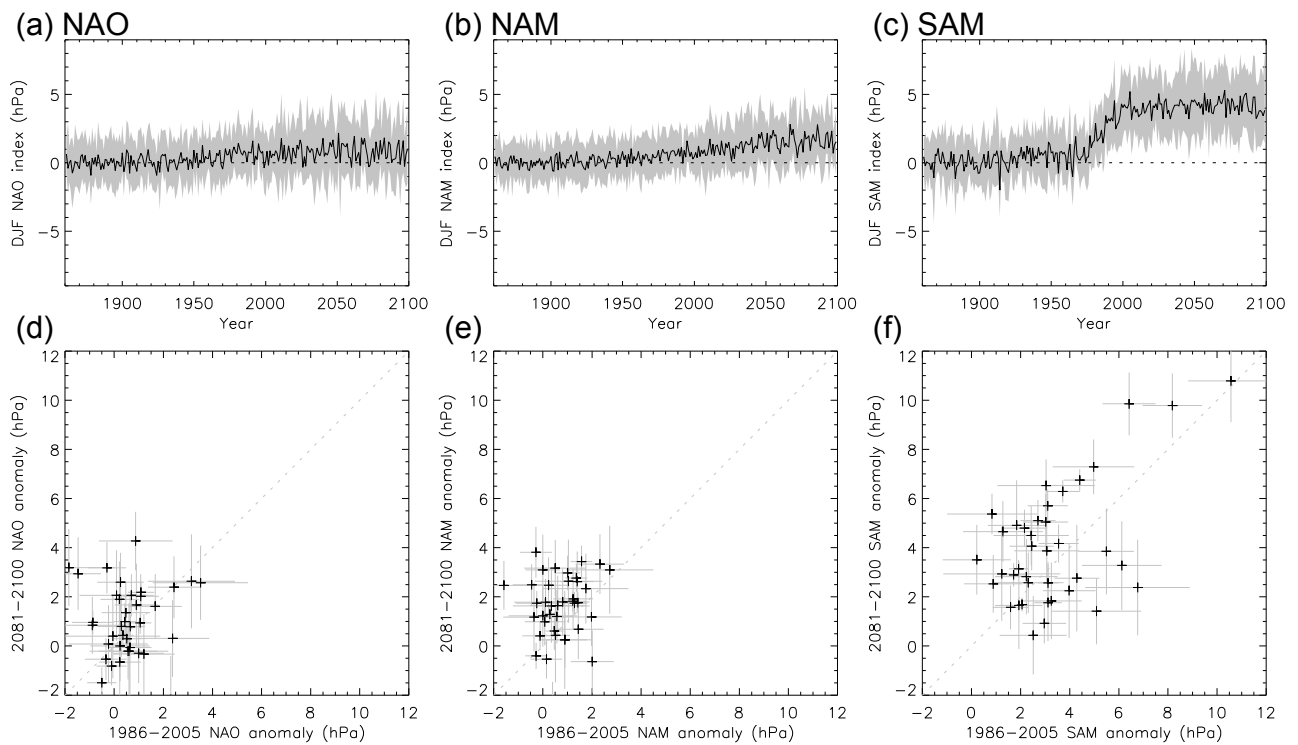

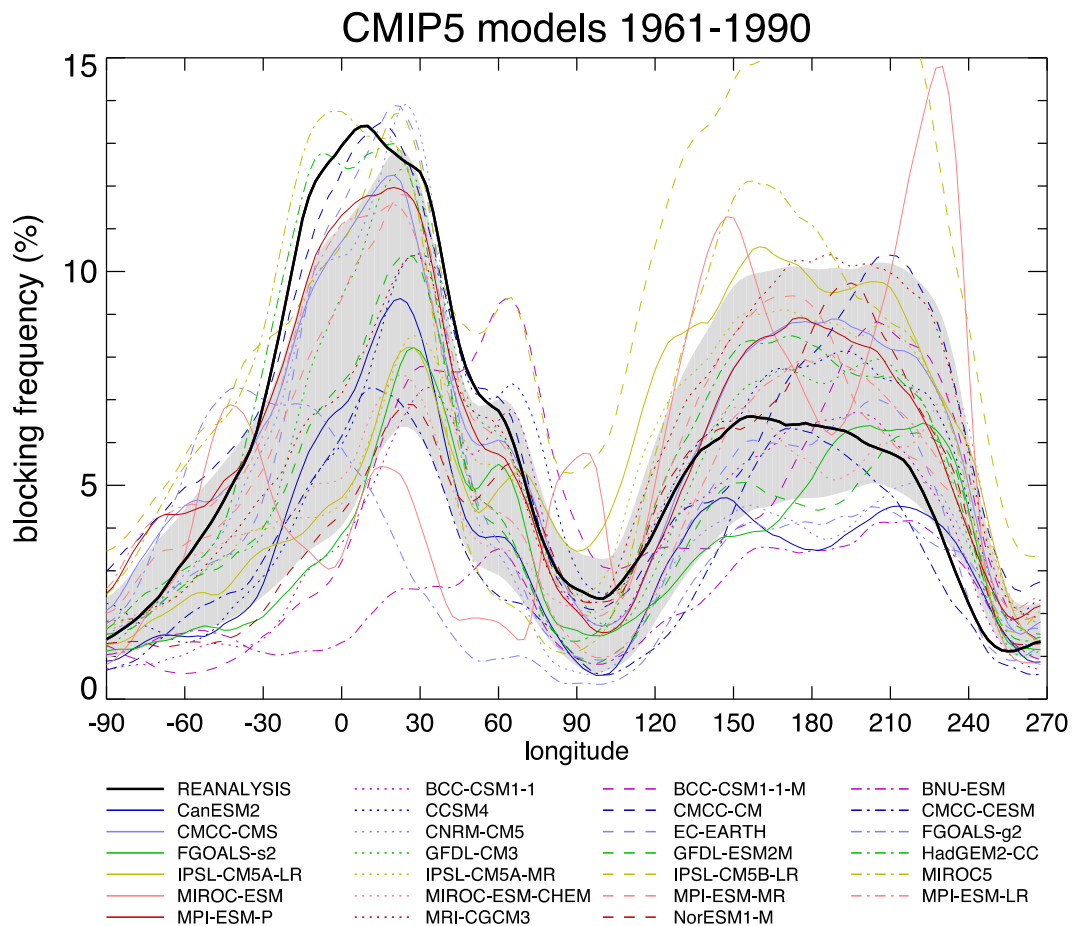

Figure 14.16: Summary of multi-model ensemble simulations of wintertime (Dec-Feb) mean NAO, NAM and SAM sea-level pressure indices for historical and RCP4.5 scenarios produced by 39 climate models participating in CMIP5. Panels a-c) show time series of the ensemble mean (black line) and inter-quartile range (grey shading) of the mean index for each model. Panels d-f) show scatter plots of individual model 2081–2100 time means versus 1986–2005 time means (black crosses) together with (–2,+2) standard error bars. The NAO index is defined here as the difference of regional averages: (90°W–60°E, 20°N–55°N) minus (90°W–60°E, 55°N–90°N) (see Stephenson et al., 2006). The NAM and SAM are defined as zonal indices: NAM as the difference in zonal mean SLP at 35°N and 65°N (Li and Wang, 2003) and SAM as the difference in zonal mean SLP at 40°S and 65°S (Gong and Wang, 1999). All indices have been centred to have zero time mean from 1861–1900. Comparison of simulated and observed trends from 1961–2011 is shown in Figure 10.12.

Box 14.2, Figure 1: Annual mean blocking frequency in the Northern Hemisphere (expressed in % of time, i.e., 1% means ~4 days per year) as simulated by a set of CMIP5 models (colour lines) for the 1961–1990 period of one run of the historical simulation. Grey shading shows the mean model result plus/minus one standard deviation. Black thick line indicates the observed blocking frequency derived from the NCEP/NCAR reanalysis. Only CMIP5 models with available 500 hPa geopotential height daily data at <http://pcmdi3.llnl.gov/esgcat/home.htm> have been used. Blocking is defined as in Barriopedro et al. (2006), which uses a modified version of the index. Daily data was interpolated to a common regular $2.5^\circ \times 2.5^\circ$ longitude-latitude grid before detecting blocking.

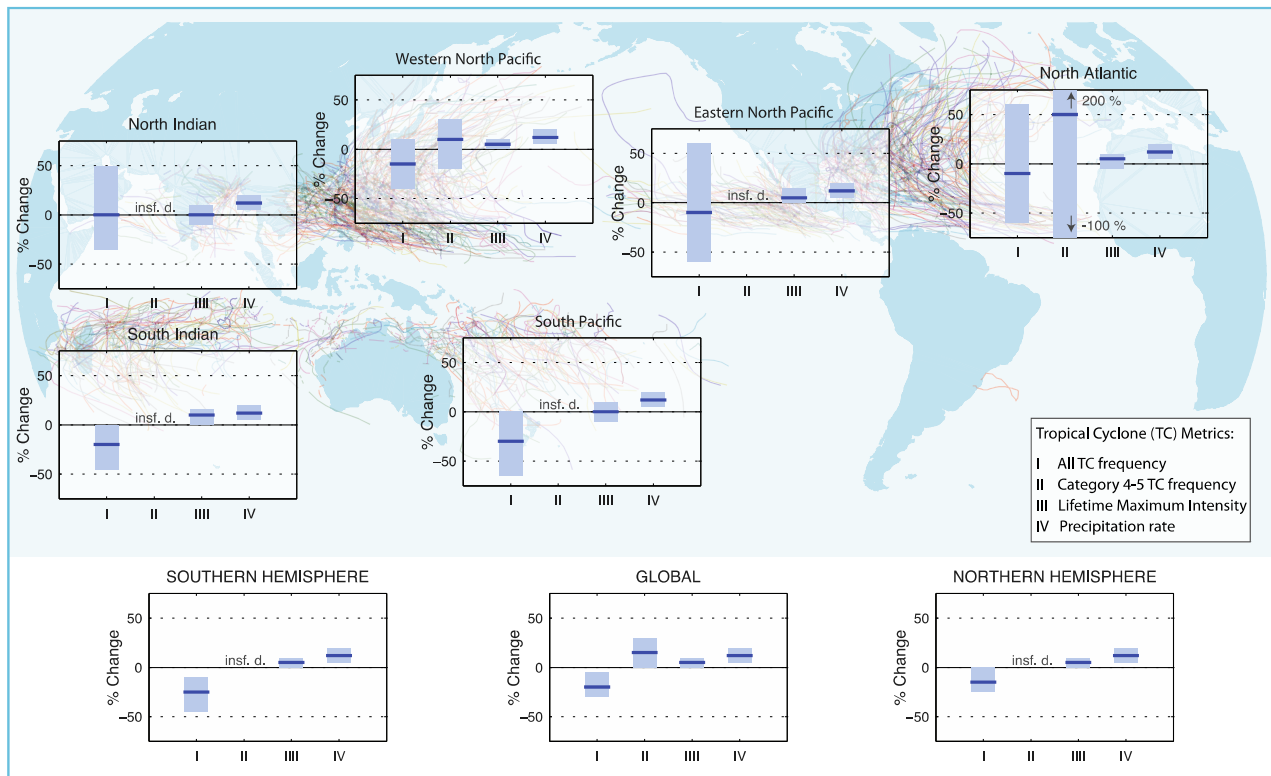

Figure 14.17: General consensus assessment of the numerical experiments described in Supplementary Material Tables 14.SM.1–14.SM.4 in the. All values represent expected percent change in the average over period 2081–2100 relative to 2000–2019, under an A1B-like scenario, based on expert judgment after subjective normalisation of the model projections. Four metrics were considered: the percent change in I) the total annual frequency of tropical storms, II) the annual frequency of Category 4 and 5 storms, III) the mean Lifetime Maximum Intensity (LMI; the maximum intensity achieved during a storm’s lifetime), and IV) the precipitation rate within 200 km of storm centre at the time of LMI. For each metric plotted, the solid blue line is the best guess of the expected percent change, and the coloured bar provides the 67% (*likely*) confidence interval for this value (note that this interval ranges across –100% to +200% for the annual frequency of Category 4 and 5 storms in the North Atlantic). Where a metric is not plotted, there is insufficient data (denoted “insf. d.”) available to complete an assessment. A randomly drawn (and coloured) selection of historical storm tracks are underlain to identify regions of tropical cyclone activity.

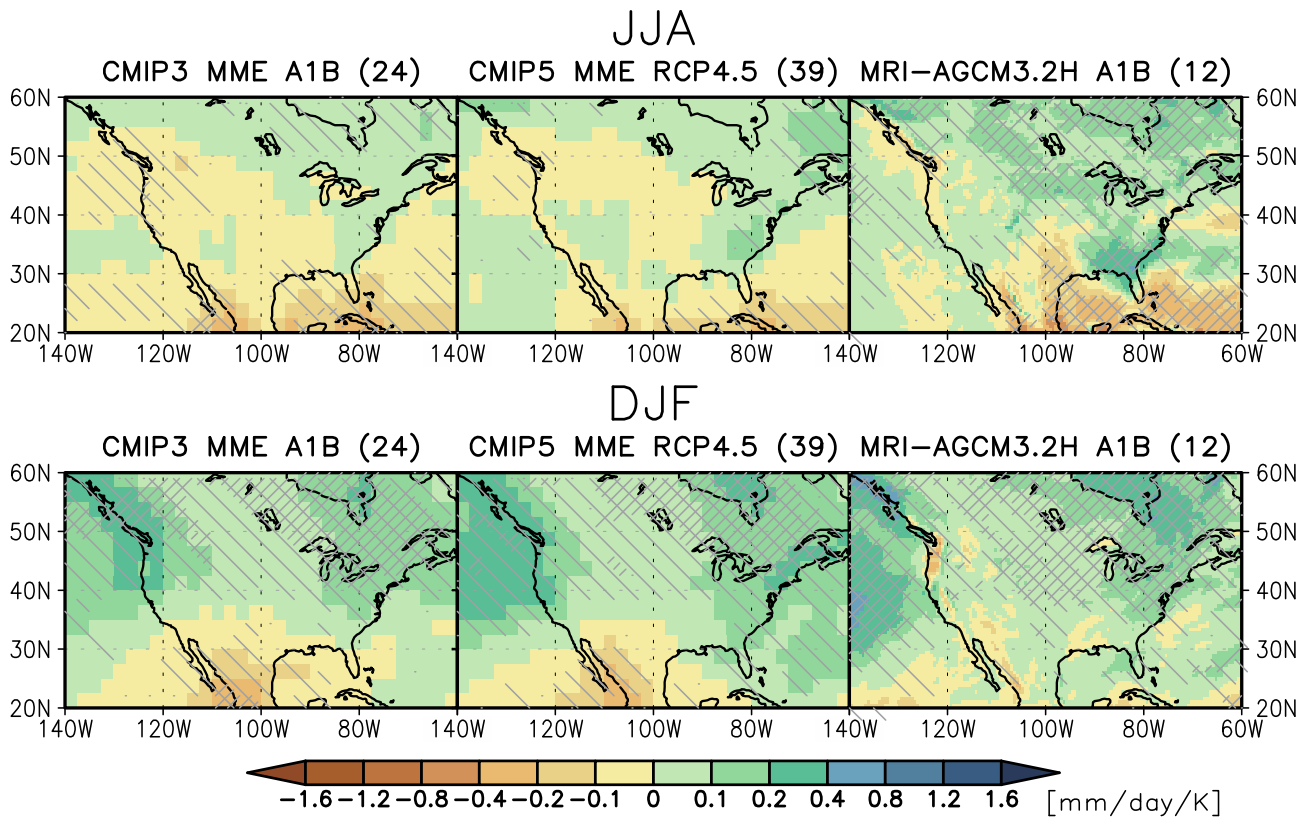

Figure 14.18: Maps of precipitation changes for North America in 2080–2099 with respect to 1986–2005 in June–August (above) and December–February (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

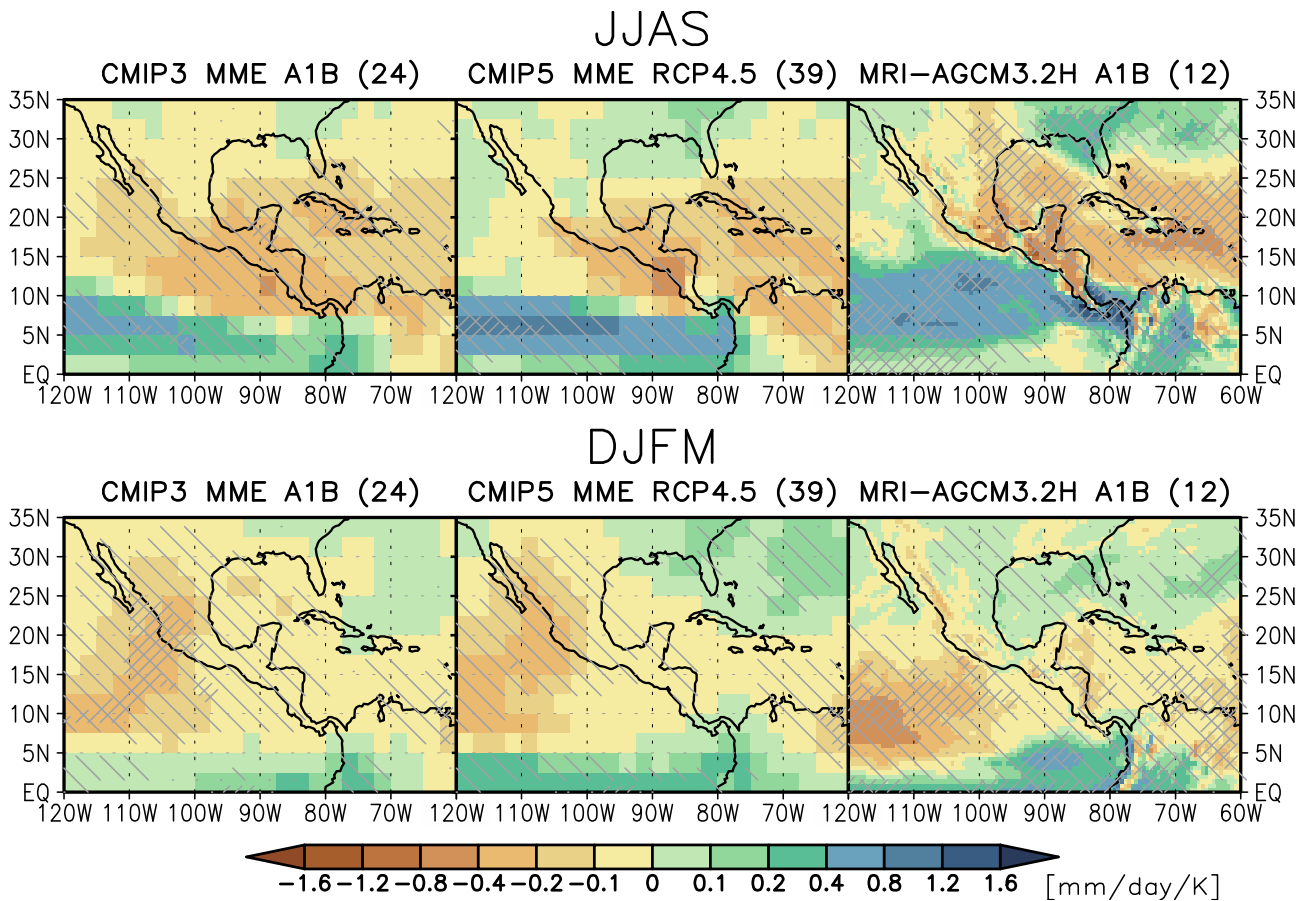

Figure 14.19: Maps of precipitation changes for Central America and Caribbean in 2080–2099 with respect to 1986–2005 in June-September (above) and December-March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

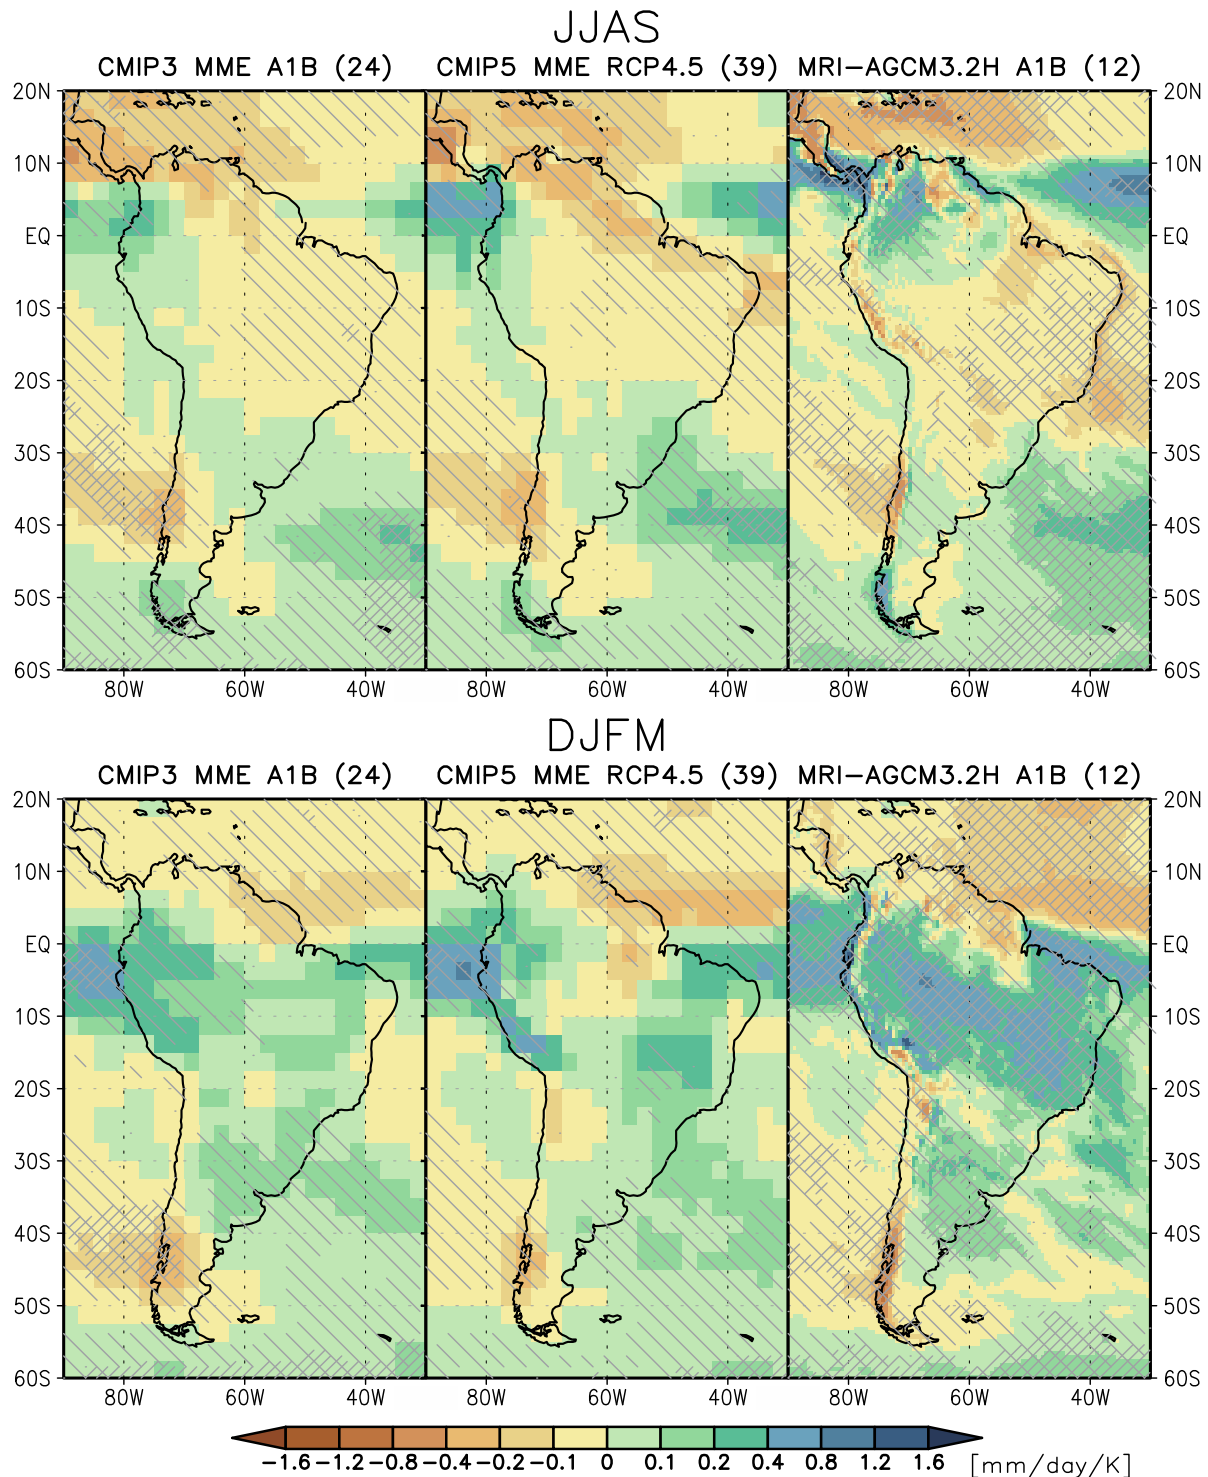

Figure 14.20: Maps of precipitation changes for South America in 2080–2099 with respect to 1986–2005 in June to September (above) and December to March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

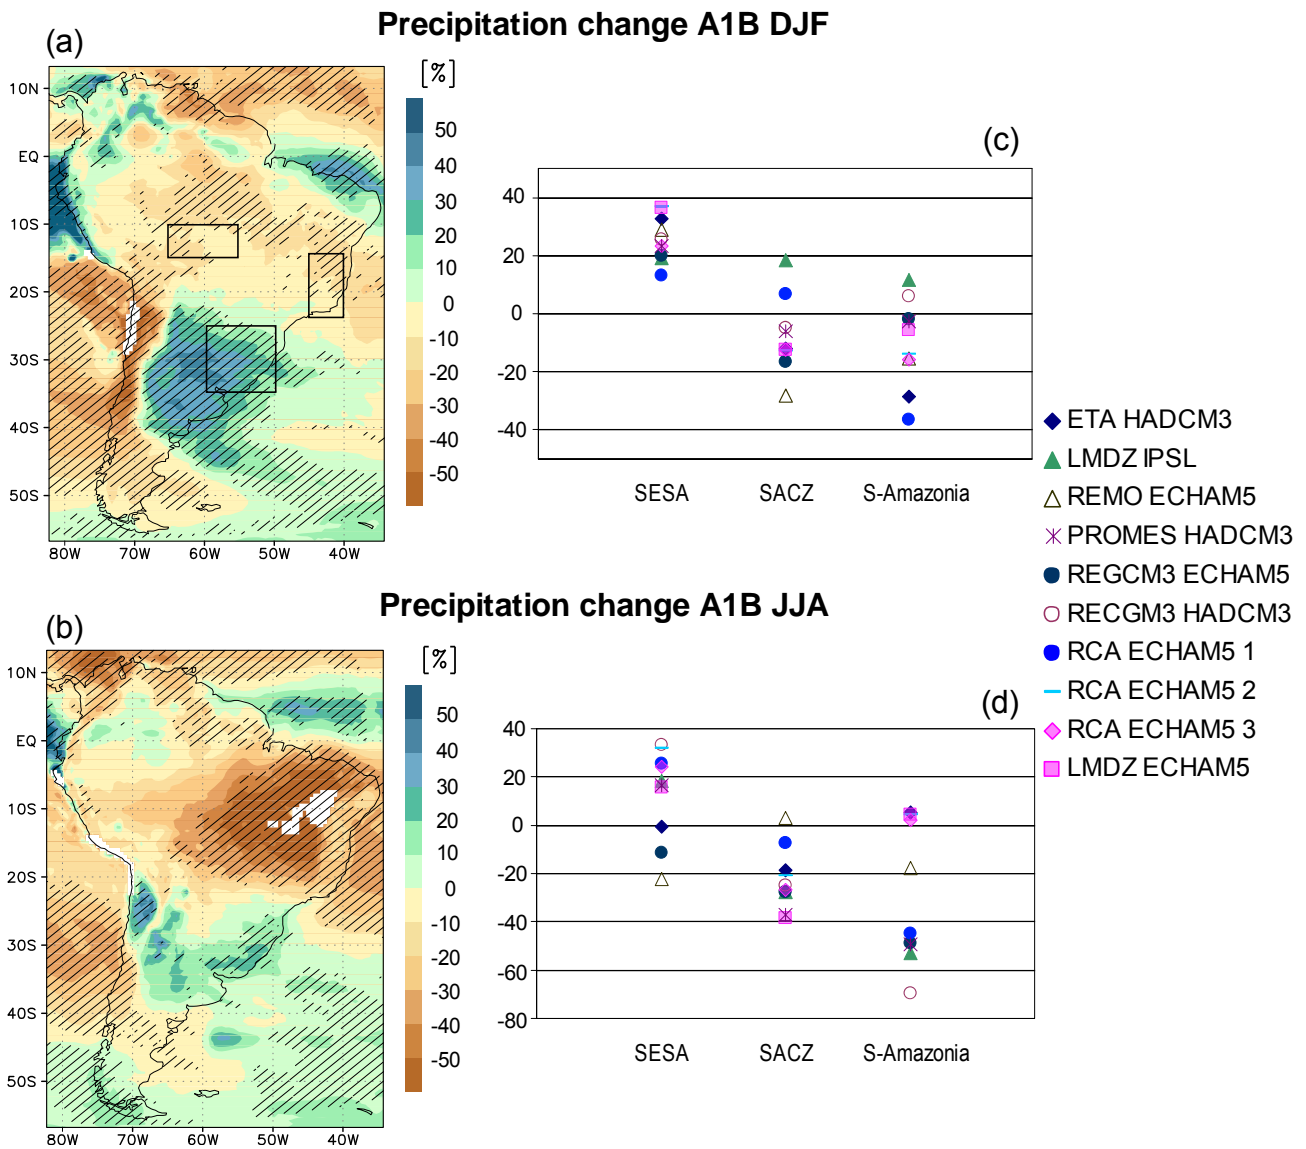

Figure 14.21: (a) DJF and (b) JJA relative precipitation change in 2071–2100 with respect to 1961–1990 in the A1B scenario from an ensemble of 10 RCMs participating in the CLARIS-LPB Project. Hatching denotes areas where 8 out of 10 RCMs agree in the sign of the relative change. (c) DJF and (d) JJA dispersion among regional model projections of precipitation changes averaged over land grid points in South Eastern South America, SESA (35°S–25°S, 60°W–50°W), South Atlantic Convergence Zone, SACZ (25°S–15°S, 45°W–40°W) and Southern Amazonia (15°S–10°S, 65°W–55°W), indicated by the boxes in (a).

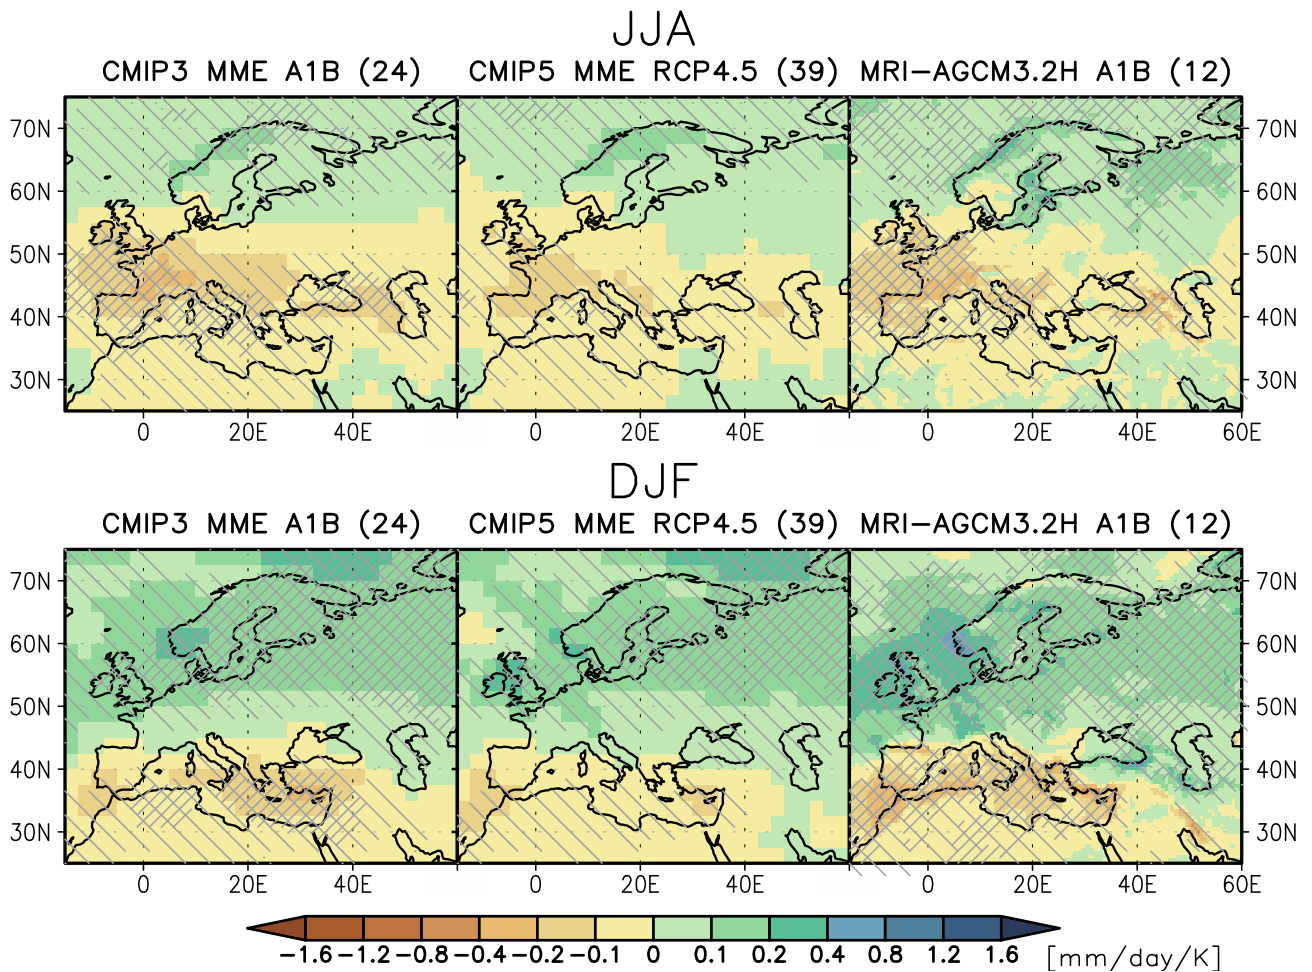

Figure 14.22: Maps of precipitation changes for Europe and Mediterranean in 2080–2099 with respect to 1986–2005 in June to August (above) and December to February (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

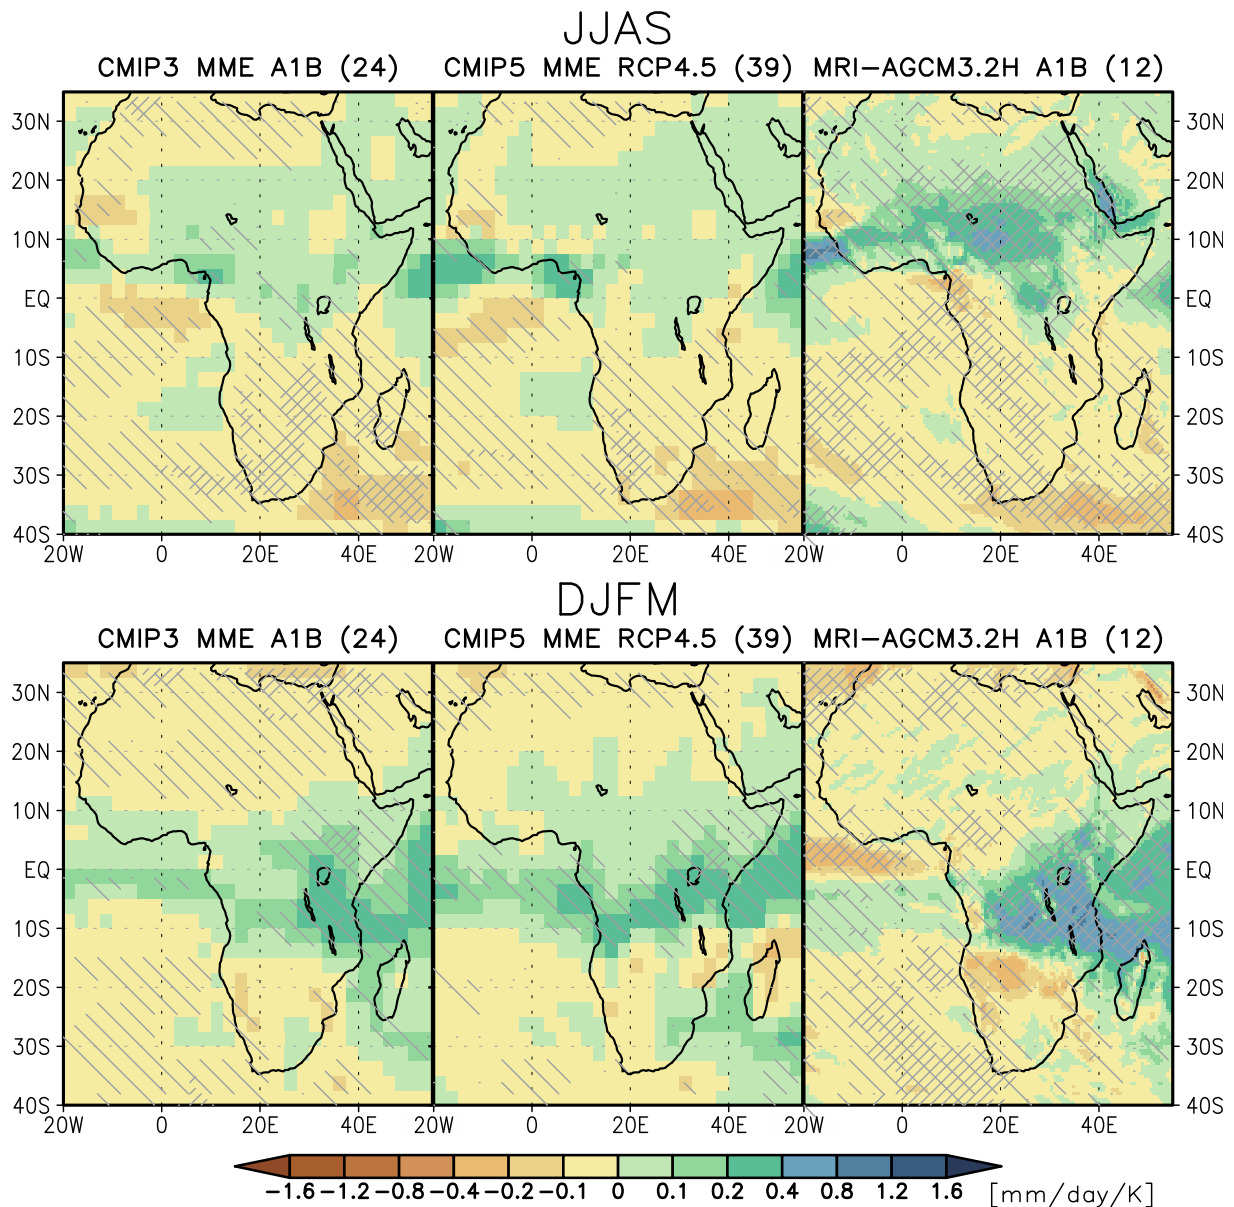

Figure 14.23: Maps of precipitation changes for Africa in 2080–2099 with respect to 1986–2005 in June to September (above) and December to March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

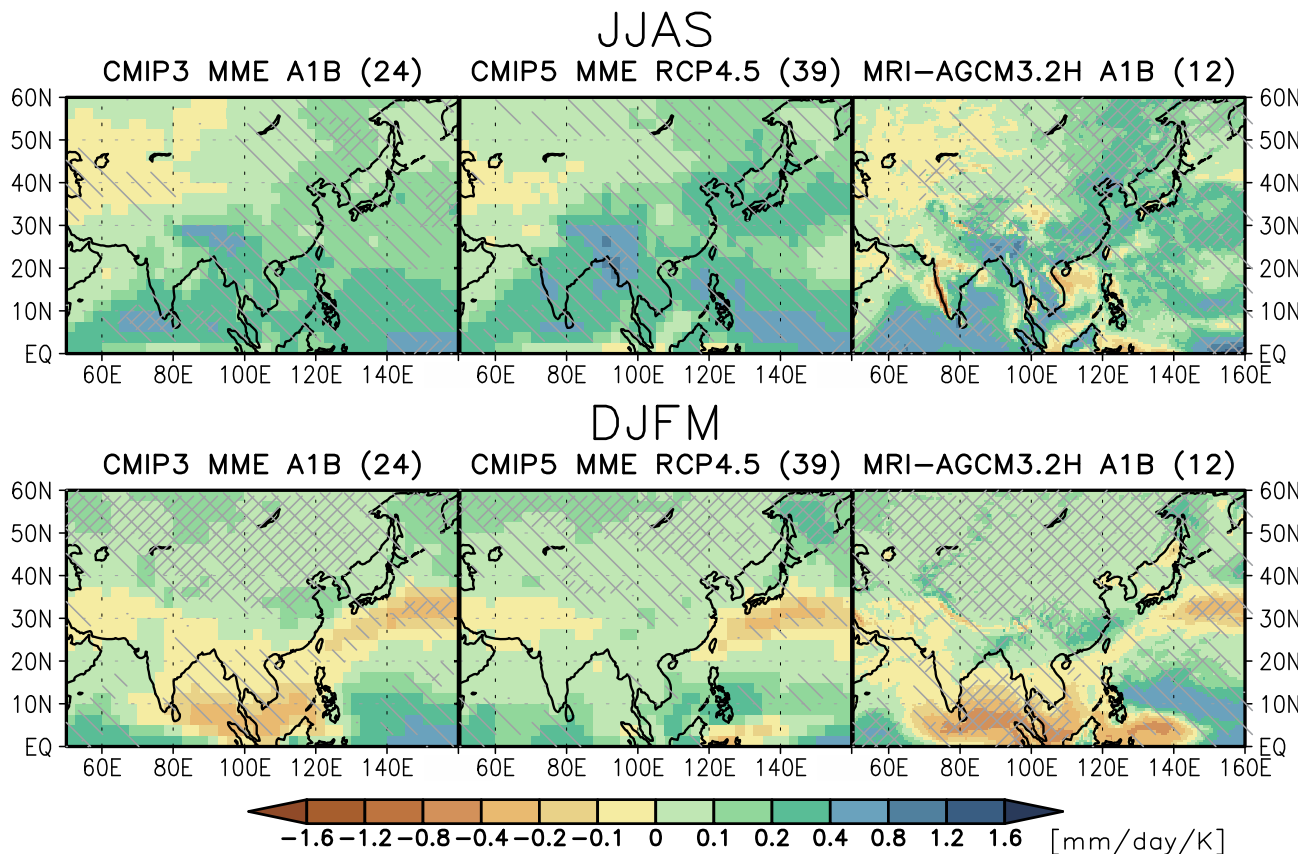

Figure 14.24: Maps of precipitation changes for Central, North, East and South Asia in 2080–2099 with respect to 1986–2005 in June to September (above) and December to March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

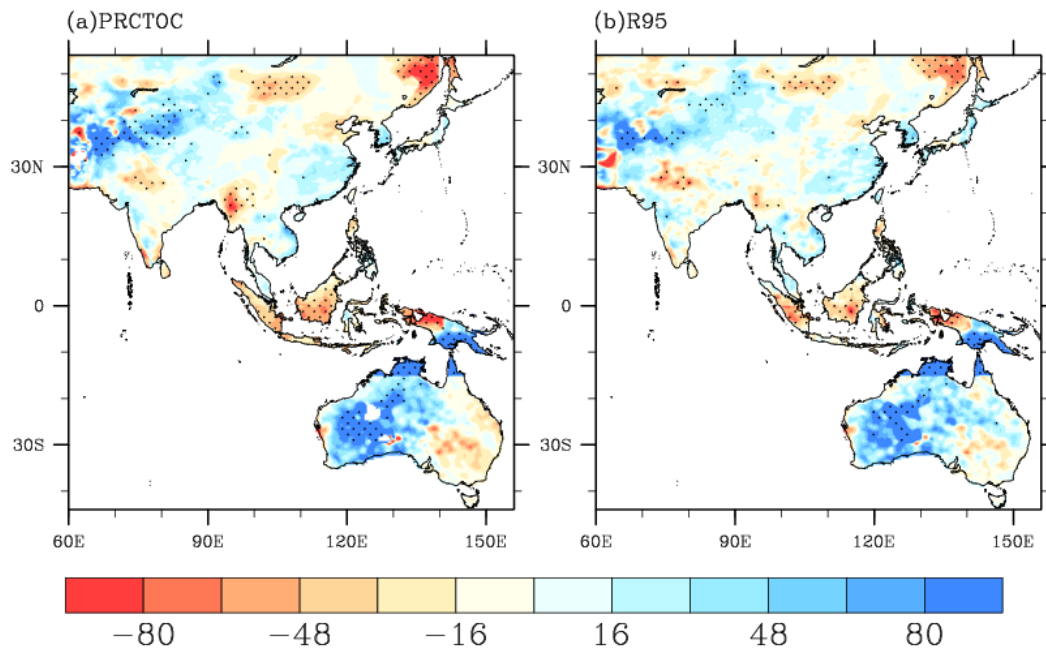

Figure 14.25: Linear trend for local summer (a) total precipitation (b) R95 (summer total precipitation when PR>95th percentile) during 1961–2006. The unit is % per 50-year. The trends statistically significant at 5% level are dotted. The daily precipitation data over Australia and China are produced by the Australian Water Availability Project (AWAP, Jones et al., 2009a) and National Climate Centre China of China Meteorological Administration (Wu and Gao, 2013), respectively, while that over the other area is compiled by the Highly Resolved Observational Data Integration Towards the Evaluation of Water Resources (APHRODITE) project (Yatagai et al., 2012). The resolution of precipitation dataset is $0.5^\circ \times 0.5^\circ$. Local summer is defined as June-July-August in the Northern Hemisphere, and December-January-February in the Southern Hemisphere.

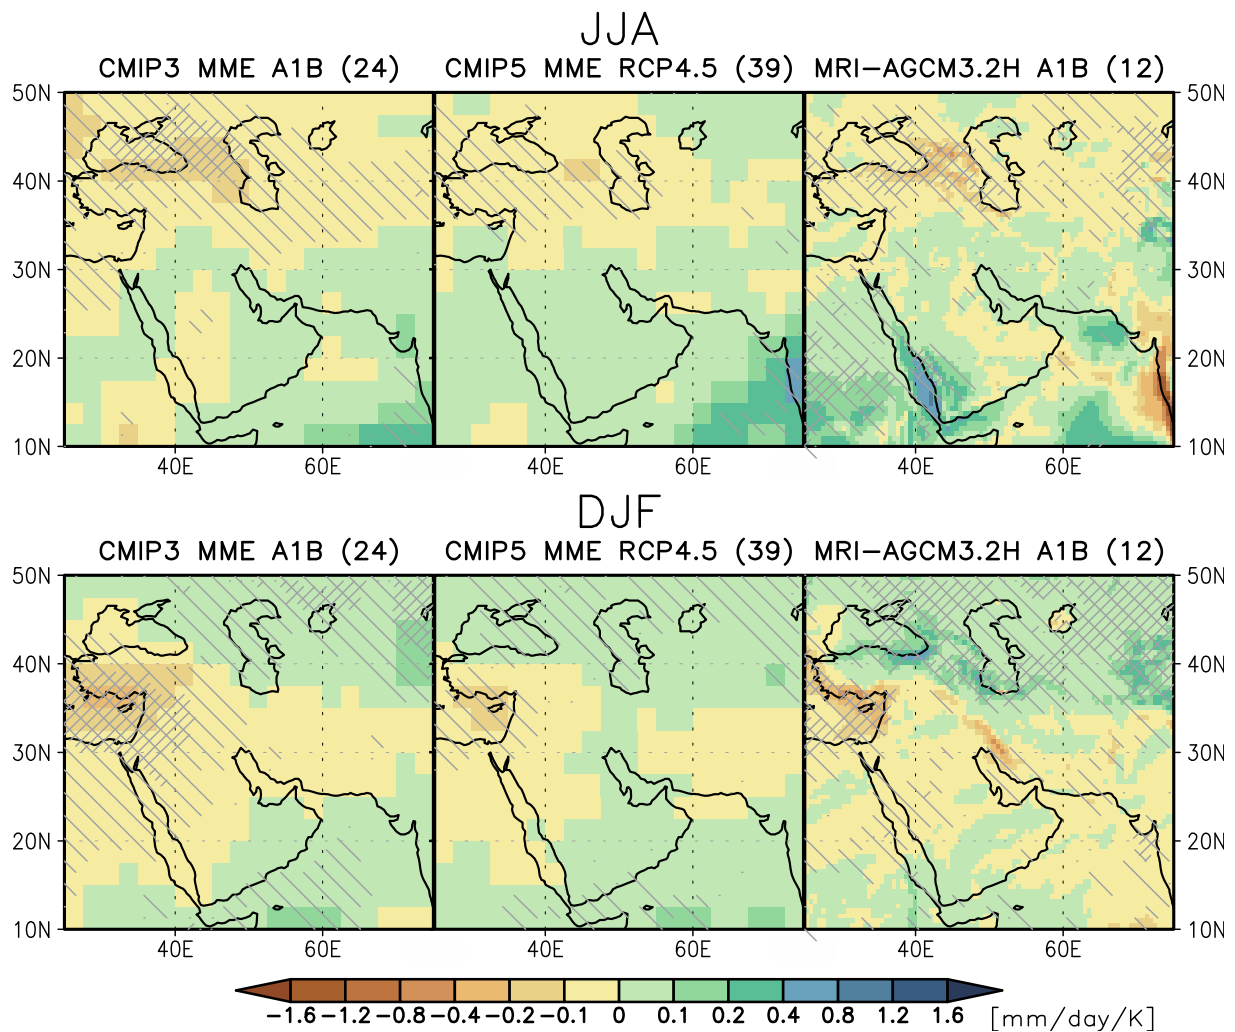

Figure 14.26: Maps of precipitation changes for West Asia in 2080-2099 with respect to 1986-2005 in June-August (above) and December-February (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075-2099 with respect to 1979-2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

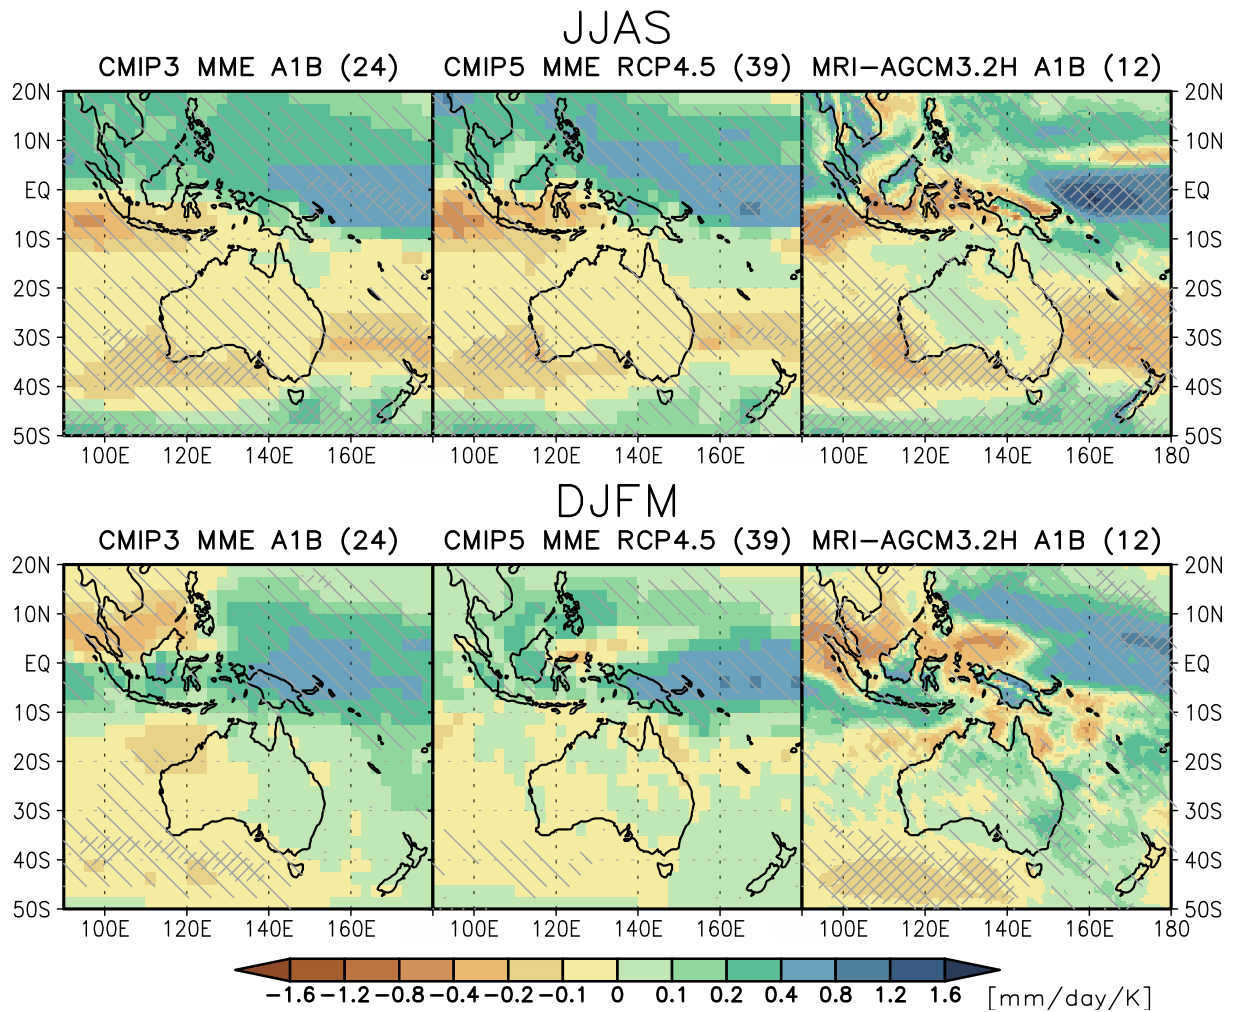

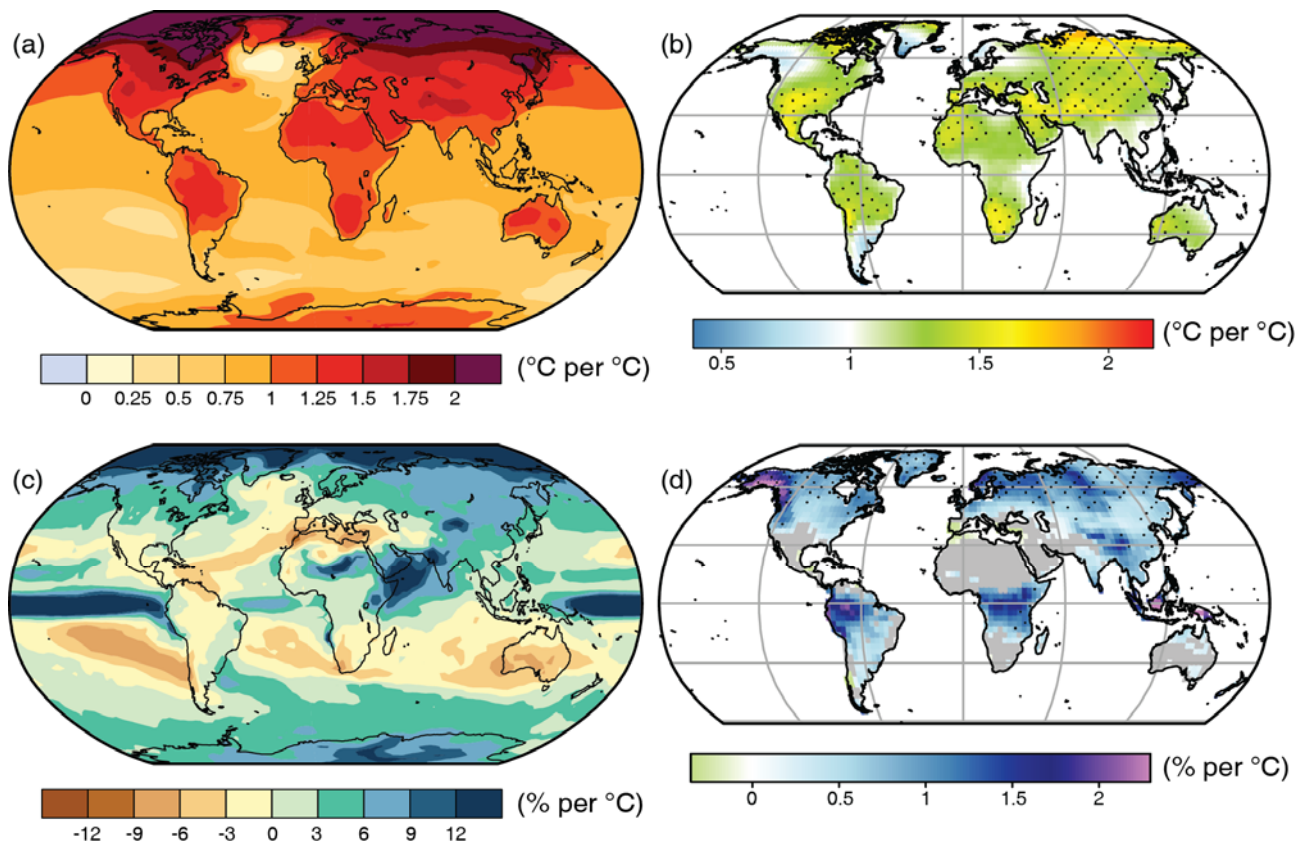

Figure 14.27: Maps of precipitation changes for Southeast Asia, Australia and New Zealand in 2080–2099 with respect to 1986–2005 in June–September (above) and December–March (below) in the SRES A1B scenario with 24 CMIP3 models (left), and in the RCP4.5 scenario with 39 CMIP5 models (middle). Right figures are the precipitation changes in 2075–2099 with respect to 1979–2003 in the SRES A1B scenario with the 12 member 60 km mesh MRI-AGCM3.2 multi-physics, multi-SST ensembles (Endo et al., 2012). Precipitation changes are normalized by the global annual mean surface air temperature changes in each scenario. Light hatching denotes where more than 66% of models (or members) have the same sign with the ensemble mean changes, while dense hatching denotes where more than 90% of models (or members) have the same sign with the ensemble mean changes.

FAQ 14.1, Figure 1: Projected 21st century changes in annual mean and annual extremes (over land) of surface air temperature and precipitation: a) mean surface temperature per °C of global mean change, b) 90th percentile of daily maximum temperature per °C of global average maximum temperature, c) mean precipitation (in % per °C of global mean temperature change), and d) fraction of days with precipitation exceeding the 95th percentile. Sources: Panels a) and c) projected changes in means between 1986–2005 and 2081–2100 from CMIP5 simulations under RCP4.5 scenario (see Chapter 12, Figure 12.40); Panels b) and d) projected changes in extremes over land between 1980–1999 and 2081–2100 (from Orłowsky and Seneviratne, 2012).

FAQ 14.2, Figure 1: Schematic diagram illustrating the main ways that human activity influences monsoon rainfall. As the climate warms, increasing water vapour transport from the ocean into land increases because warmer air contains more water vapour. This also increases the potential for heavy rainfalls. Warming-related changes in large-scale circulation influence the strength and extent of the overall monsoon circulation. Land use change and atmospheric aerosol loading can also affect the amount of solar radiation that is absorbed in the atmosphere and land, potentially moderating the land-sea temperature difference.

Annex I: Atlas of Global and Regional Climate Projections

Editorial Team: Matthew Collins (UK), Julie M. Arblaster (Australia), Jens Hesselbjerg Christensen (Denmark), Jochem Marozke (Germany), Geert Jan van Oldenborgh (Netherlands), Scott Power (Australia), Markku Rummukainen (Sweden), Tianjun Zhou (China)

Advisory Board: David Wratt (New Zealand), Francis Zwiers (Canada), Bruce Hewitson (South Africa)

Review Editor Team: Pascale Delecluse (France), John Fyfe (Canada), Karl Taylor (USA)

Date of Draft: 7 June 2013

Introduction and Scope

This Annex presents a series of figures showing global and regional patterns of climate change computed from global climate model output gathered as part of the Coupled Model Intercomparison Project Phase 5 (CMIP5; Taylor et al., 2012). Maps of surface air temperature change and relative precipitation change (i.e., change expressed as a percentage of mean precipitation) in different seasons are presented for the globe and for a number of different sub-continental-scale regions. Twenty-year average changes for the near-term (2016–2035), for mid-term (2046–2065), and for the long-term (2081–2100) are given, relative to a reference period of 1986–2005. Time series for temperature and relative precipitation changes are shown for global land and sea averages, the 26 sub-continental SREX regions (IPCC, 2012) augmented with polar regions and the Caribbean, two Indian Ocean and three Pacific Ocean regions. In total this Atlas gives projections for 35 regions, 2 variables, and 2 seasons. The projections are made under the Representative Concentration Pathway scenarios, or RCPs, which are introduced in Chapter 1 with more technical detail given in Section 12.3 (also note the discussion of near-term biases in Sections 11.3.5.1 and 11.3.6.1). Maps are only shown for the RCP4.5 scenario, however the time series presented show how the area-average response varies among the RCP2.6, RCP4.5, RCP6.0 and RCP8.5 scenarios. Spatial maps for the other RCP scenarios and additional seasons are presented in the Supplementary Material. Figures AI-1 and AI-2 give a graphical explanation of aspects of both the time series plots and the spatial maps. While some of the background to the information presented is given here, discussion of the maps and time-series, and important additional background is provided in Chapters 9, 11, 12 and 14. Figure captions on each page of the Annex reference the specific sub-sections in the report relevant to the regions considered on that page.

The projection of future climate change involves the careful evaluation of models, taking into account uncertainties in observations and consideration the physical basis of the findings, in order to characterise the credibility of the projections and assess their sensitivity to uncertainties. As discussed in Chapter 9, different climate models have varying degrees of success in simulating past climate variability and mean state when compared to observations. Verification of regional trends is discussed in Box 11.2 and provide further information on the credibility of model projections. The information presented in this Atlas is based entirely on all available CMIP5 model output with equal weight given to each model or version with different parametrisations.

Complementary methods for making quantitative projections, in which model output is combined with information about model performance using statistical techniques, exist and should be considered in impacts studies (see Sections 9.8.3, 11.3.1 and 12.2.2–12.2.3). While results from the application of such methods can be assessed alongside the projections from CMIP5 presented here, it this is beyond the scope of this Atlas. Nor do the simple maps provided represent a robust estimate of the uncertainty associated with the projections. Here the range of model spread is provided as a simple, albeit imperfect, guide to the range of possible futures (including the effect of natural variability). Alternative approaches used to estimate projection uncertainty are discussed in Sections 11.3.1 and 12.2.2–12.2.3. The reliability of past trends is assessed in Box 11.2, which concludes that the time series and maps cannot be interpreted literally as probability density functions. They should not be interpreted as 'forecasts'

Projections of future climate change are conditional on assumptions of climate forcing, affected by shortcomings of climate models and inevitably also subject to internal variability when considering specific periods. Projected patterns of climate change may differ from one climate model generation to the next due to improvements in models. Some model-inadequacies are common to all models, but so are many patterns of change across successive generations of models, which gives some confidence in projections. The information presented is intended to be a starting point only for anyone interested in more detailed information on projections of future climate change and complements the assessment in Chapters 11, 12 and 14.

Technical Notes

Data and Processing: The figures have been constructed using the CMIP5 model output available at the time of the AR5 cut-off for accepted papers (15 March 2013). This dataset comprises 32/42/25/39 scenario experiments for RCP2.6/4.5/6.0/8.5 from 42 climate models (Table AI-1). Only concentration-driven experiments are used (i.e., those in which concentrations rather than emissions of greenhouse gases are prescribed) and only one ensemble member from each model is selected, even if multiple realisations exist with different initial conditions and different realisations of natural variability. Hence each model is given equal weight. Maps from only one scenario (RCP4.5) are shown but time-series are included from all four RCPs. Maps from other RCPs are presented in the Annex I Supplementary Material.

Table AI-1: The CMIP5 models used in this Annex for each of the historical and RCP scenario experiments. A number in each column is the identifier of the single ensemble member from that model that is used. A blank indicates no run was used, usually because that scenario run was not available. For the pre-industrial control column (piControl), a ‘tas’ indicates that those control simulations are used in the estimate of internal variability of surface air temperature and a ‘pr’ indicates that those control simulations are used in the estimate of precipitation internal variability.

Reference period: Projections are expressed as anomalies with respect to the reference period of 1986–2005 for both time series and spatial maps (i.e. differences between the future period and the reference period). Thus the changes are relative the climate change that has already occurred since the pre-industrial period and which is discussed in Chapters 2 and 10. For quantities where the trend is larger than the natural variability such as large-area temperature changes, a more recent reference period would give better estimates (see Section 11.3.6.1), for quantities where the natural variability is much larger than the trend a longer reference period would be preferable.

Equal model weighting: Model evaluation uses a multitude of techniques (see Chapter 9) and there is no consensus in the community about how to use this information to assign likelihood to different model projections. Consequently, the different CMIP5 models used for the projections in this Atlas are all considered to give equally likely projections in the sense of ‘one model, one vote’. Models with variations in physical parametrisation schemes are treated as distinct models.

Variables: Two variables have been plotted: surface air temperature change and relative precipitation change. The relative precipitation change is defined as the percentage change from the 1986–2005 reference period in each ensemble member. For the time series, the variables are first averaged over the domain and then the changes from the reference period are computed. This implies that in regions with large climatological precipitation gradients, the change is generally dominated by the areas with most precipitation.

Seasons: For temperature, the standard meteorological seasons June–August and December–February are shown, as these often correspond roughly with the warmest and coldest seasons. The annual mean and remaining seasons, March–May and September–October can be found in the Supplementary Material. For precipitation, the half years April–September and October–March are shown so that in most monsoon areas the local rain seasons are entirely contained within the seasonal range plotted. Since the seasonal average is computed first, followed by the percentile change, these numbers are dominated by the rainy months within the half-year. The annual means are included in the Supplementary Material.

Regions: In addition to the global maps, the areas defined in the SREX (IPCC, 2012) are plotted with the addition of six regions containing the Caribbean, Indian Ocean and Pacific Island States and land and sea areas of the two polar regions. For regions containing large land-areas, averages are computed only over land grid points only. For ocean regions, averages are computed over both land and ocean grid points (see figure captions). A grid box is considered land if the land fraction is larger than 50% and sea if it is smaller than this. SREX regions with long coastlines (west coast of South America, North Europe, Southeast Asia) therefore include some influence of the ocean. Note that temperature and precipitation over islands may be very different from those over the surrounding sea.

Time Series: For each of the resulting areas the areal mean is computed on the original model grid using land, sea or all points, depending on the definition of the region (see above). As an indication of the model uncertainty and natural variability, the time series of each model and scenario over the common period 1900–2100 are shown on the top of the page as anomalies relative to 1986–2005 (the seasons December-February and October-March are counted towards the second year in the interval). The multi-model ensemble means are also shown. Finally, for the period 2081–2100, the 20-year means are computed and the box-and-whiskers plots show the 5th, 25th, 50th (median), 75th and 95th percentiles sampled over the distribution of the 20-year means of the model time series indicated in Table AI-1, including both natural variability and model spread. In the 20-year means the natural variability is suppressed relative to the annual values in the time series whereas the model uncertainty is the same. Note that due to a smaller number of models, the box-and-whisker plots for the RCP2.6 scenario and especially the RCP6.0 scenario are less certain than those for RCP4.5 and RCP8.5.

Spatial Maps: The maps in the Atlas show, for an area encompassing two or three regions, the difference between the periods 2016–2035, 2046–2065 and 2081–2100 and the reference period 1986–2005. As local projections of climate change are uncertain, a measure of the range of model projections is shown in addition to the median response of the model ensemble interpolated to a common 2.5° grid (the interpolation was done bilinearly for surface air temperature and first order conservatively for precipitation). It should again be emphasized (see above) that this range does not represent the full uncertainty in the projection. On the left, the 25th percentile of the distribution of ensemble members is shown, on the right the 75th percentile. The median is shown in the middle (different to similar plots in Chapters 11 and 12 and the time series which show the multi-model mean). The distribution combines the effects of natural variability and model spread. The colour scale is kept constant over all maps.

Hatching: Hatching indicates regions where the magnitude of the change of the 20-year mean is less than one standard deviation of model-estimated present-day natural variability of 20-year mean differences. The natural variability is estimated using all pre-industrial control runs which are at least 500 year long. The first 100 years of the pre-industrial are ignored. The natural variability is then calculated for every grid point as the standard deviation of non-overlapping 20-year means after a quadratic fit is subtracted at every grid point to eliminate model drift. This is multiplied by the square root of 2, a factor that arises as the comparison is between two distributions of numbers. The median across all models of that quantity is used. This characterizes the typical difference between two 20-year averages that would be expected due to unforced internal variability. The hatching is applied to all maps so, for example, if the 25th percentile of the distribution of model projections is less than one standard deviation of natural variability, it is hatched.

The hatching can be interpreted as some indication of the strength of the future anomalies from present-day climate, when compared to the strength of present day internal 20-year variability. It either means that the change is relatively small or that there is little agreement between models on the sign of the change. It is only presented as a guide to assessing the strength of change as the difference between two 20-year intervals. Using other measures of natural variability would give smaller or larger hatched areas, but the colours underneath the hatching would not be very different. Other methods of hatching and stippling are possible (see Box 12.1) and, in cases where such information is critical, it is recommended that thorough attention is paid to assessing significance using a statistical test appropriate to the problem being considered.

Scenarios: Spatial patterns of changes for scenarios other than RCP4.5 can be found in the Supplementary Material.

Figure AI-1: Explanation of the features of a typical time series figure presented in Annex I.

Figure AI-2: Explanation of the features of a typical spatial maps presented in Annex I. Hatching indicates regions where the magnitude of the 25th, median or 75th percentile of the 20-year mean change is less than one standard deviation of model-estimated natural variability of 20-year mean differences.

 14 models in this region, the model spread in the context of other methods of projecting changes and the role of
 15 modes of variability and other climate phenomena.

3 **Figure AI.17:** Top left: time series of temperature change relative to 1986–2005 averaged over land grid
 4 points in Alaska/NW Canada (60° – 72.6° N, 168° – 105° W) in June–August. Top right: same for land grid
 5 points in West North America (28.6° – 60° N, 130° – 105° W). Thin lines denote one ensemble member per model,
 6 thick lines the CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th (median), 75th and 95th
 7 percentiles of the distribution of 20-yr mean changes are given for 2081–2100 in the four RCP scenarios.

8 Below: maps of temperature changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 9 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 10 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 11 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 12 present-day natural variability of 20-yr mean differences.

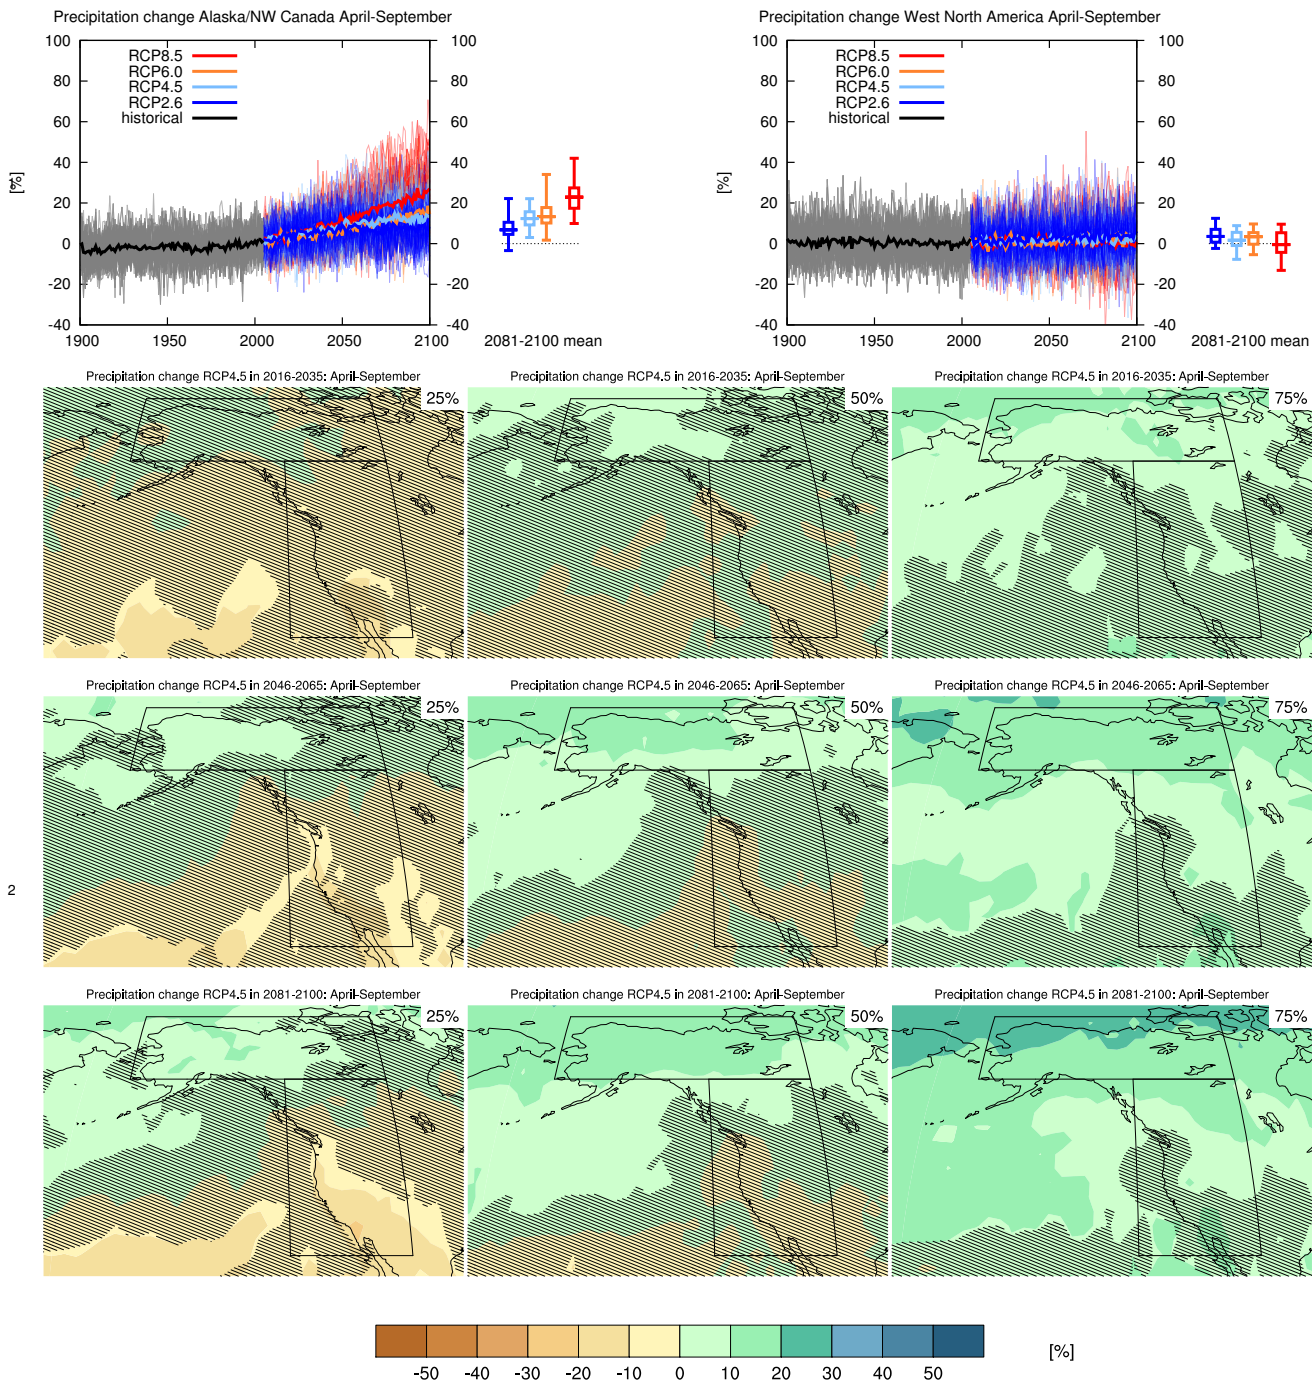

13 Sections 9.4.1.1, 9.6.1.1, 10.3.1.1.4, Box 11.2, 14.8.3 contain relevant information regarding the evaluation of
 14 models in this region, the model spread in the context of other methods of projecting changes and the role of
 15 modes of variability and other climate phenomena.

 4 points in the West Coast of South America (79.7°W,1.2°S; 66.4°W,20°S; 72.1°W,50°S; 67.3°W,56.7°S; 82.0°W
 5 56.7°S; 82.2°W,0.5°N) in December–February. Top right: same for land grid points in Southeastern South
 6 America (39.4°W,20°S; 39.4°W,56.6°S; 67.3°W,56.7°S; 72.1°W,50°S; 66°W,20°S). Thin lines denote one en-
 7 semble member per model, thick lines the CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th
 8 (median), 75th and 95th percentiles of the distribution of 20-yr mean changes are given for 2081–2100 in the
 9 four RCP scenarios.

10 Below: maps of temperature changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 11 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 12 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 13 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 14 present-day natural variability of 20-yr mean differences.

15 Sections 9.4.1.1, 9.6.1.1, 10.3.1.1.4, Box 11.2, 14.8.5 contain relevant information regarding the evaluation of
 16 models in this region, the model spread in the context of other methods of projecting changes and the role of
 17 modes of variability and other climate phenomena.

3 **Figure AI.33:** Top left: time series of temperature change relative to 1986–2005 averaged over land grid
 4 points in the West Coast of South America ($79.7^{\circ}\text{W}, 1.2^{\circ}\text{S}$; $66.4^{\circ}\text{W}, 20^{\circ}\text{S}$; $72.1^{\circ}\text{W}, 50^{\circ}\text{S}$; $67.3^{\circ}\text{W}, 56.7^{\circ}\text{S}$;
 5 $82.0^{\circ}\text{W}, 56.7^{\circ}\text{S}$; $82.2^{\circ}\text{W}, 0.5^{\circ}\text{N}$) in June–August. Top right: same for land grid points in Southeastern South America
 6 ($39.4^{\circ}\text{W}, 20^{\circ}\text{S}$; $39.4^{\circ}\text{W}, 56.6^{\circ}\text{S}$; $67.3^{\circ}\text{W}, 56.7^{\circ}\text{S}$; $72.1^{\circ}\text{W}, 50^{\circ}\text{S}$; $66^{\circ}\text{W}, 20^{\circ}\text{S}$). Thin lines denote one ensemble
 7 member per model, thick lines the CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th
 8 (median), 75th and 95th percentiles of the distribution of 20-yr mean changes are given for 2081–2100 in the
 9 four RCP scenarios.

10 Below: maps of temperature changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 11 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 12 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 13 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 14 present-day natural variability of 20-yr mean differences.

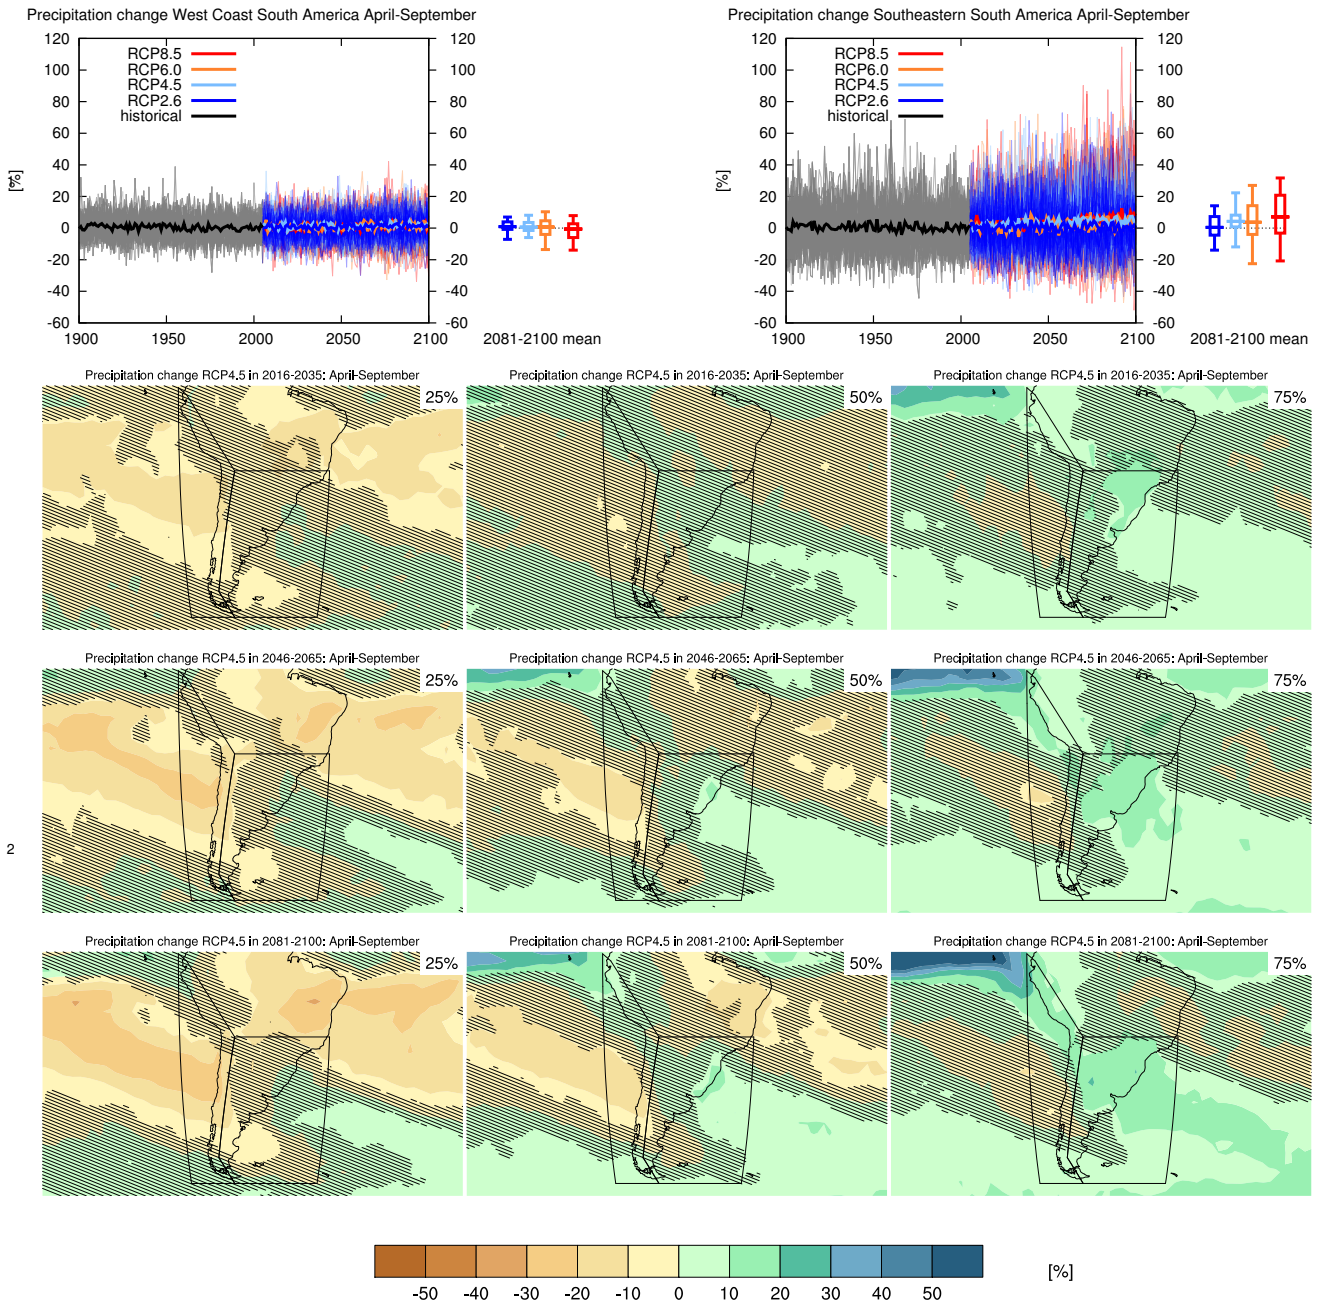

15 Sections 9.4.1.1, 9.6.1.1, 10.3.1.1.4, Box 11.2, 14.8.5 contain relevant information regarding the evaluation of
 16 models in this region, the model spread in the context of other methods of projecting changes and the role of
 17 modes of variability and other climate phenomena.

3 **Figure AI.34:** Top left: time series of relative change relative to 1986–2005 in precipitation averaged over land
 4 grid points in the West Coast of South America (79.7°W,1.2°S; 66.4°W,20°S; 72.1°W,50°S; 67.3°W,56.7°S;
 5 82.0°W 56.7°S; 82.2°W,0.5°N) in October–March. Top right: same for land grid points in Southeastern South
 6 America (39.4°W,20°S; 39.4°W,56.6°S; 67.3°W,56.7°S; 72.1°W,50°S; 66°W,20°S). Thin lines denote one en-
 7 semble member per model, thick lines the CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th
 8 (median), 75th and 95th percentiles of the distribution of 20-yr mean changes are given for 2081–2100 in the
 9 four RCP scenarios.

 4 in Southern Africa (35°–11.4°S, 10°W–52°E) in December–February. Top right: same for sea grid points in
 5 the West Indian Ocean (25°S–5°N, 52°–75°E). Thin lines denote one ensemble member per model, thick lines
 6 the CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th (median), 75th and 95th
 7 percentiles of the distribution of 20-yr mean changes are given for 2081–2100 in the four RCP scenarios.

8 Below: maps of temperature changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 9 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 10 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 11 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 12 present-day natural variability of 20-yr mean differences.

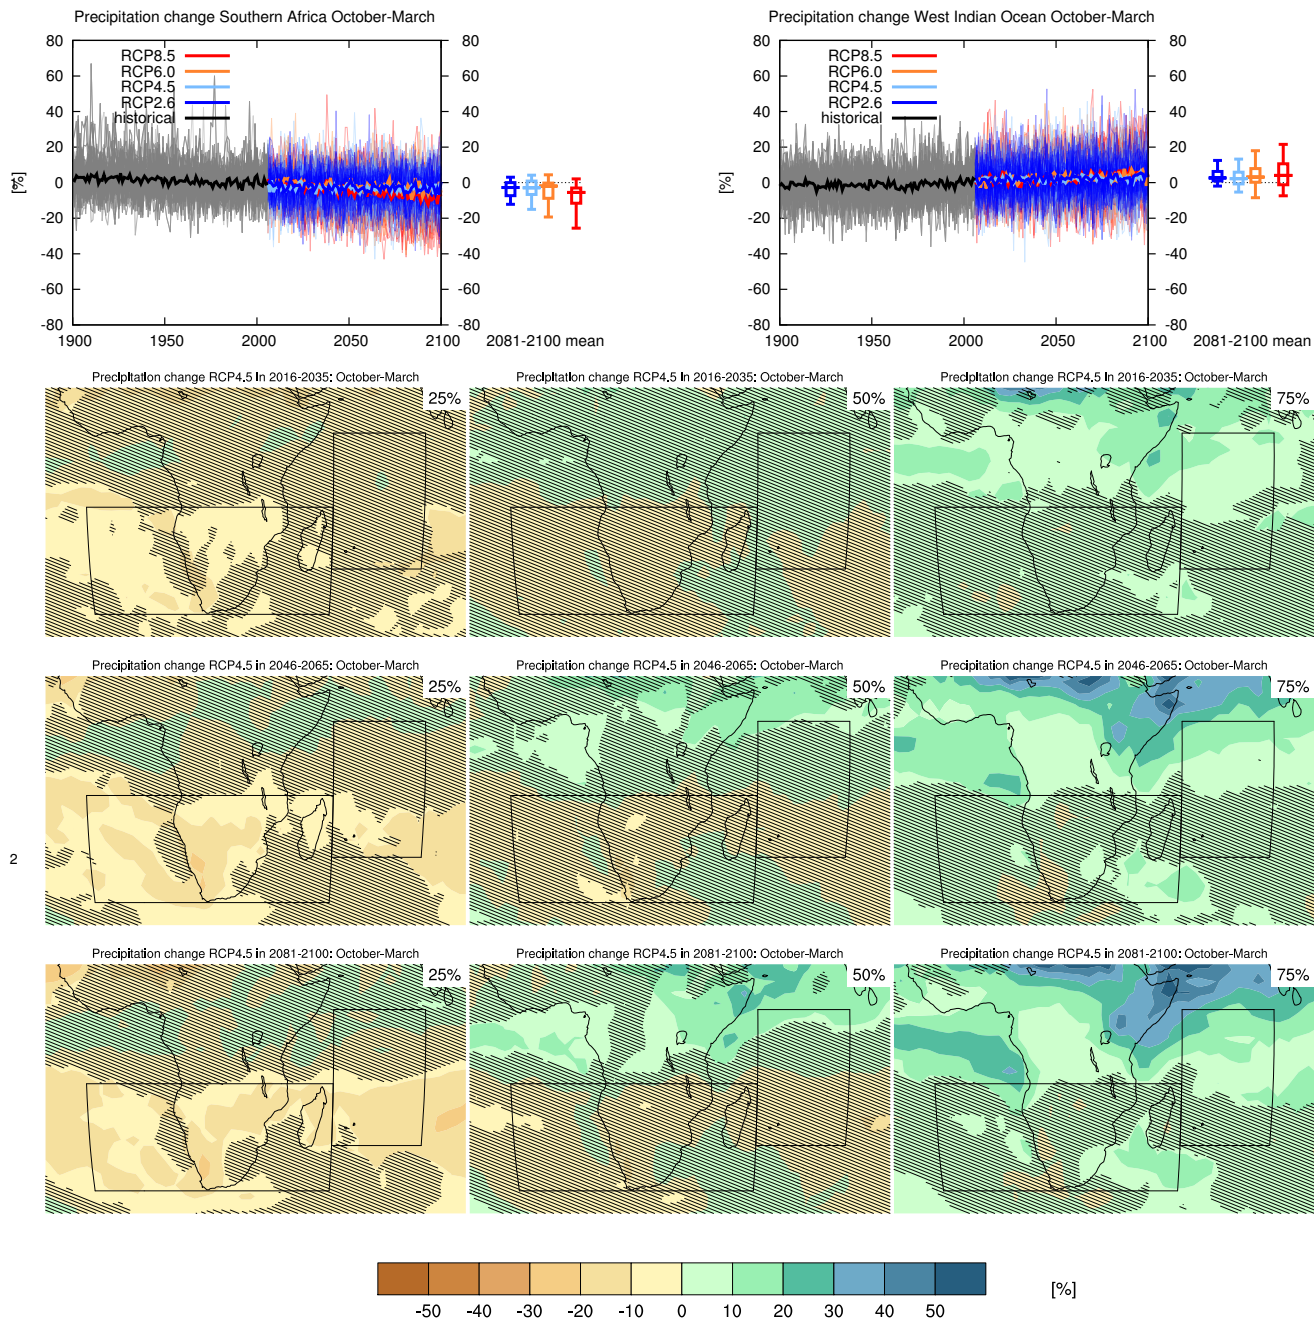

13 Sections 9.4.1.1, 9.6.1.1, 10.3.1.1.4, Box 11.2, 14.8.7 contain relevant information regarding the evaluation of
 14 models in this region, the model spread in the context of other methods of projecting changes and the role of
 15 modes of variability and other climate phenomena.

3 **Figure AI.49:** Top left: time series of temperature change relative to 1986–2005 averaged over land grid
 4 points in Southern Africa (35° – 11.4° S, 10° W– 52° E) in June–August. Top right: same for sea grid points in the
 5 West Indian Ocean (25° S– 5° N, 52° – 75° E). Thin lines denote one ensemble member per model, thick lines the
 6 CMIP5 multi-model mean. On the right-hand side the 5th, 25th, 50th (median), 75th and 95th percentiles of
 7 the distribution of 20-yr mean changes are given for 2081–2100 in the four RCP scenarios.

8 Below: maps of temperature changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 9 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 10 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 11 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 12 present-day natural variability of 20-yr mean differences.

 14 models in this region, the model spread in the context of other methods of projecting changes and the role of
 15 modes of variability and other climate phenomena.

3 **Figure AI.65:** Top left: time series of temperature change relative to 1986–2005 averaged over land grid points
 4 in Southeast Asia (10°S – 20°N , 95° – 155°E) in June–August. Top right: same for sea grid points. Thin lines
 5 denote one ensemble member per model, thick lines the CMIP5 multi-model mean. On the right-hand side
 6 the 5th, 25th, 50th (median), 75th and 95th percentiles of the distribution of 20-yr mean changes are given for
 7 2081–2100 in the four RCP scenarios.

8 Below: maps of temperature changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 9 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 10 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 11 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 12 present-day natural variability of 20-yr mean differences.

13 Sections 9.4.1.1, 9.6.1.1, 10.3.1.1.4, Box 11.2, 14.8.12 contain relevant information regarding the evaluation of
 14 models in this region, the model spread in the context of other methods of projecting changes and the role of
 15 modes of variability and other climate phenomena.

3 **Figure AI.66:** Top left: time series of relative change relative to 1986–2005 in precipitation averaged over
 4 land grid points in Southeast Asia (10°S – 20°N , 95° – 155°E) in October–March. Top right: same for sea grid
 5 points. Thin lines denote one ensemble member per model, thick lines the CMIP5 multi-model mean. On the
 6 right-hand side the 5th, 25th, 50th (median), 75th and 95th percentiles of the distribution of 20-yr mean changes
 7 are given for 2081–2100 in the four RCP scenarios.

8 Below: maps of precipitation changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 9 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 10 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 11 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 12 present-day natural variability of 20-yr mean differences.

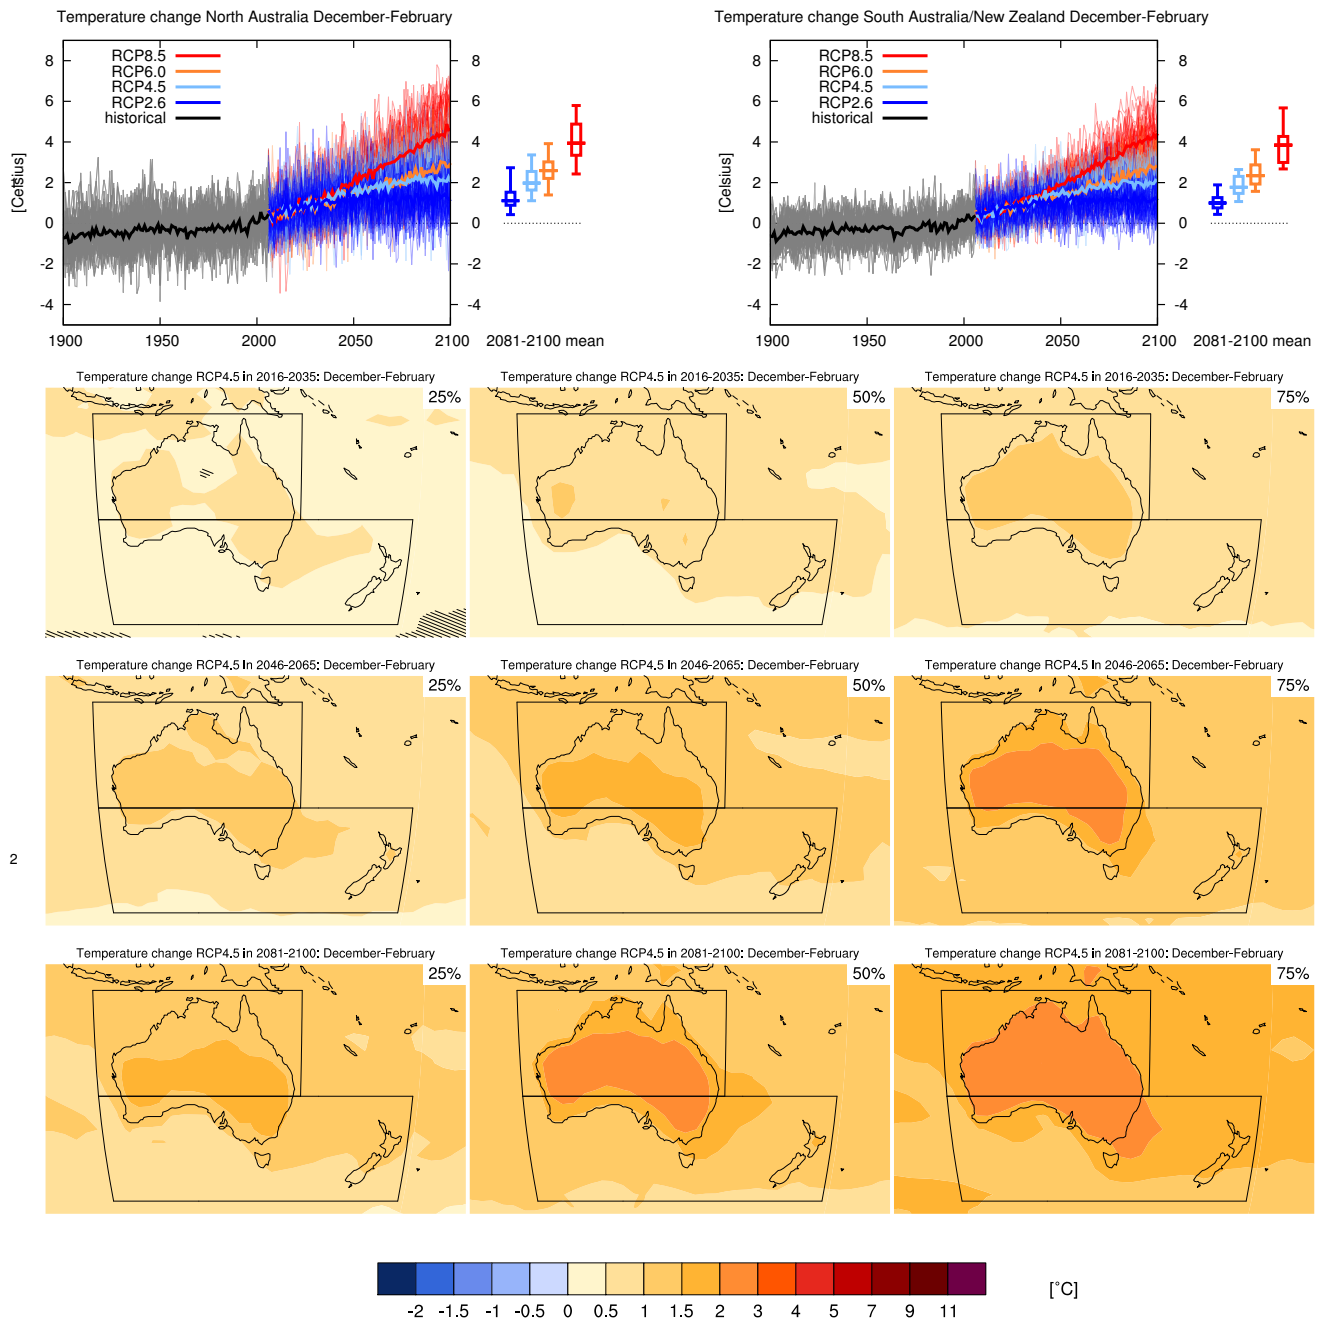

13 Sections 9.4.1.1, 9.6.1.1, Box 11.2, 14.2.2.3, 14.2.2.5, 14.8.12 contain relevant information regarding the eval-
 14 uation of models in this region, the model spread in the context of other methods of projecting changes and the
 15 role of modes of variability and other climate phenomena.

3 **Figure AI.67:** Top left: time series of relative change relative to 1986–2005 in precipitation averaged over
 4 land grid points in Southeast Asia (10°S – 20°N , 95° – 155°E) in April–September. Top right: same for sea grid
 5 points. Thin lines denote one ensemble member per model, thick lines the CMIP5 multi-model mean. On the
 6 right-hand side the 5th, 25th, 50th (median), 75th and 95th percentiles of the distribution of 20-yr mean changes
 7 are given for 2081–2100 in the four RCP scenarios.

8 Below: maps of precipitation changes in 2016–2035, 2046–2065 and 2081–2100 with respect to 1986–2005
 9 in the RCP4.5 scenario. For each point, the 25th, 50th and 75th percentile of the distribution of the CMIP5
 10 ensemble are shown, this includes both natural variability and inter-model spread. Hatching denotes areas
 11 where the 20-yr mean differences of the percentiles are less than the standard deviation of model-estimated
 12 present-day natural variability of 20-yr mean differences.

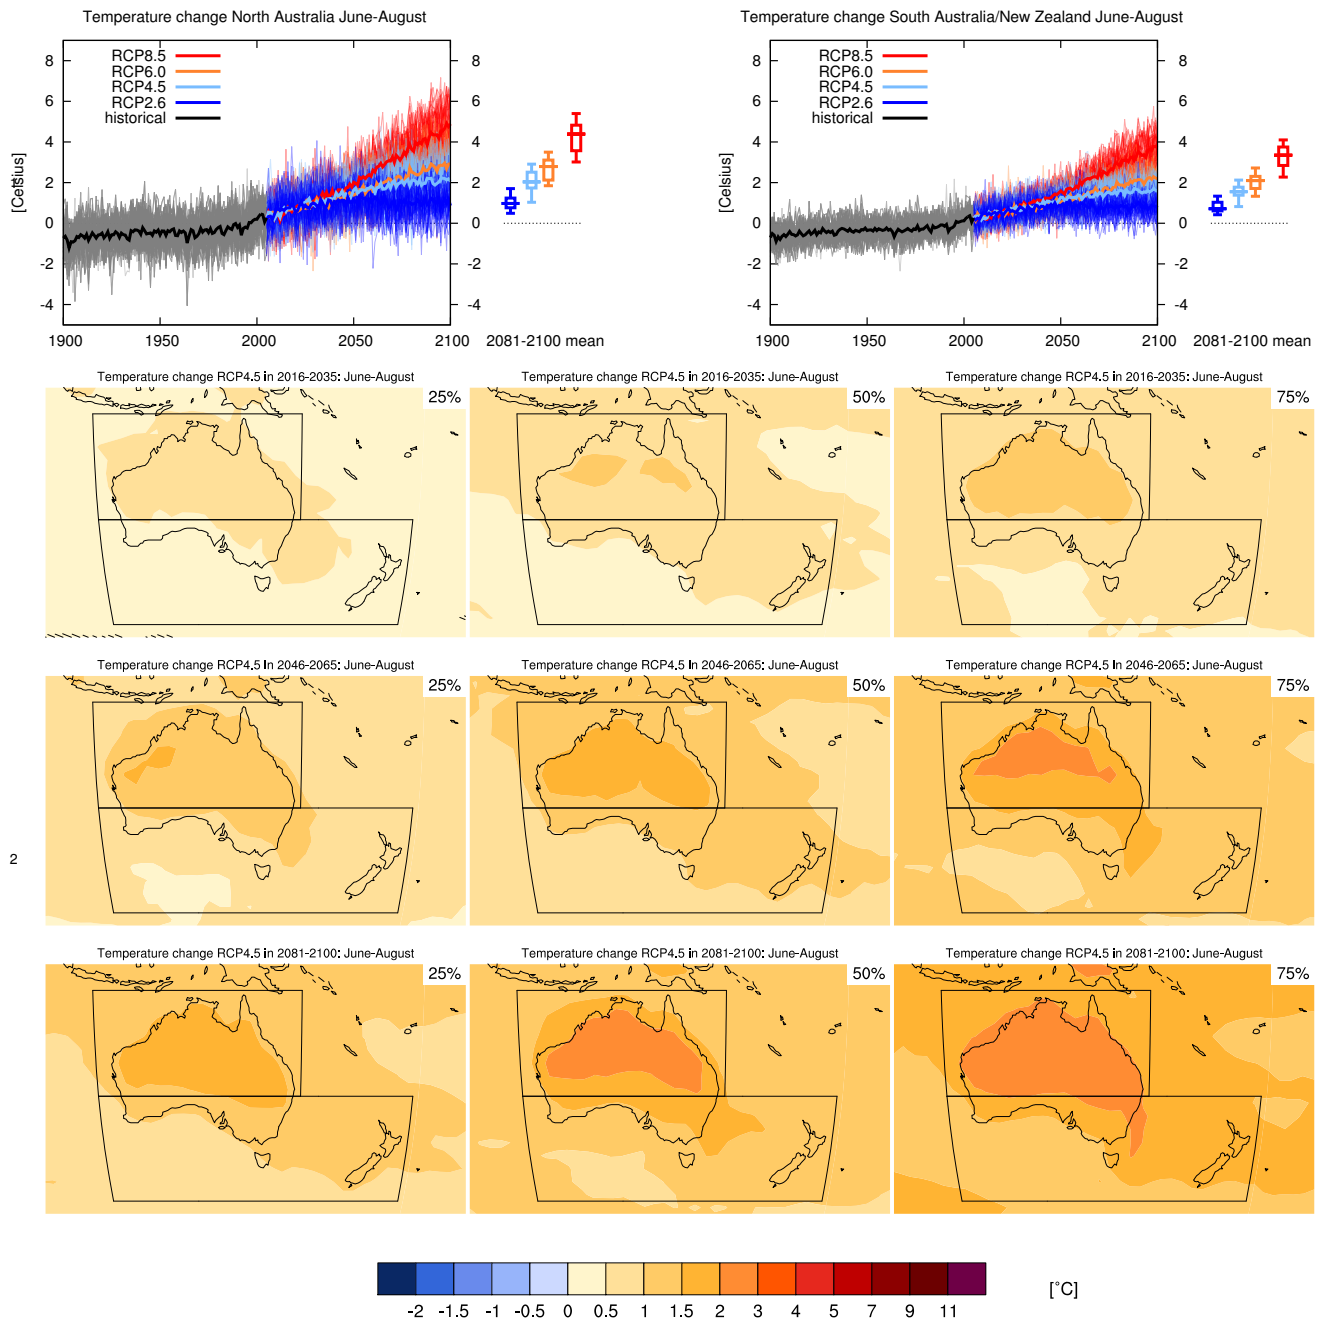

13 Sections 9.4.1.1, 9.6.1.1, Box 11.2, 14.2.2.3, 14.2.2.5, 14.8.12 contain relevant information regarding the eval-
 14 uation of models in this region, the model spread in the context of other methods of projecting changes and the
 15 role of modes of variability and other climate phenomena.

Date of Draft: 7 June 2013

Introduction

Annex II presents, in tabulated form, data related to historical and projected changes in the climate system that are assessed in the chapters of this report (see Section 1.6). It also includes some comparisons with the TAR and AR4 results. These data include values for emissions into the atmosphere, atmospheric abundances and burdens (integrated abundance), effective radiative forcing (ERF, includes adjusted forcing from aerosols, see Chapters 7 and 8), and global mean surface temperatures and sea level. Projections from 2010 to 2100 focus on the RCP scenarios (Moss et al., 2010; Lamarque et al., 2010; 2011; Meinshausen et al., 2011a; van Vuuren et al., 2011; see also Chapters 1, 6, 8, 11, 12, 13). Projections also include previous IPCC scenarios (IS92a, SRES A2 and B1, TAR Appendix II) and some alternative near-term scenarios for CH₄ and short-lived pollutants that impact climate or air quality. Emissions from biomass burning are included as anthropogenic. ERF from land use change is also included in some tables.

Where uncertainties or ranges are presented here, they are noted in each table as being a recommended value or model ensemble mean/median with a 68% confidence interval (16–84%, ± 1 sigma for a normal distribution) or 90% confidence interval (5–95%, ± 1.645 sigma for a normal distribution) or statistics (standard deviation, percentiles, or minimum/maximum) of an ensemble of models. In some cases these are a formal evaluation of uncertainty as assessed in the chapters, but in other cases (specifically Tables AII.2.1, 3.1, 4.1, 5.1, 6.10, 7.1–4, and 7.5) they just describe the statistical results from the available models, and the referenced chapters must be consulted for the assessed uncertainty or confidence level of these results. In the case of Table AII.7.5, for example, the global mean surface temperature change (°C) relative to 1986–2005 is a statistical summary of the spread in the CMIP ensembles for each of the scenarios: model biases and model dependencies are not accounted for; the percentiles do not correspond to the assessed uncertainty derived in Chapters 11 (Section 11.3.6.3) and 12 (Section 12.4.1); and statistical spread across models cannot be interpreted in terms of calibrated language (Section 12.2).

The RCP scenarios for emissions include only anthropogenic sources and use a single model to project from emissions to abundances to radiative forcing to climate change (Meinshausen et al., 2011a; 2011b). We include projected changes in natural CO₂ sources and sinks for 2010–2100 based on this assessment (Chapters 6, 12). Present-day natural and anthropogenic emissions of CH₄ and N₂O are assessed and used to scale the RCP anthropogenic emissions to be consistent with these best estimates (Chapters 6, 11). Current model evaluations of atmospheric chemistry and the carbon cycle, including results from the CMIP5 and ACCMIP projects, are used to project future composition and ERF separately from the RCP model (see Sections 6.4.3, 11.3.5, 12.3). Thus, projected changes in greenhouse gases, aerosols and ERF evaluated in this report may differ from the published RCPs and from what was used in the CMIP5 runs, and these are denoted RCP[&]. The CMIP5 climate projections used for the most part the RCP concentration pathways for WMGHG and the emissions pathways for O₃ and aerosol precursors. Such differences are discussed in the relevant chapters and noted in the tables.

For each species, the abundances (given as dry air mole fraction: ppm = micromoles per mole (10^{-6}); ppb = nanomoles per mole (10^{-9}); and ppt = picomoles per mole (10^{-12})), burdens (global total in grams, 1 Tg = 10^{12} g), average column amount (1 Dobson Unit (DU) = 2.687×10^{16} molecules per cm^2), AOD (mean aerosol optical depth at 550 nm), ERF (effective radiative forcing, W m^{-2}), and other climate system quantities are calculated for scenarios using methodologies based on the latest climate chemistry and climate carbon models (see Chapters 2, 6, 7, 8, 10, 11, 12). Results are shown for individual years (e.g., 2010 = year 2010) and decadal averages (e.g., 2020^d = average of years 2016 through 2025), although some ten-year periods are different, see table notes. Year 2011 is the last year for observed quantities (denoted 2011* or 2011^{obs}). Results are shown as global mean values except for environmental data focusing on air quality (AII.7.1–AII.7.4), which give regional mean surface abundances of O₃ and PM_{2.5}. Results for global mean surface temperature (AII.7.5 and AII.7.6) only show raw CMIP5 data or data from previous assessments. For best estimates of near-term and long-term temperature change see Chapters 11 and 12, respectively. Results for global mean sea level rise (AII.7.7) are assessed values with uncertainties described in Chapter 13.

Chemical Abbreviations and Symbols

Well Mixed Greenhouse Gases (WMGHG)

CO ₂	carbon dioxide (KP, Kyoto Protocol gas)
CH ₄	methane (KP)
N ₂ O	nitrous oxide (KP)
HFC	hydrofluorocarbon ¹ (a class of compounds: HFC-32, HFC-134a, ...) (KP)
PFC	perfluorocarbon (a class of compounds: CF ₄ , C ₂ F ₆ , ...) (KP)
SF ₆	sulphur hexafluoride (KP)
CFC	chlorofluorocarbon (a class of compounds: CFC1 ₃ , CF ₂ Cl ₂ , ...) (MP, Montreal Protocol gas)
HCFC	hydrochlorofluorocarbon ¹ (a class of compounds: HCFC-22, HCFC-141b, ...) (MP)
CCl ₄	carbon tetrachloride (MP)
CH ₃ CCl ₃	methyl chloroform (MP)

Ozone and Aerosols, and their Precursors

O ₃	ozone (both stratospheric and tropospheric)
NO _x	sum of NO (nitric oxide) and NO ₂ (nitrogen dioxide)
NH ₃	ammonia
CO	carbon monoxide
NMVOC	a class of compounds comprising all non-methane volatile organic compounds (i.e., hydrocarbons that may also contain oxygen, also known as biogenic VOC or NMHC)
OH	hydroxyl radical
PM _{2.5}	any aerosols with diameter less than 2.5 micrometers
BC	black carbon aerosol
OC	organic carbon aerosol
SO ₂	sulphur dioxide, a gas
SO _x	oxidized sulphur in gaseous form, including SO ₂
SO ₄ ⁼	sulphate ion, usually as sulphuric acid or ammonium sulphate in aerosol

List of Tables

AII.1: Historical Climate System Data

Table AII.1.1a: Historical abundances of the Kyoto greenhouse gases

Table AII.1.1b: Historical abundances of the Montreal Protocol greenhouse gas (all ppt)

Table AII.1.2: Historical effective radiative forcing (ERF) (W m^{-2}), including land use change (LUC)

Table AII.1.3: Historical global decadal-mean global surface-air temperature ($^{\circ}\text{C}$) relative to 1961–1990 average

AII.2: Anthropogenic Emissions

Table AII.2.1a: Anthropogenic CO₂ emissions from fossil fuels and other industrial sources (FF) (PgC yr^{-1})

Table AII.2.1b: Anthropogenic CO₂ emissions from agriculture, forestry, land use (AFOLU) (PgC yr^{-1})

Table AII.2.1c: Anthropogenic total CO₂ emissions (PgC yr^{-1})

¹ A few HFCs and HCFCs are very short lived in the atmosphere and therefore not well mixed.

Table AII.2.2: Anthropogenic CH₄ emissions (Tg yr⁻¹)
Table AII.2.3: Anthropogenic N₂O emissions (TgN yr⁻¹)
Table AII.2.4: Anthropogenic SF₆ emissions (Gg yr⁻¹)
Table AII.2.5: Anthropogenic CF₄ emissions (Gg yr⁻¹)
Table AII.2.6: Anthropogenic C₂F₆ emissions (Gg yr⁻¹)
Table AII.2.7: Anthropogenic C₆F₁₄ emissions (Gg yr⁻¹)
Table AII.2.8: Anthropogenic HFC-23 emissions (Gg yr⁻¹)
Table AII.2.9: Anthropogenic HFC-32 emissions (Gg yr⁻¹)
Table AII.2.10: Anthropogenic HFC-125 emissions (Gg yr⁻¹)
Table AII.2.11: Anthropogenic HFC-134a emissions (Gg yr⁻¹)
Table AII.2.12: Anthropogenic HFC-143a emissions (Gg yr⁻¹)
Table AII.2.13: Anthropogenic HFC-227ea emissions (Gg yr⁻¹)
Table AII.2.14: Anthropogenic HFC-245fa emissions (Gg yr⁻¹)
Table AII.2.15: Anthropogenic HFC-43-10mee emissions (Gg yr⁻¹)
Table AII.2.16: Anthropogenic CO emissions (Tg yr⁻¹)
Table AII.2.17: Anthropogenic NMVOC emissions (Tg yr⁻¹)
Table AII.2.18: Anthropogenic NO_x emissions (TgN yr⁻¹)
Table AII.2.19: Anthropogenic NH₃ emissions (TgN yr⁻¹)
Table AII.2.20: Anthropogenic SO_x emissions (TgS yr⁻¹)
Table AII.2.21: Anthropogenic OC aerosols emissions (Tg yr⁻¹)
Table AII.2.22: Anthropogenic BC aerosols emissions (Tg yr⁻¹)
Table AII.2.23: Anthropogenic nitrogen fixation (Tg-N yr⁻¹)

AII.3: Natural Emissions

Table AII.3.1a: Net land (natural and land use) CO₂ emissions (PgC yr⁻¹)
Table AII.3.1b: Net ocean CO₂ emissions (PgC yr⁻¹)

AII.4: Abundances of the Well Mixed Greenhouse Gases

Table AII.4.1: CO₂ abundance (ppm)
Table AII.4.2: CH₄ abundance (ppb)
Table AII.4.3: N₂O abundance (ppb)
Table AII.4.4: SF₆ abundance (ppt)
Table AII.4.5: CF₄ abundance (ppt)
Table AII.4.6: C₂F₆ abundance (ppt)
Table AII.4.7: C₆F₁₄ abundance (ppt)
Table AII.4.8: HFC-23 abundance (ppt)
Table AII.4.9: HFC-32 abundance (ppt)
Table AII.4.10: HFC-125 abundance (ppt)
Table AII.4.11: HFC-134a abundance (ppt)
Table AII.4.12: HFC-143a abundance (ppt)
Table AII.4.13: HFC-227ea abundance (ppt)
Table AII.4.14: HFC-245fa abundance (ppt)
Table AII.4.15: HFC-43-10mee abundance (ppt)
Table AII.4.16: Montreal Protocol greenhouse gas abundances (ppt)

AII.5: Column Abundances, Burdens, and Lifetimes

Table AII.5.1: Stratospheric O₃ column changes (DU)
Table AII.5.2: Tropospheric O₃ column changes (DU)
Table AII.5.3: Total aerosol optical depth (AOD)
Table AII.5.4: Absorbing aerosol optical depth (AAOD)
Table AII.5.5: Sulphate aerosol atmospheric burden (TgS)
Table AII.5.6: OC aerosol atmospheric burden (Tg)
Table AII.5.7: BC aerosol atmospheric burden (Tg)
Table AII.5.8: CH₄ atmospheric lifetime (yr) against loss by tropospheric OH
Table AII.5.9: N₂O atmospheric lifetime (yr)

AII.6: Effective Radiative Forcing

Table AII.6.1: ERF from CO₂ (W m⁻²)
Table AII.6.2: ERF from CH₄ (W m⁻²)
Table AII.6.3: ERF from N₂O (W m⁻²)
Table AII.6.4: ERF from all HFCs (W m⁻²)
Table AII.6.5: ERF from all PFCs and SF₆ (W m⁻²)

Table AII.6.6: ERF from Montreal Protocol greenhouse gases (W m^{-2})

Table AII.6.7a: ERF from stratospheric O_3 changes since 1850 (W m^{-2})

Table AII.6.7b: ERF from tropospheric O_3 changes since 1850 (W m^{-2})

Table AII.6.8: Total anthropogenic ERF from published RCPs and SRES (W m^{-2})

Table AII.6.9: ERF components relative to 1850 (W m^{-2}) derived from ACCMIP

Table AII.6.10: Total anthropogenic plus natural ERF (W m^{-2}) from CMIP5 and CMIP3, including historical

AII.7: Environmental Data

Table AII.7.1: Global mean surface O_3 change (ppb)

Table AII.7.2: Surface O_3 change (ppb) for HTAP regions

Table AII.7.3: Surface O_3 change (ppb) from CMIP5/ACCMIP for continental regions

Table AII.7.4: Surface particulate matter change ($\log_{10}[\text{PM}_{2.5} \text{ (microgram/m}^3\text{)}]$) from CMIP5/ACCMIP for continental regions

Table AII.7.5: CMIP5 (RCP) and CMIP3 (SRES A1B) global mean surface temperature change ($^{\circ}\text{C}$) relative to 1986–2005 reference period

Table AII.7.6: Global mean surface temperature change ($^{\circ}\text{C}$) relative to 1990 from the TAR

Table AII.7.7: Global mean sea level rise (m) with respect to 1986–2005 at 1 January on the years indicated

Notes:

Abundances are mole fraction of dry air for the lower, well mixed atmosphere (ppm = micromoles/mole, ppb = nanomoles/mole, ppt = picomoles/mole). Values refer to single-year average. Uncertainties (5–95% confidence intervals) are only given for 2011 when more than one laboratory reports global data. Pre-industrial (PI*, taken to be 1750 for GHG) and present day (2011*) abundances are from Chapter 2, Tables 2.1 and 2.SM.1; see also Chapter 6 for Holocene variability (10 ppm CO₂, 40 ppb CH₄, 10 ppb N₂O). Intermediate data for CO₂, CH₄, and N₂O are from Chapters 2 and 8, Figure 8.6. See also Appendix 1.A. Intermediate data for the F-gases are taken from Meinshausen et al. (2011).

Notes:

See Figure 8.18, also Sections 8.1 and 11.3.6.1. To get the total ERF (Effective Radiative Forcing) all components can be summed. Small negative values for CO₂ prior to 1800 are due to uncertainty in PI values. GHG other* includes only WMGHG. Aerosol is the sum of direct and indirect effects. LUC includes land use land cover change. Contrails combines aviation contrails (~20% of total) and contrail-induced cirrus.

Table AII.1.3: Historical global decadal-mean global surface-air temperature (°C) relative to 1961–1990 average

1946–2012 minus 1880–1945		+0.38 ± 0.04		+0.40	+0.39

Notes:

Decadal average (1990^d = 1990–1999) median global surface air temperatures from HadCRUT4, GISS, and NCDC analyses. See Chapter 2, Sections 2.4.3 and 2.SM.4.3.3, Table 2.7, Figures 2.19, 2.20, 2.21 and 2.22, and also Figure 11.24a. Confidence intervals (5–95% for HadCRUT4 only) take into account measurement, sampling, bias and coverage uncertainties. Also shown are temperature increases between the CMIP5 reference period (1986–2005) and four earlier averaging periods, where 1850–1900 is taken as pre-industrial for the temperature record. Uncertainties in these temperature differences are 5–95% confidence intervals.

Annex II.2: Anthropogenic Emissions

See discussion Figure 8.2 and Section 11.3.5.

Notes:

Decadal mean values (2010^d = average of 2005–2014) are used for emissions because linear interpolation between decadal means conserves total emissions. Data are taken from RCP database (Meinshausen et al., 2011a);

<http://www.iiasa.ac.at/web-apps/tnt/RcpDb>) and may be different from yearly snapshots; for 2100 the average (2095–2100) is used. SRES A2 and B1 and IS92a are taken from TAR Appendix II. RCPn.n[&] values are inferred from ESMS used in CMIP5. The model mean and standard deviation is shown. ESM fossil emissions are taken from 14 models as described in Jones et al. (2013) although not every model has performed every scenario. See Chapter 6, Sections 6.4.3, 6.4.3.3, and Figure 6.25.

Notes:

For all anthropogenic emissions see Box 1.1 (Figure 4), Section 8.2.2, Figure 8.2, Sections 11.3.5.1.1–3, 11.3.5.2, 11.3.6.1. Ten-year average values (2010^d = average of 2005–2014; but 2100^d = average of 2095–2100) are given for RCP-based emissions, but single-year emissions are shown for other scenarios. RCPn.n = harmonized anthropogenic emissions as reported. SRES A2 and B1 and IS92a are from TAR Appendix II. AR5 RCPn.n[&] emissions have ± 1-sigma (16–84% confidence) uncertainties and are based on the methodology of Prather et al. (2012) updated with CMIP5 results (Holmes et al., 2013; Voulgarakis et al., 2013). Projections of CH₄ lifetimes are harmonized based on PI (1750) and PD (2010) budgets that include uncertainties in lifetimes and abundances. All projected RCP abundances for CH₄ and N₂O (AII.4.2–3) rescale each of the RCP emissions by a fixed factor equal to the ratio of RCP to AR5 anthropogenic emissions at year 2010 to ensure harmonization between total emissions, lifetimes, and observed abundances. Natural emissions are kept constant but included as additional uncertainty. Independent emission estimates are shown as follows: MFR/CLE are the maximum feasible reduction and current legislation scenarios from Dentener et al. (2005; 2006), while MFR*/CLE* are the similarly labeled scenarios from Cofala et al. (2007). REF^L/REF^U are Lower/Upper bounds from the reference scenario of van Vuuren et al. (2008), while POL^L/POL^U are the Lower/Upper bounds from their policy scenario. AME^L/AME^U are Lower/Upper bounds from Calvin et al. (2012). Rog^L/Rog^U are Lower/Upper bounds from Rogelj et al. (2011).

Notes:

For observations (2011^{obs}) see Chapter 2; and for projections see Box 1.1 (Figure 2), Sections 6.4.3.1, 11.3.1.1, 11.3.5.1.1. RCPn.n refers to values taken directly from the published RCP scenarios using the MAGICC model (Meinshausen et al., 2011a; 2011b). These are harmonized to match observations up to 2005 (378.8 ppm) and project future abundances thereafter. RCP8.5[&] shows the average and assessed 90% confidence interval for year 2100, plus the

min-max full range derived from the CMIP5 archive for all years (P. Friedlingstein, based on Friedlingstein et al., 2006). 11 ESMs participated (BCC-CSM-1, CanESM2, CESM1-BGC, GFDL-ESM2G, HadGem-2ES, INMCM4, IPSLCM5-LR, MIROC-ESM, MPI-ESM-LR, MRI-ESM1, and Nor-ESM1-ME), running the RCP8.5 anthropogenic emission scenario forced by the RCP8.5 climate change scenario (see Figure 12.36). All abundances are mid-year. Projected values for SRES A2 and B1 and IS92 are the average of reference models taken from the TAR Appendix II.

Notes:

RCPn.n refers to values taken directly from the published RCP scenarios using the MAGICC model (Meinshausen et al., 2011b) and initialized in year 2005 at 1754 ppb. Values for SRES A2 and B1 and IS92 are from the TAR Appendix II. RCPn.n[&] values are best estimates with uncertainties (68% confidence intervals) from Chapter 11 (Section 11.3.5) based on Holmes et al. (2013) and using RCP[&] emissions and uncertainties tabulated above. For RCP[&] the PI, year 2011 and year 2010 values are based on observations. RCP models used slightly different PI abundances than recommended here (AII.1.1, Chapter 2).

Notes:

RCPn.n HFC abundances (Tables AII.4.8–15) are as reported (Meinshausen et al., 2011a). SRES A2 and B1 and IS92a (where available) are taken from TAR Appendix II. Observed values are shown for 2011 (see Chapter 2, and AII.1.1). The AR5 RCPn.n[&] abundances are calculated starting with observed abundances (adopted for 2010) and future tropospheric OH changes using the methodology of Prather et al. (2012), updated for uncertainty in lifetime and scenario changes in OH using Holmes et al. (2013) and ACCMIP results (Stevenson et al., 2013; Voulgarakis et al., 2013). Projected RCP_& abundances are best estimates with 68% confidence range as uncertainties. See also notes Tables AII.4.2 and AII.5.9.

2100		15	13	17	20

Notes:

Observed O₃ columns and trends taken from WMO (Douglass and Filetov, 2010) subtracting tropospheric column O₃ (AII.5.2) with uncertainty estimates driven by polar variability. CMIP5 RCP results are from Eyring et al. (2013). The multi-model mean is derived from the CMIP5 models with predictive (interactive or semi-offline) stratospheric and tropospheric ozone chemistry. The absolute value is shown for year 2000. All other years are differences relative to (minus) year 2000. The multi-model standard deviation is shown only for year 2000; it does not change much over time; and, representing primarily the spread in absolute O₃ column, it is larger than the standard deviation of the changes (not evaluated here). All models used the same projections for ozone depleting substances. Near-term differences in projected O₃ columns across scenarios reflect model sampling (i.e., different sets of models contributing to each RCP), while long-term changes reflect changes in N₂O, CH₄, and climate. See Section 11.3.5.1.2.

2090	18.0	-2.8	12.1		
2100	20.8	-3.9	13.2		

Notes:

RCP results from CMIP5 (Eyring et al., 2013) and ACCMIP (Young et al., 2013). For ACCMIP all models have interactive tropospheric ozone chemistry and are included, in contrast to the CMIP5 multi-model mean which includes only those models with predictive (interactive or semi-offline) stratospheric and tropospheric ozone chemistry. The absolute value is shown for year 2000. All other years are differences relative to (minus) year 2000. The multi-model standard deviation is shown only for year 2000; it does not change much over time; and, representing primarily the spread in absolute O₃ columns, it is larger than the standard deviation of the changes across individual models (not evaluated here). SRES values are from TAR Appendix II. CLE/MFR scenarios are from Dentener et al. (2005; 2006): CLE includes climate change, MFR does not. See Section 11.3.5.1.2.

Number of models	21	15	21	13	19

Notes:

Multi-model decadal global means (2030^d = 2025–2034, 2100^d = 2095–2100) from CMIP5 models reporting AOD. The number of models for each experiment indicated in the bottom row. The full range of models (given only for historical period for AOD and AAOD) is large and systematic in that models tend to scale relative to one another. Historical estimates for different RCPs vary because of the models included. RCP4.5 included the full set of CMIP5 models contributing aerosol results (21). The standard deviation of the models is 28% (AOD) and 62% (AAOD) (N. Mahowald, CMIP5 archive; Lamarque et al., 2013; Shindell et al., 2013). See Sections 11.3.5.1.3 and 11.3.6.1.

Notes:

RCPn.n[&] lifetimes based on best estimate with uncertainty for 2000–2010 (Prather et al., 2012) and then projecting changes in key factors (Holmes et al., 2013). All uncertainties are 68% confidence intervals. RCPn.n[^] lifetimes are from ACCMIP results (Voulgarakis et al., 2013) scaled to 11.2 ± 1.3 yr for year 2000; the ACCMIP mean and standard deviation in 2000 are 9.8 ± 1.5 yr. Projected ACCMIP values combine the present day uncertainty with the model standard deviation of future change. Note that the total atmospheric lifetime of CH₄ must include other losses (e.g., stratosphere, surface, tropospheric chlorine), and for 2010 it is 9.1 ± 0.9 yr, see Chapter 8, Section 11.3.5.1.1.

Table AII.6.6: ERF from Montreal Protocol greenhouse gases ($W m^{-2}$)

Year	Historical	WMO A1
2011*	0.328	
2020		0.33 ± 0.01
2030		0.29 ± 0.01
2040		0.24 ± 0.01
2050		0.20 ± 0.01
2060		0.17 ± 0.02
2070		0.15 ± 0.02
2080		0.13 ± 0.02
2090		0.11 ± 0.02
2100		0.10 ± 0.02

Notes:

See Table 8.3, 8.A.1. ERF is calculated from AR5 radiative efficiency and projected abundances in Scenario A1 of WMO/UNEP assessment (WMO 2010). The 68% confidence interval shown is approximated by combining uncertainty in the radiative efficiency of each gas ($\pm 6.1\%$) and the decay of each gas since 2010 from Table AII.4.16 ($\pm 15\%$). All sources of uncertainty are assumed to be independent (see Chapters 2, 8).

Table AII.6.7a: ERF from stratospheric O₃ changes since 1850 ($W m^{-2}$)

Year	AR5	CCMVal-2
1960		0.0
1980		-0.033
2000		-0.079
2011*	-0.05	
2050		-0.055
2100		-0.075

Notes:

AR5 results are from Chapter 8, see also Sections 11.3.5.1.2, 11.3.6.1. CCMVal-2 results (Cionni et al. 2011) are the multi-model average (13 chemistry-climate models) running a single scenario for stratospheric change: REF-B2 scenario of CCMVal-2 with SRES A1B climate scenario.

Table AII.6.7b: ERF from tropospheric O₃ changes since 1850 ($W m^{-2}$)

Year	AR5	RCP2.6	RCP4.5	RCP6.0	RCP8.5
1980		0.31 ± 0.05	0.31 ± 0.05	0.31 ± 0.05	0.31 ± 0.05
2000		0.36	0.36	0.36	0.36
2011*	0.40				
2030		0.32	0.38	0.36	0.44
2100		0.17	0.27	0.27	0.60 ± 0.11

Notes:

AR5 results from Chapter 8, see also Sections 11.3.5.1.2, 11.3.6.1. Model mean results from ACCMIP (Stevenson et al., 2013) using a consistent model set (FGKN), which is similar to the all-model mean. Standard deviation across models shown for 1980s decade is similar for all scenarios except for RCP8.5 at 2100, which is twice as large.

Table AII.6.8: Total anthropogenic ERF from published RCPs and SRES ($W m^{-2}$)

Year	RCP2.6	RCP4.5	RCP6.0	RCP8.5	A2	A1B	B1	IS92a	AR5 Historical
1850	0.12	0.12	0.12	0.12					0.06
1990	1.23	1.23	1.23	1.23	1.03	1.03	1.03	1.03	1.60
2000	1.45	1.45	1.45	1.45	1.33	1.33	1.33	1.31	1.87
2010	1.81	1.81	1.78	1.84	1.74	1.65	1.73	1.63	2.25
2020	2.25	2.25	2.15	2.32	2.04	2.16	2.15	2.00	
2030	2.52	2.67	2.52	2.91	2.56	2.84	2.56	2.40	
2040	2.65	3.07	2.82	3.61	3.22	3.61	2.93	2.82	
2050	2.64	3.42	3.20	4.37	3.89	4.16	3.30	3.25	
2060	2.55	3.67	3.58	5.13	4.71	4.79	3.65	3.76	
2070	2.47	3.84	4.11	5.89	5.56	5.28	3.92	4.24	
2080	2.41	3.90	4.60	6.60	6.40	5.62	4.09	4.74	
2090	2.35	3.91	4.93	7.32	7.22	5.86	4.18	5.26	
2100	2.30	3.94	5.15	7.97	8.07	6.05	4.19	5.79	

Notes:

Derived from RCP published CO₂-eq concentrations that aggregate all anthropogenic forcings including greenhouse gases plus aerosols. These results may not be directly comparable to ERF values used in AR5 because of how aerosol indirect effects are included, but results are similar to those derived using ERF in Chapter 12 (see Figure 12.4).

Comparisons with the TAR Appendix II (SRES A2 and B1) may not be equivalent because those total RF values (TAR II.3.11) were made using the TAR Chapter 9 Simple Model, not always consistent with the individual components in that appendix (TAR II.3.1–9). See Chapter 1, Sections 11.3.6.1, 12.3.1.3–4, Figures 12.3–4. For AR5 Historical, see AII.1.2 and Chapter 8.

Table AII.6.9: ERF components relative to 1850 (W m⁻²) derived from ACCMIP

Year		WMGHG	Ozone	Aerosol	ERF Net
1930		0.58 ± 0.04	0.09 ± 0.03	-0.24 ± 0.06	0.44 ± 0.07
1980		1.56 ± 0.10	0.30 ± 0.10	-0.90 ± 0.22	1.00 ± 0.26
2000		2.30 ± 0.14	0.33 ± 0.11	-1.17 ± 0.28	1.51 ± 0.33
2030	RCP8.5	3.64 ± 0.22	0.43 ± 0.12	-0.91 ± 0.22	3.20 ± 0.33
2100	RCP2.6	2.83 ± 0.17	0.14 ± 0.07	-0.12 ± 0.06*	2.86 ± 0.19
2100	RCP4.5	4.33 ± 0.26	0.23 ± 0.09	-0.12 ± 0.06*	4.44 ± 0.28
2100	RCP6.0	5.60 ± 0.34	0.25 ± 0.05	-0.12 ± 0.06*	5.74 ± 0.35
2100	RCP8.5	8.27 ± 0.50	0.55 ± 0.18	-0.12 ± 0.03	8.71 ± 0.53

Notes:

Radiative forcing and adjusted forcing from the ACCMIP results (Shindell et al., 2013) are given for all well mixed greenhouse gases (WMGHG), ozone, aerosols, and the net. Original 90% confidence intervals have been reduced to 68% confidence to compare with the CMIP5 model standard deviations in AII.6.10. Some uncertainty ranges (*) are estimated from the 2100 RCP8.5 results (see Chapter 12). See Sections 11.3.5.1.3, 11.3.6.1, Figure 12.4.

Table AII.6.10: Total anthropogenic plus natural ERF (W m⁻²) from CMIP5 and CMIP3, including historical

Year	SRES A1B	RCP2.6 ^{&}	RCP4.5 ^{&}	RCP6.0 ^{&}	RCP8.5 ^{&}

2090 ^d	6.00 ± 0.83	2.44 ± 0.49	3.78 ± 0.58	4.64 ± 0.71	7.13 ± 0.89
2081–2100	5.99 ± 0.78	2.40 ± 0.46	3.73 ± 0.56	4.56 ± 0.70	7.02 ± 0.92

Notes:

CMIP5 historical and RCP results (Forster et al., 2013) are shown with CMIP3 SRES A1B results (Forster and Taylor, 2006). The alternative results for 1986–2005 with CMIP5 are derived from: all models contributing historical experiments (1986–2005^H), and the subsets of models contributing to each RCP experiment (next line, 1986–2005). For SRES A1B the same set of models is used from 1850 to 2100. Values are ten-year averages (2090^d = 2086–2095) and show multi-model means and standard deviations. See Chapter 12, Section 12.3 and discussion of Figure 12.4, also Figure 1.15, Sections 8.1, 9.3.2.2, 11.3.6.1, 11.3.6.3. Due to lack of reporting, for RCP8.5 the 2081–2100 result contains one fewer model than the 2090^d decade, and for A1B the 1850s result has just 5 models and the 2081–2100 result has 3 fewer models than the 2090^d decade.

Notes:

HTAP results are from Wild et al. (2012) and use the published O₃ sensitivities to regional emissions from the HTAP multi-model study (HTAP 2010) and scale those O₃ changes to the RCP emission scenarios. The ±1 standard deviation (68% confidence interval) over the range of 14 parametric models is shown for year 2000 and is similar for all years. Results from the SRES A2 and B1 scenarios are from the TAR OxComp studies diagnosed by Wild (Prather et al., 2001; 2003). CLE and MFR results (Dentener et al., 2005; 2006) include uncertainty (standard deviation of model results) in the change since year 2000, and CLE alone includes climate effects. The CMIP5 and ACCMIP results are from V. Naik and A. Fiore based on Fiore et al. (2012) and include the standard deviation over the models in year 2000, which is similar for following years. This does not necessarily reflect the uncertainty in the projected change, which may be smaller, see Fiore et al. (2012). The difference in year 2000 between CMIP5 (4 models) and ACCMIP (12

models) reflect different model biases. Even though ACCMIP only has three decades (2000, 2030, 2100), the greater number of models (5 to 11 depending on time slice and scenario) makes this a more robust estimate. See Chapter 11, ES, Section 11.3.5.2.2.

Notes:

Decadal average of the $\log_{10}[\text{PM}_{2.5}]$ values are given only where results include at least 4 models from either ACCMIP or CMIP5. Results are from A. Fiore and V. Naik based on Fiore et al. (2012) using the CMIP5/ACCMIP archive. Due to the very large systematic spread across models, the statistics were calculated for the log values, but Figure 11.23 shows statistics for direct $\text{PM}_{2.5}$ values. Due to the large spatial variations no global average is given. Model mean and standard deviation are shown for year 2000; differences in $\log_{10}[\text{PM}_{2.5}]$ are shown for 2030, 2050 and 2100. See notes for AII.7.3 and Figure 11.23 for regions, see also Chapter 11, ES.

Table AII.7.5: CMIP5 (RCP) and CMIP3 (SRES A1B) global mean surface temperature change (°C) relative to 1986–2005 reference period. Results here are a statistical summary of the spread in the CMIP ensembles for each of the scenarios. They do not account for model biases and model dependencies, and the percentiles do not correspond to the assessed uncertainty in Chapters 11 (11.3.6.3) and 12 (12.4.1). The statistical spread across models cannot be interpreted as uncertainty ranges or in terms of calibrated language (12.2).

Notes:

This spread in the model ensembles (as shown in Figures 11.26a and 12.5, and discussed in Section 11.3.6) is not a measure of uncertainty. For the AR5 assessment of global mean surface temperature changes and uncertainties see: Section 11.3.6.3 and Figure 11.25 for the near-term (2016–2035) temperatures; and Section 12.4.1 and Tables 12.2–3 for the long-term (2081–2100). See discussion about uncertainty and ensembles in Section 12.2, which explains how model spread is not equivalent to uncertainty. Results here are shown for the CMIP5 archive (Annex I, frozen as of March 15, 2013) for the RCPs and the similarly current CMIP3 archive for SRES A1B, which is not the same set of models used in AR4 (Figure SPM.5). Ten-year averages are shown (2030^d = 2026–2035). Temperature changes are relative to the reference period (1986–2005, defined as zero in this table), using CMIP5 for all four RCPs (G. J. van Oldenborgh, <http://climexp.knmi.nl/>; see Annex I for listing of models included) and CMIP3 for SRES A1B (22 models). The warming from pre-industrial (PI* = 1850–1900) to the modern reference period (1986–2005) is derived from HadCRUT4 observations as 0.61°C (C. Morice; see Chapter 2 and AII.1.3).

Annex III: Glossary

Editor: Serge Planton (France)

Date of Draft: 7 June 2013

This glossary defines some specific terms as the Lead Authors intend them to be interpreted in the context of this report.

Abrupt climate change A large-scale change in the *climate system* that takes place over a few decades or less, persists (or is anticipated to persist) for at least a few decades, and causes substantial disruptions in human and natural systems.

Active layer The layer of ground that is subject to annual thawing and freezing in areas underlain by *permafrost*.

Adjustment time See *Lifetime*. See also *Response time*.

Advection Transport of water or air along with its properties (e.g., temperature, chemical tracers) by winds or currents. Regarding the general distinction between advection and *convection*, the former describes transport by large-scale motions of the *atmosphere* or ocean, while convection describes the predominantly vertical, locally induced motions.

Aerosols A suspension of airborne solid or liquid particles, with a typical size between a few nm and 10 µm that reside in the *atmosphere* for at least several hours. Aerosols may be of either natural or *anthropogenic* origin. Aerosols may influence *climate* in several ways: directly through scattering and absorbing radiation (see *Aerosol-radiation interaction*), and indirectly by acting as *cloud condensation nuclei* or *ice nuclei*, modifying the optical properties and *lifetime* of clouds (see *Aerosol-cloud interaction*).

Aerosol-cloud interaction A process by which a perturbation to *aerosol* affects the microphysical properties and evolution of clouds through the aerosol role as *cloud condensation nuclei* or ice nuclei, particularly in ways that affect radiation or precipitation; such processes can also include the effect of clouds and precipitation on aerosol. The aerosol perturbation can be *anthropogenic* or come from some natural *source*. The *radiative forcing* from such interactions has traditionally been attributed to numerous *indirect aerosol effects*, but in this report, only two levels of radiative forcing (or effect) are distinguished:

Radiative forcing (or effect) due to aerosol-cloud interactions (RF_{aci}) The radiative forcing (or *radiative effect*, if the perturbation is internally generated) due to the change in number or size distribution of cloud droplets or ice crystals that is the proximate result of an aerosol perturbation, with other variables (in particular total cloud water content) remaining equal. In liquid clouds, an increase in cloud droplet concentration and surface area would increase the cloud *albedo*. This effect is also known as the *cloud albedo effect*, *first indirect effect*, or *Twomey effect*. It is a largely theoretical concept that cannot readily be isolated in observations or comprehensive process models due to the rapidity and ubiquity of *rapid adjustments*.

Effective radiative forcing (or effect) due to aerosol-cloud interactions (ERF_{aci}) The final radiative forcing (or effect) from the aerosol perturbation including the rapid adjustments to the initial change in droplet or crystal formation rate. These adjustments include changes in the strength of *convection*, precipitation efficiency, cloud fraction, *lifetime* or water content of clouds, and the formation or suppression of clouds in remote areas due to altered circulations.

The total effective radiative forcing due to both aerosol-cloud and aerosol-radiation interactions is denoted *aerosol effective radiative forcing (ERF_{ari+aci})*. See also *aerosol-radiation interaction*.

Aerosol-radiation interaction An interaction of *aerosol* directly with radiation produce *radiative effects*. In this report two levels of radiative forcing (or effect) are distinguished:

Radiative forcing (or effect) due to aerosol-radiation interactions (RFari) The *radiative forcing* (or radiative effect, if the perturbation is internally generated) of an aerosol perturbation due directly to aerosol-radiation interactions, with all environmental variables remaining unaffected. Traditionally known in the literature as the *direct aerosol forcing (or effect)*.

Effective radiative forcing (or effect) due to aerosol-radiation interactions (ERFari) The final radiative forcing (or effect) from the aerosol perturbation including the *rapid adjustments* to the initial change in radiation. These adjustments include changes in cloud caused by the impact of the radiative heating on convective or larger-scale atmospheric circulations, traditionally known as *semi-direct aerosol forcing (or effect)*.

The total effective radiative forcing due to both aerosol-cloud and aerosol-radiation interactions is denoted *aerosol effective radiative forcing (ERFari+aci)*. See also *aerosol-cloud interaction*.

Afforestation Planting of new *forests* on lands that historically have not contained forests. For a discussion of the term *forest* and related terms such as *afforestation*, *reforestation* and *deforestation*, see the IPCC Special Report on Land Use, Land-Use Change and Forestry (IPCC, 2000). See also the report on Definitions and Methodological Options to Inventory Emissions from Direct Human-induced Degradation of Forests and Devegetation of Other Vegetation Types (IPCC, 2003).

Airborne fraction The fraction of total *CO₂* emissions (from fossil fuel and land-use change) remaining in the *atmosphere*.

Air mass A widespread body of air, the approximately homogeneous properties of which (1) have been established while that air was situated over a particular *region* of the Earth's surface, and (2) undergo specific modifications while in transit away from the source region (AMS, 2000).

Albedo The fraction of *solar radiation* reflected by a surface or object, often expressed as a percentage. Snow-covered surfaces have a high albedo, the albedo of soils ranges from high to low, and vegetation-covered surfaces and oceans have a low albedo. The Earth's planetary albedo varies mainly through varying cloudiness, snow, ice, leaf area and land cover changes.

Alkalinity A measure of the capacity of an aqueous solution to neutralize acids.

Altimetry A technique for measuring the height of the Earth's surface with respect to the geocentre of the Earth within a defined terrestrial reference frame (geocentric sea level).

Annular modes See *Northern Annular Mode (NAM)* and *Southern Annular Mode (SAM)*.

Anthropogenic Resulting from or produced by human activities.

Atlantic Multi-decadal Oscillation/Variability (AMO/AMV) A multi-decadal (65 to 75 year) fluctuation in the North Atlantic, in which *sea surface temperatures* showed warm phases during roughly 1860 to 1880 and 1930 to 1960 and cool phases during 1905 to 1925 and 1970 to 1990 with a range of approximately 0.4°C. See AMO Index, Box 2.5.

Atmosphere The gaseous envelope surrounding the Earth. The dry atmosphere consists almost entirely of nitrogen (78.1% *volume mixing ratio*) and oxygen (20.9% *volume mixing ratio*), together with a number of trace gases, such as argon (0.93% *volume mixing ratio*), helium and radiatively active *greenhouse gases* such as *carbon dioxide* (0.035% *volume mixing ratio*) and *ozone*. In addition, the atmosphere contains the greenhouse gas water vapour, whose amounts are highly variable but typically around 1% *volume mixing ratio*. The atmosphere also contains clouds and *aerosols*.

Atmosphere-Ocean General Circulation Model (AOGCM) See *Climate model*.

Atmospheric boundary layer The atmospheric layer adjacent to the Earth's surface that is affected by friction against that boundary surface, and possibly by transport of heat and other variables across that surface (AMS, 2000). The lowest 100 metres of the boundary layer (about 10 % of the boundary layer thickness), where mechanical generation of turbulence is dominant, is called the *surface boundary layer* or *surface layer*.

Atmospheric lifetime See *Lifetime*.

Attribution See *Detection and attribution*.

Autotrophic respiration *Respiration* by *photosynthetic* (see *photosynthesis*) organisms (e.g. plants and algae).

Basal lubrication Reduction of friction at the base of an *ice sheet* or *glacier* due to lubrication by meltwater. This can allow the glacier or ice sheet to slide over its base. Meltwater may be produced by pressure-induced melting, friction or geothermal heat, or surface melt may drain to the base through holes in the ice.

Baseline/reference The baseline (or reference) is the state against which change is measured. A *baseline period* is the period relative to which anomalies are computed. The baseline concentration of a trace gas is that measured at a location not influenced by local *anthropogenic* emissions.

Bayesian method/approach A Bayesian method is a method by which a statistical analysis of an unknown or uncertain quantity(ies) is carried out in two steps. First, a prior probability distribution for the uncertain quantity(ies) is formulated on the basis of existing knowledge (either by eliciting expert opinion or by using existing data and studies). At this first stage, an element of subjectivity may influence the choice, but in many cases, the prior probability distribution can be chosen as neutrally as possible, in order not to influence the final outcome of the analysis. In the second step, newly acquired data are used to update the prior distribution into a posterior distribution. The update is carried out either through an analytic computation or through numeric approximation, using a theorem formulated by and named after the British mathematician Thomas Bayes (1702–1761).

Biological pump The process of transporting carbon from the ocean's surface layers to the deep ocean by the primary production of marine phytoplankton, which converts dissolved inorganic carbon (DIC) and nutrients into organic matter through *photosynthesis*. This natural cycle is limited primarily by the availability of light and nutrients like phosphate, nitrate and silicic acid, and micronutrients, such as iron. See also *Solubility pump*.

Biomass The total mass of living organisms in a given area or volume; dead plant material can be included as dead biomass. *Biomass burning* is the burning of living and dead vegetation.

Biome A biome is a major and distinct regional element of the *biosphere*, typically consisting of several *ecosystems* (e.g., *forests*, rivers, ponds, swamps within a *region*). Biomes are characterised by typical communities of plants and animals.

Biosphere (terrestrial and marine) The part of the Earth system comprising all *ecosystems* and living organisms, in the *atmosphere*, on land (*terrestrial biosphere*) or in the oceans (*marine biosphere*), including derived dead organic matter, such as litter, soil organic matter and oceanic detritus.

Black carbon (BC) Operationally defined *aerosol* species based on measurement of light absorption and chemical reactivity and/or thermal stability. It is sometimes referred to as *soot*.

Blocking Associated with persistent, slow-moving high-pressure systems that obstruct the prevailing westerly winds in the middle and high latitudes and the normal eastward progress of extra-tropical transient storm systems. It is an important component of the intraseasonal *climate variability* in the extratropics and can cause long-lived weather conditions such as cold spells in winter and summer *heat waves*.

Brewer-Dobson circulation The meridional overturning circulation of the *stratosphere* transporting air upward in the tropics, poleward to the winter hemisphere, and downward at polar and sub-polar latitudes. The Brewer-Dobson circulation is driven by the interaction between upward propagating planetary waves and the mean flow.

Burden The total mass of a gaseous substance of concern in the *atmosphere*.

¹³C Stable *isotope* of carbon having an atomic weight of approximately 13. Measurements of the ratio of ¹³C/¹²C in *carbon dioxide* molecules are used to infer the importance of different *carbon cycle* and climate processes and the size of the terrestrial carbon *reservoir*.

¹⁴C Unstable *isotope* of carbon having an atomic weight of approximately 14, and a half-life of about 5700 years. It is often used for dating purposes going back some 40 000 years. Its variation in time is affected by the magnetic fields of the Sun and Earth, which influence its production from cosmic rays (see *Cosmogenic radioisotopes*).

Calving The breaking off of discrete pieces of ice from a *glacier*, *ice sheet* or an *ice shelf* into lake or seawater, producing icebergs. This is a form of mass loss from an ice body. See also *mass balance/budget (of glaciers or ice sheets)*.

Carbonaceous aerosol *Aerosol* consisting predominantly of organic substances and *black carbon*.

Carbon cycle The term used to describe the flow of carbon (in various forms, e.g., as *carbon dioxide*) through the *atmosphere*, ocean, terrestrial and marine *biosphere* and *lithosphere*. In this report, the reference unit for the global carbon cycle is GtC or equivalently PgC (10¹⁵g).

Carbon dioxide (CO₂) A naturally occurring gas, also a by-product of burning fossil fuels from fossil carbon deposits, such as oil, gas and coal, of *burning biomass*, of *land use* changes and of industrial processes (e.g., cement production). It is the principal *anthropogenic greenhouse gas* that affects the Earth's radiative balance. It is the reference gas against which other greenhouse gases are measured and therefore has a *Global Warming Potential* of 1.

Carbon dioxide (CO₂) fertilization The enhancement of the growth of plants as a result of increased atmospheric *carbon dioxide (CO₂)* concentration.

Carbon Dioxide Removal (CDR) Carbon Dioxide Removal methods refer to a set of techniques that aim to remove *CO₂* directly from the *atmosphere* by either (1) increasing natural *sinks* for carbon or (2) using chemical engineering to remove the *CO₂*, with the intent of reducing the atmospheric *CO₂* concentration. CDR methods involve the ocean, land, and technical systems, including such methods as *iron fertilization*, large-scale *afforestation*, and direct capture of *CO₂* from the atmosphere using engineered chemical means. Some CDR methods fall under the category of *geoengineering*, while this may not be the case for others, with the distinction being based upon the magnitude, scale, and impact of the particular CDR activities. The boundary between CDR and *mitigation* is not clear and there could be some overlap between the two given current definitions (IPCC, 2012, p. 2). See also *Solar Radiation Management (SRM)*.

CFC See *Halocarbons*.

Chaotic A *dynamical system* such as the *climate system*, governed by nonlinear deterministic equations (see *Nonlinearity*), may exhibit erratic or chaotic behaviour in the sense that very small changes in the initial state of the system in time lead to large and apparently unpredictable changes in its temporal evolution. Such chaotic behaviour limits the *predictability* of the state of a nonlinear dynamical system at specific future times, although changes in its statistics may still be predictable given changes in the system parameters or boundary conditions.

Charcoal Material resulting from charring of *biomass*, usually retaining some of the microscopic texture typical of plant tissues; chemically it consists mainly of carbon with a disturbed graphitic structure, with lesser amounts of oxygen and hydrogen.

Chronology Arrangement of events according to dates or times of occurrence.

Clathrate (methane) A partly frozen slushy mix of *methane* gas and ice, usually found in sediments.

Clausius-Clapeyron equation/relationship The thermodynamic relationship between small changes in temperature and vapour pressure in an equilibrium system with condensed phases present. For trace gases such as water vapour, this relation gives the increase in equilibrium (or saturation) water vapour pressure per unit change in air temperature.

Climate Climate in a narrow sense is usually defined as the average weather, or more rigorously, as the statistical description in terms of the mean and variability of relevant quantities over a period of time ranging from months to thousands or millions of years. The classical period for averaging these variables is 30 years, as defined by the World Meteorological Organization. The relevant quantities are most often surface variables such as temperature, precipitation and wind. Climate in a wider sense is the state, including a statistical description, of the *climate system*.

Climate-carbon cycle feedback A *climate feedback* involving changes in the properties of land and ocean *carbon cycle* in response to *climate change*. In the ocean, changes in oceanic temperature and circulation could affect the *atmosphere*-ocean CO_2 flux; on the continents, climate change could affect plant *photosynthesis* and soil microbial *respiration* and hence the flux of CO_2 between the atmosphere and the land *biosphere*.

Climate change Climate change refers to a change in the state of the *climate* that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties, and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or *external forcings* such as modulations of the *solar cycles*, volcanic eruptions and persistent *anthropogenic* changes in the composition of the *atmosphere* or in *land use*. Note that the *Framework Convention on Climate Change (UNFCCC)*, in its Article 1, defines climate change as: ‘a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural *climate variability* observed over comparable time periods’. The UNFCCC thus makes a distinction between climate change attributable to human activities altering the atmospheric composition, and climate variability attributable to natural causes. See also *Climate change commitment, Detection and Attribution*.

Climate change commitment Due to the thermal inertia of the ocean and slow processes in the *cryosphere* and land surfaces, the *climate* would continue to change even if the atmospheric composition were held fixed at today’s values. Past change in atmospheric composition leads to a *committed climate change*, which continues for as long as a radiative imbalance persists and until all components of the *climate system* have adjusted to a new state. The further change in temperature after the composition of the *atmosphere* is held constant is referred to as the *constant composition temperature commitment* or simply *committed warming* or *warming commitment*. Climate change commitment includes other future changes, for example in the *hydrological cycle*, in *extreme weather events*, in *extreme climate events*, and in *sea level change*. The *constant emission commitment* is the committed climate change that would result from keeping *anthropogenic* emissions constant and the *zero emission commitment* is the climate change commitment when emissions are set to zero. See also *Climate change*.

Climate feedback An interaction in which a perturbation in one climate quantity causes a change in a second, and the change in the second quantity ultimately leads to an additional change in the first. A negative *feedback* is one in which the initial perturbation is weakened by the changes it causes; a positive feedback is one in which the initial perturbation is enhanced. In this Assessment Report, a somewhat narrower definition is often used in which the climate quantity that is perturbed is the *global mean surface temperature*, which in turn causes changes in the global radiation budget. In either case, the initial perturbation can either be externally forced or arise as part of *internal variability*. See also *Climate Feedback Parameter*.

Climate Feedback Parameter A way to quantify the radiative response of the *climate system* to a *global mean surface temperature* change induced by a *radiative forcing* (units: $W\ m^{-2}\ ^\circ C^{-1}$). It varies as the inverse

of the *effective climate sensitivity*. Formally, the Climate Feedback Parameter (Λ) is defined as: $\Lambda = (\Delta Q - \Delta F) / \Delta T$, where Q is the global mean radiative forcing, T is the global mean air surface temperature, F is the heat flux into the ocean and Δ represents a change with respect to an unperturbed *climate*.

Climate forecast See *Climate prediction*.

Climate index A time series constructed from climate variables that provides an aggregate summary of the state of the *climate system*. For example, the difference between sea-level pressure in Iceland and the Azores provides a simple yet useful historical *NAO* index. Because of their optimal properties, climate indices are often defined using *principal components* – linear combinations of climate variables at different locations that have maximum variance subject to certain normalisation constraints (e.g., the *NAM* and *SAM* indices which are principal components of Northern Hemisphere and Southern Hemisphere gridded pressure anomalies, respectively). See Box 2.5 for a summary of definitions for established observational indices. See also *Climate pattern*.

Climate model (spectrum or hierarchy) A numerical representation of the *climate system* based on the physical, chemical and biological properties of its components, their interactions and *feedback* processes, and accounting for some of its known properties. The climate system can be represented by models of varying complexity, that is, for any one component or combination of components a *spectrum* or *hierarchy* of models can be identified, differing in such aspects as the number of spatial dimensions, the extent to which physical, chemical or biological processes are explicitly represented, or the level at which empirical *parametrizations* are involved. Coupled *Atmosphere-Ocean General Circulation Models (AOGCMs)* provide a representation of the climate system that is near or at the most comprehensive end of the spectrum currently available. There is an evolution towards more complex models with interactive chemistry and biology. Climate models are applied as a research tool to study and simulate the *climate*, and for operational purposes, including monthly, seasonal and interannual *climate predictions*. See also *Earth System Model*, *Earth-System Model of Intermediate Complexity*, *Energy Balance Model*, *Process Based Model*, *Regional Climate Model* and *Semi-empirical model*.

Climate pattern A set of spatially varying coefficients obtained by “projection” (regression) of climate variables onto a *climate index* time series. When the climate index is a principal component, the climate pattern is an eigenvector of the covariance matrix, referred to as an *Empirical Orthogonal Function (EOF)* in climate science.

Climate prediction A climate prediction or *climate forecast* is the result of an attempt to produce (starting from a particular state of the *climate system*) an estimate of the actual evolution of the *climate* in the future, for example, at seasonal, interannual or decadal time scales. Since the future evolution of the *climate system* may be highly sensitive to initial conditions, such predictions are usually probabilistic in nature. See also *Climate projection*, *Climate scenario*, *Model initialization* and *Predictability*.

Climate projection A climate *projection* is the simulated response of the *climate system* to a *scenario* of future emission or concentration of *greenhouse gases* and *aerosols*, generally derived using *climate models*. Climate projections are distinguished from *climate predictions* by their dependence on the emission/concentration/*radiative forcing* scenario used, which is in turn based on assumptions concerning, for example, future socioeconomic and technological developments that may or may not be realised. See also *Climate scenario*.

Climate regime A state of the *climate system* that occurs more frequently than nearby states due to either more persistence or more frequent recurrence. In other words, a cluster in climate state space associated with a local maximum in the *probability density function*.

Climate response See *Climate sensitivity*.

Climate scenario A plausible and often simplified representation of the future *climate*, based on an internally consistent set of climatological relationships that has been constructed for explicit use in investigating the potential consequences of *anthropogenic climate change*, often serving as input to impact models. *Climate projections* often serve as the raw material for constructing climate scenarios, but climate

scenarios usually require additional information such as the observed current climate. A *climate change scenario* is the difference between a climate scenario and the current climate. See also *Emission scenario, scenario*.

Climate sensitivity In IPCC reports, *equilibrium climate sensitivity* (units: °C) refers to the equilibrium (steady state) change in the annual *global mean surface temperature* following a doubling of the atmospheric *equivalent carbon dioxide concentration*. Due to computational constraints, the equilibrium climate sensitivity in a *climate model* is sometimes estimated by running an atmospheric general circulation model coupled to a mixed-layer ocean model, because equilibrium climate sensitivity is largely determined by atmospheric processes. Efficient models can be run to equilibrium with a dynamic ocean. The *climate sensitivity parameter* (units: °C (W m⁻²)⁻¹) refers to the equilibrium change in the annual global mean surface temperature following a unit change in *radiative forcing*.

The *effective climate sensitivity* (units: °C) is an estimate of the global mean surface temperature response to doubled *carbon dioxide* concentration that is evaluated from model output or observations for evolving non-equilibrium conditions. It is a measure of the strengths of the *climate feedbacks* at a particular time and may vary with forcing history and *climate* state, and therefore may differ from equilibrium climate sensitivity.

The *transient climate response* (units: °C) is the change in the global mean surface temperature, averaged over a 20-year period, centred at the time of atmospheric carbon dioxide doubling, in a climate model simulation in which CO₂ increases at 1% yr⁻¹. It is a measure of the strength and rapidity of the surface temperature response to *greenhouse gas* forcing.

Climate sensitivity parameter See *climate sensitivity*.

Climate system The climate system is the highly complex system consisting of five major components: the *atmosphere*, the *hydrosphere*, the *cryosphere*, the *lithosphere* and the *biosphere*, and the interactions between them. The climate system evolves in time under the influence of its own internal dynamics and because of *external forcings* such as volcanic eruptions, solar variations and *anthropogenic forcings* such as the changing composition of the atmosphere and *land use change*.

Climate variability Climate variability refers to variations in the mean state and other statistics (such as standard deviations, the occurrence of extremes, etc.) of the *climate* on all *spatial and temporal scales* beyond that of individual weather events. Variability may be due to natural internal processes within the *climate system* (*internal variability*), or to variations in natural or *anthropogenic external forcing* (*external variability*). See also *Climate change*.

Cloud condensation nuclei (CCN) The subset of *aerosol* particles that serve as an initial site for the condensation of liquid water, which can lead to the formation of cloud droplets, under typical cloud formation conditions. The main factor that determines which aerosol particles are CCN at a given supersaturation is their size.

Cloud feedback A *climate feedback* involving changes in any of the properties of clouds as a response to a change in the local or *global mean surface temperature*. Understanding cloud feedbacks and determining their magnitude and sign require an understanding of how a change in *climate* may affect the spectrum of cloud types, the cloud fraction and height, the radiative properties of clouds, and finally the Earth's radiation budget. At present, cloud feedbacks remain the largest source of *uncertainty* in *climate sensitivity* estimates. See also *Cloud radiative effect*.

Cloud radiative effect The *radiative effect* of clouds relative to the identical situation without clouds. In previous IPCC reports this was called *cloud radiative forcing*, but that terminology is inconsistent with other uses of the forcing term and is not maintained in this report. See also *Cloud feedback*.

CO₂-equivalent See *Equivalent carbon dioxide*.

Cold days/cold nights Days where maximum temperature, or nights where minimum temperature, falls below the 10th *percentile*, where the respective temperature distributions are generally defined with respect to the 1961–1990 *reference* period. For the corresponding indices, see Box 2.4.

Compatible emissions *Earth System Models* that simulate the land and ocean *carbon cycle* can calculate *CO₂* emissions that are compatible with a given atmospheric *CO₂* concentration trajectory. The compatible emissions over a given period of time are equal to the increase of carbon over that same period of time in the sum of the three active *reservoirs*: the *atmosphere*, the land and the ocean.

Confidence The validity of a finding based on the type, amount, quality, and consistency of evidence (e.g., mechanistic understanding, theory, data, models, expert judgment) and on the degree of agreement. Confidence is expressed qualitatively (Mastrandrea et al., 2010). See Figure 1.12 for the levels of confidence and Table 1.1 for the list of *likelihood* qualifiers. See also *Uncertainty*.

Convection Vertical motion driven by buoyancy forces arising from static instability, usually caused by near-surface cooling or increases in salinity in the case of the ocean and near-surface warming or cloud-top radiative cooling in the case of the *atmosphere*. In the atmosphere convection gives rise to cumulus clouds and precipitation and is effective at both scavenging and vertically transporting chemical species. In the ocean convection can carry surface waters to deep within the ocean.

Cosmogenic radioisotopes Rare radioactive *isotopes* that are created by the interaction of a high-energy cosmic ray particle with the nucleus of an atom. They are often used as indicator of *solar activity* which modulates the cosmic rays intensity or as tracers of atmospheric transport processes, and are also called *cosmogenic radionuclides*.

Cryosphere All regions on and beneath the surface of the Earth and ocean where water is in solid form, including *sea ice*, lake ice, river ice, snow cover, *glaciers* and *ice sheets*, and *frozen ground* (which includes *permafrost*).

Dansgaard-Oeschger events Abrupt events characterized in Greenland *ice cores* and in *palaeoclimate* records from the nearby North Atlantic by a cold glacial state, followed by a rapid transition to a warmer phase, and a slow cooling back to glacial conditions. Counter-parts of Dansgaard-Oeschger events are observed in other regions as well.

Deforestation Conversion of *forest* to non-forest. For a discussion of the term *forest* and related terms such as *afforestation*, *reforestation*, and *deforestation* see the IPCC Special Report on Land Use, Land-Use Change and Forestry (IPCC, 2000). See also the report on Definitions and Methodological Options to Inventory Emissions from Direct Human-induced Degradation of Forests and Devegetation of Other Vegetation Types (IPCC, 2003).

Deglaciation/glacial termination Transitions from full glacial conditions (*ice age*) to warm *interglacials* characterised by global warming and sea level rise due to change in continental ice volume.

Detection and attribution *Detection of change* is defined as the process of demonstrating that *climate* or a system affected by climate has changed in some defined statistical sense, without providing a reason for that change. An identified change is detected in observations if its *likelihood* of occurrence by chance due to *internal variability* alone is determined to be small, for example, <10%. *Attribution* is defined as the process of evaluating the relative contributions of multiple causal factors to a change or event with an assignment of statistical confidence (Hegerl et al., 2009).

Diatoms Silt-sized algae that live in surface waters of lakes, rivers and oceans and form shells of opal. Their species distribution in ocean cores is often related to past *sea surface temperatures*.

Direct (aerosol) effect See *Aerosol-radiation interaction*.

Direct Air Capture: Chemical process by which a pure *CO₂* stream is produced by capturing *CO₂* from the ambient air.

Diurnal temperature range The difference between the maximum and minimum temperature during a 24-hour period.

Dobson unit (DU) A unit to measure the total amount of *ozone* in a vertical column above the Earth's surface (*total column ozone*). The number of Dobson units is the thickness in units of 10^{-5} m that the ozone column would occupy if compressed into a layer of uniform density at a pressure of 1013 hPa and a temperature of 0°C. One DU corresponds to a column of ozone containing 2.69×10^{20} molecules per square metre. A typical value for the amount of ozone in a column of the Earth's *atmosphere*, although very variable, is 300 DU.

Downscaling Downscaling is a method that derives local- to regional-scale (10 to 100 km) information from larger-scale models or data analyses. Two main methods exist: *dynamical downscaling* and *empirical/statistical downscaling*. The dynamical method uses the output of *regional climate models*, global models with variable spatial *resolution* or high-resolution global models. The empirical/statistical methods develop statistical relationships that link the large-scale atmospheric variables with local/regional climate variables. In all cases, the quality of the driving model remains an important limitation on the quality of the downscaled information.

Drought A period of abnormally dry weather long enough to cause a serious hydrological imbalance. Drought is a relative term, therefore any discussion in terms of precipitation deficit must refer to the particular precipitation-related activity that is under discussion. For example, shortage of precipitation during the growing season impinges on crop production or *ecosystem* function in general (due to *soil moisture* drought, also termed *agricultural drought*), and during the *runoff* and percolation season primarily affects water supplies (*hydrological drought*). Storage changes in soil moisture and groundwater are also affected by increases in actual *evapotranspiration* in addition to reductions in precipitation. A period with an abnormal precipitation deficit is defined as a *meteorological drought*. A *megadrought* is a very lengthy and pervasive drought, lasting much longer than normal, usually a decade or more. For the corresponding indices, see Box 2.4.

Dynamical system A process or set of processes whose evolution in time is governed by a set of deterministic physical laws. The *climate system* is a dynamical system. See also *Abrupt climate change*, *Chaotic*, *Nonlinearity* and *Predictability*.

Earth System Model (ESM) A coupled *atmosphere-ocean general circulation model* in which a representation of the *carbon cycle* is included, allowing for interactive calculation of atmospheric *CO₂* or *compatible emissions*. Additional components (e.g., atmospheric chemistry, *ice sheets*, dynamic vegetation, nitrogen cycle, but also urban or crop models) may be included. See also *Climate model*.

Earth-System Model of Intermediate Complexity (EMIC) A *climate model* attempting to include all the most important earth system processes as in ESMs but at a lower *resolution* or in a simpler, more idealised fashion.

Earth System sensitivity The equilibrium temperature response of the coupled *atmosphere-ocean-cryosphere-vegetation-carbon cycle* system to a doubling of the atmospheric *CO₂* concentration is referred to as Earth System sensitivity. Because it allows slow components (e.g., *ice sheets*, vegetation) of the *climate system* to adjust to the external perturbation, it may differ substantially from the *climate sensitivity* derived from coupled atmosphere-ocean models.

Ecosystem An ecosystem is a functional unit consisting of living organisms, their non-living environment, and the interactions within and between them. The components included in a given ecosystem and its spatial boundaries depend on the purpose for which the ecosystem is defined: in some cases they are relatively sharp, while in others they are diffuse. Ecosystem boundaries can change over time. Ecosystems are nested within other ecosystems, and their scale can range from very small to the entire *biosphere*. In the current era, most ecosystems either contain people as key organisms, or are influenced by the effects of human activities in their environment.

Effective climate sensitivity See *Climate sensitivity*.

Effective radiative forcing See *Radiative forcing*.

Efficacy A measure of how effective a *radiative forcing* from a given *anthropogenic* or natural mechanism is at changing the equilibrium *global mean surface temperature* compared to an equivalent *radiative forcing* from *carbon dioxide*. A carbon dioxide increase by definition has an efficacy of 1.0. Variations in climate efficacy may result from *rapid adjustments* to the applied forcing, which differ with different forcings.

Ekman pumping Frictional stress at the surface between two fluids (*atmosphere* and ocean) or between a fluid and the adjacent solid surface (Earth's surface) forces a circulation. When the resulting mass transport is converging, mass conservation requires a vertical flow away from the surface. This is called Ekman pumping. The opposite effect, in case of divergence, is called *Ekman suction*. The effect is important in both the atmosphere and the ocean.

Ekman transport The total transport resulting from a balance between the Coriolis force and the frictional stress due to the action of the wind on the ocean surface. See also *Ekman pumping*.

Electromagnetic spectrum Wavelength or energy range of all electromagnetic radiation. In terms of *solar radiation*, the *spectral irradiance* is the power arriving at the Earth per unit area, per unit wavelength.

El Niño-Southern Oscillation (ENSO) The term *El Niño* was initially used to describe a warm-water current that periodically flows along the coast of Ecuador and Peru, disrupting the local fishery. It has since become identified with a basin-wide warming of the tropical Pacific Ocean east of the dateline. This oceanic event is associated with a fluctuation of a global-scale tropical and subtropical surface pressure pattern called the *Southern Oscillation*. This coupled *atmosphere*-ocean phenomenon, with preferred time scales of two to about seven years, is known as the El Niño-Southern Oscillation (ENSO). It is often measured by the surface pressure anomaly difference between Darwin and Tahiti or the *sea surface temperatures* in the central and eastern equatorial Pacific. During an ENSO event, the prevailing trade winds weaken, reducing upwelling and altering ocean currents such that the sea surface temperatures warm, further weakening the trade winds. This event has a great impact on the wind, sea surface temperature and precipitation patterns in the tropical Pacific. It has climatic effects throughout the Pacific *region* and in many other parts of the world, through global *teleconnections*. The cold phase of ENSO is called *La Niña*. For the corresponding indices, see Box 2.5.

Emission scenario A plausible representation of the future development of emissions of substances that are potentially radiatively active (e.g., *greenhouse gases*, *aerosols*) based on a coherent and internally consistent set of assumptions about driving forces (such as demographic and socioeconomic development, technological change) and their key relationships. *Concentration scenarios*, derived from emission scenarios, are used as input to a *climate model* to compute *climate projections*. In IPCC (1992) a set of emission scenarios was presented which were used as a basis for the climate projections in IPCC (1996). These emission scenarios are referred to as the IS92 scenarios. In the IPCC Special Report on Emission Scenarios (Nakićenović and Swart, 2000) emission scenarios, the so-called *SRES scenarios*, were published, some of which were used, among others, as a basis for the climate projections presented in Chapters 9 to 11 of IPCC (2001) and Chapters 10 and 11 of IPCC (2007). New emission scenarios for *climate change*, the four *Representative Concentration Pathways*, were developed for, but independently of, the present IPCC assessment. See also *Climate scenario* and *scenario*.

Energy balance The difference between the total incoming and total outgoing energy. If this balance is positive, warming occurs; if it is negative, cooling occurs. Averaged over the globe and over long time periods, this balance must be zero. Because the *climate system* derives virtually all its energy from the Sun, zero balance implies that, globally, the absorbed *solar radiation*, i.e., *incoming solar radiation* minus reflected solar radiation at the top of the *atmosphere*, and *outgoing longwave radiation* emitted by the climate system are equal. See also *Energy budget*.

Energy Balance Model (EBM) An energy balance model is a simplified model that analyses the *energy budget* of the Earth to compute changes in the *climate*. In its simplest form, there is no explicit spatial

dimension and the model then provides an estimate of the changes in globally averaged temperature computed from the changes in radiation. This zero dimensional energy balance model can be extended to a one-dimensional or two-dimensional model if changes to the energy budget with respect to latitude, or both latitude and longitude, are explicitly considered. See also *Climate model*.

Energy budget (of the Earth) The Earth is a physical system with an energy budget that includes all gains of incoming energy and all losses of outgoing energy. The Earth's energy budget is determined by measuring how much energy comes into the Earth system from the Sun, how much energy is lost to space, and accounting for the remainder on Earth and its *atmosphere*. *Solar radiation* is the dominant source of energy into the Earth system. Incoming solar energy may be scattered and reflected by clouds and *aerosols* or absorbed in the atmosphere. The transmitted radiation is then either absorbed or reflected at the Earth's surface. The average *albedo* of the Earth is about 0.3, which means that 30% of the incident solar energy is reflected into space, while 70% is absorbed by the Earth. Radiant solar or shortwave energy is transformed into sensible heat, latent energy (involving different water states), potential energy, and kinetic energy before being emitted as *infrared radiation*. With the average *surface temperature* of the Earth of about 15°C (288 K), the main outgoing energy flux is in the infrared part of the spectrum. See also *Energy balance*, *Latent heat flux*, *Sensible heat flux*.

Ensemble A collection of model simulations characterizing a *climate prediction* or *projection*. Differences in initial conditions and model formulation result in different evolutions of the modelled system and may give information on *uncertainty* associated with model error and error in initial conditions in the case of *climate forecasts* and on uncertainty associated with model error and with internally generated *climate variability* in the case of climate projections.

Equilibrium and transient climate experiment An *equilibrium climate experiment* is a *climate model* experiment in which the model is allowed to fully adjust to a change in *radiative forcing*. Such experiments provide information on the difference between the initial and final states of the model, but not on the time-dependent response. If the forcing is allowed to evolve gradually according to a prescribed *emission scenario*, the time-dependent response of a climate model may be analysed. Such an experiment is called a *transient climate experiment*. See also *Climate projection*.

Equilibrium climate sensitivity See *Climate sensitivity*.

Equilibrium line The spatially averaged boundary at a given moment, usually chosen as the seasonal *mass budget* minimum at the end of summer, between the region on a *glacier* where there is a net annual loss of ice mass (*ablation* area) and that where there is a net annual gain (*accumulation* area). The altitude of this boundary is referred to as equilibrium line altitude (ELA).

Equivalent carbon dioxide (CO₂) concentration The concentration of *carbon dioxide* that would cause the same *radiative forcing* as a given mixture of carbon dioxide and other forcing components. Those values may consider only *greenhouse gases*, or a combination of greenhouse gases and *aerosols*.

Equivalent carbon dioxide (CO₂) emission The amount of *carbon dioxide* emission that would cause the same integrated *radiative forcing*, over a given time horizon, as an emitted amount of a well-mixed *greenhouse gas* or a mixture of well-mixed greenhouse gases. The equivalent carbon dioxide emission is obtained by multiplying the emission of a well-mixed greenhouse gas by its *Global Warming Potential* for the given time horizon. For a mix of greenhouse gases it is obtained by summing the equivalent carbon dioxide emissions of each gas. Equivalent carbon dioxide emission is a standard and useful *metric* for comparing emissions of different greenhouse gases but does not imply exact equivalence of the corresponding *climate change* responses.

Extended Concentration Pathways See *Representative Concentration Pathways*.

Evapotranspiration The combined process of evaporation from the Earth's surface and transpiration from vegetation.

External forcing External forcing refers to a forcing agent outside the *climate system* causing a change in the climate system. Volcanic eruptions, solar variations and *anthropogenic* changes in the composition of the *atmosphere* and *land use change* are external forcings. Orbital forcing is also an external forcing as the *insolation* changes with orbital parameters eccentricity, tilt and precession of the equinox.

Extratropical cyclone A large-scale (of order 1000 km) storm in the middle or high latitudes having low central pressure and fronts with strong horizontal gradients in temperature and humidity. A major cause of extreme wind speeds and heavy precipitation especially in wintertime.

Extreme climate event See *Extreme weather event*.

Extreme sea level See *Storm surge*.

Extreme weather event An extreme weather event is an event that is rare at a particular place and time of year. Definitions of *rare* vary, but an extreme weather event would normally be as rare as or rarer than the 10th or 90th *percentile* of a *probability density function* estimated from observations. By definition, the characteristics of what is called *extreme weather* may vary from place to place in an absolute sense. When a pattern of extreme weather persists for some time, such as a season, it may be classed as an *extreme climate event*, especially if it yields an average or total that is itself extreme (e.g., *drought* or heavy rainfall over a season).

Faculae Bright patches on the Sun. The area covered by faculae is greater during periods of high *solar activity*.

Feedback See *Climate feedback*.

Fingerprint The *climate* response pattern in space and/or time to a specific forcing is commonly referred to as a fingerprint. The spatial patterns of sea level response to melting of *glaciers* or *ice sheets* (or other changes in surface loading) are also referred to as fingerprints. Fingerprints are used to detect the presence of this response in observations and are typically estimated using forced *climate model* simulations.

Flux adjustment To avoid the problem of coupled *Atmosphere-Ocean General Circulation Models (AOGCMs)* drifting into some unrealistic *climate* state, adjustment terms can be applied to the atmosphere-ocean fluxes of heat and moisture (and sometimes the surface stresses resulting from the effect of the wind on the ocean surface) before these fluxes are imposed on the model ocean and atmosphere. Because these adjustments are pre-computed and therefore independent of the coupled model integration, they are uncorrelated with the anomalies that develop during the integration.

Forest A vegetation type dominated by trees. Many definitions of the term *forest* are in use throughout the world, reflecting wide differences in biogeophysical conditions, social structure and economics. For a discussion of the term *forest* and related terms such as *afforestation*, *reforestation* and *deforestation* see the IPCC Report on Land Use, Land-Use Change and Forestry (IPCC, 2000). See also the Report on Definitions and Methodological Options to Inventory Emissions from Direct Human-induced Degradation of Forests and Devegetation of Other Vegetation Types (IPCC, 2003).

Fossil fuel emissions Emissions of *greenhouse gases* (in particular *carbon dioxide*), other trace gases and *aerosols* resulting from the combustion of fuels from fossil carbon deposits such as oil, gas and coal.

Framework Convention on Climate Change See *United Nations Framework Convention on Climate Change (UNFCCC)*.

Free atmosphere The atmospheric layer that is negligibly affected by friction against the Earth's surface, and which is above the *atmospheric boundary layer*.

Frozen ground Soil or rock in which part or all of the *pore water* is frozen. Frozen ground includes *permafrost*. Ground that freezes and thaws annually is called *seasonally frozen ground*.

General circulation The large-scale motions of the *atmosphere* and the ocean as a consequence of differential heating on a rotating Earth. General circulation contributes to the *energy balance* of the system through transport of heat and momentum.

General Circulation Model (GCM) See *Climate model*.

Geoengineering Geoengineering refers to a broad set of methods and technologies that aim to deliberately alter the *climate system* in order to alleviate the impacts of *climate change*. Most, but not all, methods seek to either (a) reduce the amount of absorbed solar energy in the climate system (*Solar Radiation Management*) or (b) increase net carbon sinks from the *atmosphere* at a scale sufficiently large to alter *climate* (*Carbon Dioxide Removal*). Scale and intent are of central importance. Two key characteristics of geoengineering methods of particular concern are that they use or affect the climate system (e.g., atmosphere, land or ocean) globally or regionally and/or could have substantive unintended effects that cross national boundaries. Geoengineering is different from weather modification and ecological engineering, but the boundary can be fuzzy (IPCC, 2012, p. 2).

Geoid The equipotential surface having the same geopotential at each latitude and longitude around the world (geodesists denoting this potential W_0) that best approximates the *mean sea level*. It is the surface of reference for measurement of altitude. In practice, several variations of definitions of the geoid exist depending on the way the permanent tide (the zero-frequency gravitational tide due to the Sun and Moon) is considered in geodetic studies.

Geostrophic winds or currents A wind or current that is in balance with the horizontal pressure gradient and the Coriolis force, and thus is outside of the influence of friction. Thus, the wind or current is directly parallel to isobars and its speed is proportional to the horizontal pressure gradient.

Glacial-interglacial cycles Phase of Earth's history marked by large changes in continental ice volume and global sea level. See also *Ice age* and *Interglacials*.

Glacial isostatic adjustment (GIA) The deformation of the Earth and its gravity field due to the response of the earth-ocean system to changes in ice and associated water loads. It is sometimes referred to as *glacio-hydro isostasy*. It includes vertical and horizontal deformations of the earth's surface and changes in *geoid* due to the redistribution of mass during the ice-ocean mass exchange.

Glacier A perennial mass of land ice that originates from compressed snow, shows evidence of past or present flow (through internal deformation and/or sliding at the base) and is constrained by internal stress and friction at the base and sides. A glacier is maintained by accumulation of snow at high altitudes, balanced by melting at low altitudes and/or discharge into the sea. An ice mass of the same origin as glaciers, but of continental size, is called an *ice sheet*. For the purpose of simplicity in this Assessment Report, all ice masses other than ice sheets are referred to as glaciers. See also *Equilibrium line* and *Mass balance/budget (of glaciers or ice sheets)*.

Global dimming Global dimming refers to a widespread reduction of *solar radiation* received at the surface of the Earth from about the year 1961 to around 1990.

Global mean surface temperature An estimate of the global mean surface air temperature. However, for changes over time, only anomalies, as departures from a climatology, are used, most commonly based on the area-weighted global average of the *sea surface temperature* anomaly and *land surface air temperature* anomaly.

Global Warming Potential (GWP) An index, based upon radiative properties of *well-mixed greenhouse gases*, measuring the *radiative forcing following a pulse emission* of a unit mass of a given well-mixed greenhouse gas in the present-day *atmosphere* integrated over a chosen time horizon, relative to that of *carbon dioxide*. The GWP represents the combined effect of the differing times these gases remain in the atmosphere and their relative effectiveness in absorbing outgoing *terrestrial radiation*. The *Kyoto Protocol* is based on GWPs from pulse emissions over a 100-year time frame.

Greenhouse effect The infrared *radiative effect* of all infrared-absorbing constituents in the *atmosphere*. *Greenhouse gases*, clouds, and (to a small extent) *aerosols* absorb *terrestrial radiation* emitted by the Earth's surface and elsewhere in the atmosphere. These substances emit *infrared radiation* in all directions, but, everything else being equal, the net amount emitted to space is normally less than would have been emitted in the absence of these absorbers because of the decline of temperature with altitude in the *troposphere* and the consequent weakening of emission. An increase in the concentration of greenhouse gases increases the magnitude of this effect; the difference is sometimes called the enhanced greenhouse effect. The change in a greenhouse gas concentration because of *anthropogenic* emissions contributes to an *instantaneous radiative forcing*. Surface temperature and troposphere warm in response to this forcing, gradually restoring the radiative balance at the top of the atmosphere.

Greenhouse gas (GHG) Greenhouse gases are those gaseous constituents of the *atmosphere*, both natural and *anthropogenic*, that absorb and emit radiation at specific wavelengths within the spectrum of *terrestrial radiation* emitted by the Earth's surface, the atmosphere itself, and by clouds. This property causes the *greenhouse effect*. Water vapour (H₂O), *carbon dioxide* (CO₂), *nitrous oxide* (N₂O), *methane* (CH₄) and *ozone* (O₃) are the primary greenhouse gases in the Earth's atmosphere. Moreover, there are a number of entirely human-made greenhouse gases in the atmosphere, such as the *halocarbons* and other chlorine- and bromine-containing substances, dealt with under the *Montreal Protocol*. Beside CO₂, N₂O and CH₄, the *Kyoto Protocol* deals with the greenhouse gases sulphur hexafluoride (SF₆), hydrofluorocarbons (*HFCs*) and perfluorocarbons (PFCs). For a list of *well-mixed greenhouse gases*, see Table 2.A.1.

Gross Primary Production (GPP) The amount of carbon fixed by the autotrophs (e.g. plants and algae).

Grounding line The junction between a *glacier* or *ice sheet* and *ice shelf*; the place where ice starts to float. This junction normally occurs over a finite zone, rather than at a line.

Gyre Basin-scale ocean horizontal circulation pattern with slow flow circulating around the ocean basin, closed by a strong and narrow (100–200 km wide) boundary current on the western side. The subtropical gyres in each ocean are associated with high pressure in the centre of the gyres; the subpolar gyres are associated with low pressure.

Hadley Circulation A direct, thermally driven overturning cell in the *atmosphere* consisting of poleward flow in the upper *troposphere*, subsiding air into the subtropical anticyclones, return flow as part of the trade winds near the surface, and with rising air near the equator in the so-called *Inter-Tropical Convergence Zone*.

Halocarbons A collective term for the group of partially halogenated organic species, which includes the chlorofluorocarbons (*CFCs*), hydrochlorofluorocarbons (*HCFCs*), hydrofluorocarbons (*HFCs*), halons, methyl chloride and methyl bromide. Many of the halocarbons have large *Global Warming Potentials*. The chlorine and bromine-containing halocarbons are also involved in the depletion of the *ozone layer*.

Halocline A layer in the oceanic water column in which salinity changes rapidly with depth. Generally saltier water is denser and lies below less salty water. In some high latitude oceans the surface waters may be colder than the deep waters and the halocline is responsible for maintaining water column stability and isolating the surface waters from the deep waters. See also *Thermocline*.

Halosteric See *Sea level change*.

HCFC See *Halocarbons*.

Heat wave A period of abnormally and uncomfortably hot weather. See also *Warm spell*.

HFC See *Halocarbons*.

Heterotrophic respiration The conversion of organic matter to *carbon dioxide* by organisms other than autotrophs.

Hindcast or retrospective forecast A forecast made for a period in the past using only information available before the beginning of the forecast. A sequence of hindcasts can be used to calibrate the forecast system and/or provide a measure of the average skill that the forecast system has exhibited in the past as a guide to the skill that might be expected in the future.

Holocene The Holocene Epoch is the latter of two epochs in the *Quaternary* System, extending from 11.65 ka (thousand years before 1950) to the present. It is also known as *Marine Isotopic Stage (MIS) 1* or *current interglacial*.

Hydroclimate Part of the *climate* pertaining to the hydrology of a *region*.

Hydrological cycle The cycle in which water evaporates from the oceans and the land surface, is carried over the Earth in atmospheric circulation as water vapour, condenses to form clouds, precipitates over ocean and land as rain or snow, which on land can be intercepted by trees and vegetation, provides *runoff* on the land surface, infiltrates into soils, recharges groundwater, discharges into streams, and ultimately, flows out into the oceans, from which it will eventually evaporate again. The various systems involved in the hydrological cycle are usually referred to as hydrological systems.

Hydrosphere The component of the *climate system* comprising liquid surface and subterranean water, such as oceans, seas, rivers, fresh water lakes, underground water, etc.

Hypsometry The distribution of land or ice surface as a function of altitude.

Ice age An ice age or *glacial period* is characterised by a long-term reduction in the temperature of the Earth's *climate*, resulting in growth of *ice sheets* and *glaciers*.

Ice-albedo feedback A *climate feedback* involving changes in the Earth's surface *albedo*. Snow and ice have an albedo much higher (up to ~0.8) than the average planetary albedo (~0.3). With increasing temperatures, it is anticipated that snow and ice extent will decrease, the Earth's overall albedo will decrease and more *solar radiation* will be absorbed, warming the Earth further.

Ice core A cylinder of ice drilled out of a *glacier* or *ice sheet*.

Ice sheet A mass of land ice of continental size that is sufficiently thick to cover most of the underlying bed, so that its shape is mainly determined by its dynamics (the flow of the ice as it deforms internally and/or slides at its base). An ice sheet flows outward from a high central ice plateau with a small average surface slope. The margins usually slope more steeply, and most ice is discharged through fast flowing *ice streams* or *outlet glaciers*, in some cases into the sea or into *ice shelves* floating on the sea. There are only two ice sheets in the modern world, one on Greenland and one on Antarctica. During glacial periods there were others.

Ice shelf A floating slab of ice of considerable thickness extending from the coast (usually of great horizontal extent with a very gently sloping surface), often filling embayments in the coastline of an *ice sheet*. Nearly all ice shelves are in Antarctica, where most of the ice discharged into the ocean flows via ice shelves.

Ice stream A stream of ice with strongly enhanced flow that is part of an *ice sheet*. It is often separated from surrounding ice by strongly sheared, crevassed margins. See also *Outlet glacier*.

Incoming solar radiation See *Insolation*.

Indian Ocean Dipole (IOD) Large-scale mode of interannual variability of *sea surface temperature* in the Indian Ocean. This pattern manifests through a zonal gradient of tropical sea surface temperature, which in one extreme phase in boreal autumn shows cooling off Sumatra and warming off Somalia in the west, combined with anomalous easterlies along the equator.

Indirect aerosol effect See *Aerosol-cloud interaction*.

Industrial Revolution A period of rapid industrial growth with far-reaching social and economic consequences, beginning in Britain during the second half of the eighteenth century and spreading to Europe and later to other countries including the United States. The invention of the steam engine was an important trigger of this development. The industrial revolution marks the beginning of a strong increase in the use of fossil fuels and emission of, in particular, fossil *carbon dioxide*. In this report the terms *pre-industrial* and *industrial* refer, somewhat arbitrarily, to the periods before and after 1750, respectively.

Infrared radiation See *Terrestrial radiation*.

Insolation The amount of *solar radiation* reaching the Earth by latitude and by season measured in W m^{-2} . Usually *insolation* refers to the radiation arriving at the top of the *atmosphere*. Sometimes it is specified as referring to the radiation arriving at the Earth's surface. See also *Total Solar Irradiance*.

Interglacials or interglaciations The warm periods between *ice age* glaciations. Often defined as the periods at which sea levels were close to present sea level. For the *Last Interglacial (LIG)* this occurred between about 129 and 116 ka (thousand years) before present (defined as 1950) although the warm period started in some areas a few thousand years earlier. In terms of the oxygen *isotope* record interglaciations are defined as the interval between the mid point of the preceding termination and the onset of the next glaciation. The present interglaciation, the *Holocene*, started at 11.65 ka before present although globally sea levels did not approach their present position until about 7000 years before present.

Internal variability See *Climate variability*.

Inter-Tropical Convergence Zone (ITCZ) The Inter-Tropical Convergence Zone is an equatorial zonal belt of low pressure, strong *convection* and heavy precipitation near the equator where the northeast trade winds meet the southeast trade winds. This band moves seasonally.

Iron fertilization Deliberate introduction of iron to the upper ocean intended to enhance biological productivity which can sequester additional atmospheric *carbon dioxide* into the oceans.

Irreversibility A perturbed state of a *dynamical system* is defined as irreversible on a given timescale, if the recovery timescale from this state due to natural processes is significantly longer than the time it takes for the system to reach this perturbed state. In the context of WGI, the time scale of interest is centennial to millennial. See also *Tipping point*.

Isostatic or Isostasy Isostasy refers to the response of the earth to changes in surface load. It includes the deformational and gravitational response. This response is elastic on short time scales, as in the earth-ocean response to recent changes in mountain glaciation, or viscoelastic on longer time scales, as in the response to the last *deglaciation* following the *Last Glacial Maximum*. See also *Glacial Isostatic Adjustment (GIA)*.

Isotopes Atoms of the same chemical element that have the same the number of protons but differ in the number of neutrons. Some proton-neutron configurations are stable (stable isotopes), others are unstable undergoing spontaneous radioactive decay (*radioisotopes*). Most elements have more than one stable isotope. Isotopes can be used to trace transport processes or to study processes which change the isotopic ratio. Radioisotopes provide in addition time information which can be used for radiometric dating.

Kyoto Protocol The Kyoto Protocol to the *United Nations Framework Convention on Climate Change (UNFCCC)* was adopted in 1997 in Kyoto, Japan, at the Third Session of the Conference of the Parties (COP) to the UNFCCC. It contains legally binding commitments, in addition to those included in the UNFCCC. Countries included in Annex B of the Protocol (most Organisation for Economic Cooperation and Development countries and countries with economies in transition) agreed to reduce their *anthropogenic greenhouse gas* emissions (*carbon dioxide*, *methane*, *nitrous oxide*, hydrofluorocarbons, perfluorocarbons, and sulphur hexafluoride) by at least 5% below 1990 levels in the commitment period 2008 to 2012. The Kyoto Protocol entered into force on 16 February 2005.

Land use and Land use change *Land use* refers to the total of arrangements, activities and inputs undertaken in a certain land cover type (a set of human actions). The term *land use* is also used in the sense of the social and economic purposes for which land is managed (e.g., grazing, timber extraction and conservation). *Land use change* refers to a change in the use or management of land by humans, which may lead to a change in land cover. Land cover and land use change may have an impact on the surface *albedo*, *evapotranspiration*, *sources* and *sinks* of *greenhouse gases*, or other properties of the *climate system* and may thus give rise to *radiative forcing* and/or other impacts on *climate*, locally or globally. See also the IPCC Report on Land Use, Land-Use Change, and Forestry (IPCC, 2000).

Land surface air temperature The surface air temperature as measured in well-ventilated screens over land at 1.5 m above the ground.

La Niña See *El Niño-Southern Oscillation*.

Lapse rate The rate of change of an atmospheric variable, usually temperature, with height. The lapse rate is considered positive when the variable decreases with height.

Last Glacial Maximum (LGM) The period during the last *ice age* when the *glaciers* and *ice sheets* reached their maximum extent, approximately 21 ka ago. This period has been widely studied because the *radiative forcings* and boundary conditions are relatively well known.

Last Interglacial (LIG) See *Interglacials*.

Latent heat flux The turbulent flux of heat from the Earth's surface to the *atmosphere* that is associated with evaporation or condensation of water vapour at the surface; a component of the surface *energy budget*.

Level of Scientific Understanding (LOSU) This is an index on a 5-step scale (high, medium, medium-low, low and very low) designed to characterise the degree of scientific understanding of the *radiative forcing* agents that affect *climate change*. For each agent, the index represents a subjective judgement about the evidence for the physical/chemical mechanisms determining the forcing and the consensus surrounding the quantitative estimate and its *uncertainty*.

Lifetime Lifetime is a general term used for various time scales characterising the rate of processes affecting the concentration of trace gases. The following lifetimes may be distinguished:

Turnover time (T) (also called *global atmospheric lifetime*) is the ratio of the mass *M* of a *reservoir* (e.g., a gaseous compound in the *atmosphere*) and the total rate of removal *S* from the reservoir: $T = M / S$. For each removal process, separate turnover times can be defined. In soil carbon biology, this is referred to as *Mean Residence Time*.

Adjustment time or response time (T_a) is the time scale characterising the decay of an instantaneous pulse input into the reservoir. The term *adjustment time* is also used to characterise the adjustment of the mass of a reservoir following a step change in the *source* strength. *Half-life* or *decay constant* is used to quantify a first-order exponential decay process. See *Response time* for a different definition pertinent to *climate* variations.

The term *lifetime* is sometimes used, for simplicity, as a surrogate for *adjustment time*.

In simple cases, where the global removal of the compound is directly proportional to the total mass of the reservoir, the adjustment time equals the turnover time: $T = T_a$. An example is *CFC-11*, which is removed from the atmosphere only by photochemical processes in the *stratosphere*. In more complicated cases, where several reservoirs are involved or where the removal is not proportional to the total mass, the equality $T = T_a$ no longer holds. *Carbon dioxide (CO₂)* is an extreme example. Its turnover time is only about four years because of the rapid exchange between the atmosphere and the ocean and terrestrial biota. However, a large part of that CO₂ is returned to the atmosphere within a few years. Thus, the adjustment time of CO₂ in the atmosphere is actually determined by the rate of removal of carbon from the surface layer of the oceans into its deeper layers. Although an approximate value of 100 years may be given for the adjustment time of CO₂

in the atmosphere, the actual adjustment is faster initially and slower later on. In the case of *methane (CH₄)*, the adjustment time is different from the turnover time because the removal is mainly through a chemical reaction with the hydroxyl radical OH, the concentration of which itself depends on the CH₄ concentration. Therefore, the CH₄ removal rate S is not proportional to its total mass M.

Likelihood The chance of a specific outcome occurring, where this might be estimated probabilistically. This is expressed in this report using a standard terminology, defined in Table 1.1. See also *Confidence* and *Uncertainty*.

Lithosphere The upper layer of the solid Earth, both continental and oceanic, which comprises all crustal rocks and the cold, mainly elastic part of the uppermost mantle. Volcanic activity, although part of the lithosphere, is not considered as part of the *climate system*, but acts as an *external forcing* factor. See also *Isostatic*.

Little Ice Age (LIA) An interval during the last millennium characterized by a number of extensive expansions of mountain *glaciers* and moderate retreats in between them, both in the Northern and Southern Hemispheres. The timing of glacial advances differs between *regions* and the LIA is, therefore, not clearly defined in time. Most definitions lie in the period 1400 CE and 1900 CE. Currently available *reconstructions* of average Northern Hemisphere temperature indicate that the coolest periods at the hemispheric scale may have occurred from 1450 to 1850 CE.

Longwave radiation See *Terrestrial radiation*.

Madden-Julian Oscillation (MJO) The largest single component of tropical atmospheric intraseasonal variability (periods from 30 to 90 days). The MJO propagates eastwards at around 5 m s⁻¹ in the form of a large-scale coupling between atmospheric circulation and deep *convection*. As it progresses, it is associated with large regions of both enhanced and suppressed rainfall, mainly over the Indian and western Pacific Oceans. Each MJO event lasts approximately 30–60 days, hence the MJO is also known as the 30–60 day wave, or the intraseasonal oscillation.

Mass balance/budget (of glaciers or ice sheets) The balance between the mass input to the ice body (*accumulation*) and the mass loss (*ablation* and iceberg *calving*) over a stated period of time, which is often a year or a season. Point mass balance refers to the mass balance at a particular location on the *glacier* or *ice sheet*. Surface mass balance is the difference between surface accumulation and surface ablation. The input and output terms for mass balance are:

Accumulation All processes that add to the mass of a glacier. The main contribution to accumulation is snowfall. Accumulation also includes deposition of hoar, freezing rain, other types of solid precipitation, gain of wind-blown snow, and avalanching.

Ablation Surface processes that reduce the mass of a glacier. The main contributor to ablation is melting with *runoff* but on some glaciers sublimation, loss of wind-blown snow and avalanching are also significant processes of ablation.

Discharge/outflow Mass loss by iceberg calving or ice discharge across the *grounding line* of a floating *ice shelf*. Although often treated as an ablation term, in this report iceberg calving and discharge is considered separately from surface ablation.

Mean sea level The surface level of the ocean at a particular point averaged over an extended period of time such as a month or year. Mean sea level is often used as a national datum to which heights on land are referred.

Medieval Climate Anomaly (MCA) See *Medieval Warm Period*.

Medieval Warm Period (MWP) An interval of relatively warm conditions and other notable *climate* anomalies such as more extensive *drought* in some continental *regions*. The timing of this interval is not clearly defined, with different records showing onset and termination of the warmth at different times, and

some showing intermittent warmth. Most definitions lie within the period 900 to 1400 CE. Currently available reconstructions of average Northern Hemisphere temperature indicate that the warmest period at the hemispheric scale may have occurred from 950 to 1250 CE. Currently available records and temperature *reconstructions* indicate that average temperatures during parts of the MWP were indeed warmer in the context of the last 2000 years, though the warmth may not have been as ubiquitous across seasons and geographical regions as the 20th century warming. It is also called *Medieval Climate Anomaly*.

Meridional Overturning Circulation (MOC) Meridional (north-south) overturning circulation in the ocean quantified by zonal (east-west) sums of mass transports in depth or density layers. In the North Atlantic, away from the sub-polar *regions*, the MOC (which is in principle an observable quantity) is often identified with the *thermohaline circulation* (THC), which is a conceptual and incomplete interpretation. It must be borne in mind that the MOC is also driven by wind, and can also include shallower overturning cells such as occur in the upper ocean in the tropics and subtropics, in which warm (light) waters moving poleward are transformed to slightly denser waters and *subducted* equatorward at deeper levels.

Metadata Information about meteorological and climatological data concerning how and when they were measured, their quality, known problems and other characteristics.

Methane (CH₄) Methane is one of the six *greenhouse gases* to be mitigated under the *Kyoto Protocol* and is the major component of natural gas and associated with all hydrocarbon fuels, animal husbandry and agriculture.

Metric A consistent measurement of a characteristic of an object or activity that is otherwise difficult to quantify. Within the context of the evaluation of *climate models*, this is a quantitative measure of agreement between a simulated and observed quantity which can be used to assess the performance of individual models.

Microwave Sounding Unit (MSU) A microwave sounder on NOAA polar orbiter satellites, that estimates the temperature of thick layers of the *atmosphere* by measuring the thermal emission of oxygen molecules from a complex of emission lines near 60 GHz. A series of nine MSUs began making this kind of measurement in late 1978. Beginning in mid 1998, a follow-on series of instruments, the Advanced Microwave Sounding Units (AMSUs), began operation.

Mineralization/Remineralization The conversion of an element from its organic form to an inorganic form as a result of microbial decomposition. In nitrogen mineralization, organic nitrogen from decaying plant and animal residues (proteins, nucleic acids, amino sugars, and urea) is converted to ammonia (NH₃) and ammonium (NH₄⁺) by biological activity.

Mitigation A human intervention to reduce the *sources* or enhance the *sinks* of *greenhouse gases*.

Mixing ratio See *Mole fraction*.

Model drift Since model *climate* differs to some extent from observed climate, *climate forecasts* will typically “drift” from the initial observation-based state towards the model's climate. This drift occurs at different time scales for different variables, can obscure the initial-condition forecast information and is usually removed a posteriori by an empirical, usually linear, adjustment.

Model hierarchy See *Climate model* (spectrum or hierarchy).

Model initialization A *climate forecast* typically proceeds by integrating a *climate model* forward in time from an initial state that is intended to reflect the actual state of the *climate system*. Available observations of the climate system are “assimilated” into the model. Initialization is a complex process which is limited by available observations, observational errors and, depending on the procedure used, may be affected by *uncertainty* in the history of climate forcing. The initial conditions will contain errors that grow as the forecast progresses thereby limiting the time for which the forecast will be useful. See also *Climate prediction*.

Model spread The range or spread in results from *climate models*, such as those assembled for CMIP5. Does not necessarily provide an exhaustive and formal estimate of the *uncertainty* in *feedbacks*, forcing or *projections* even when expressed numerically e.g., by computing a standard deviation of the models' responses. In order to quantify uncertainty, information from observations, physical constraints and expert judgement must be combined, using a statistical framework.

Mode of climate variability Underlying space-time structure with preferred spatial pattern and temporal variation that helps account for the gross features in variance and for *teleconnections*. A mode of variability is often considered to be the product of a spatial *climate pattern* and an associated *climate index* time series.

Mole fraction Mole fraction, or *mixing ratio*, is the ratio of the number of moles of a constituent in a given volume to the total number of moles of all constituents in that volume. It is usually reported for dry air. Typical values for *well-mixed greenhouse gases* are in the order of $\mu\text{mol mol}^{-1}$ (parts per million: *ppm*), nmol mol^{-1} (parts per billion: *ppb*), and fmol mol^{-1} (parts per trillion: *ppt*). Mole fraction differs from *volume mixing ratio*, often expressed in ppmv etc., by the corrections for non-ideality of gases. This correction is significant relative to measurement precision for many greenhouse gases (Schwartz and Warneck, 1995).

Monsoon A monsoon is a tropical and subtropical seasonal reversal in both the surface winds and associated precipitation, caused by differential heating between a continental-scale land mass and the adjacent ocean. Monsoon rains occur mainly over land in summer.

Montreal Protocol The Montreal Protocol on Substances that Deplete the *Ozone Layer* was adopted in Montreal in 1987, and subsequently adjusted and amended in London (1990), Copenhagen (1992), Vienna (1995), Montreal (1997) and Beijing (1999). It controls the consumption and production of chlorine- and bromine- containing chemicals that destroy stratospheric *ozone*, such as chlorofluorocarbons, methyl chloroform, carbon tetrachloride and many others.

Nitrogen deposition: Nitrogen deposition is defined as the nitrogen transferred from the *atmosphere* to the Earth's surface by the processes of wet deposition and dry deposition.

Nitrous oxide (N₂O) One of the six *greenhouse gases* to be mitigated under the *Kyoto Protocol*. The main *anthropogenic source* of nitrous oxide is agriculture (soil and animal manure management), but important contributions also come from sewage treatment, combustion of fossil fuel, and chemical industrial processes. Nitrous oxide is also produced naturally from a wide variety of biological sources in soil and water, particularly microbial action in wet tropical *forests*.

Nonlinearity A process is called *nonlinear* when there is no simple proportional relation between cause and effect. The *climate system* contains many such nonlinear processes, resulting in a system with potentially very complex behaviour. Such complexity may lead to *abrupt climate change*. See also *Chaos* and *Predictability*.

North Atlantic Oscillation (NAO) The North Atlantic Oscillation consists of opposing variations of surface pressure near Iceland and near the Azores. It therefore corresponds to fluctuations in the strength of the main westerly winds across the Atlantic into Europe, and thus to fluctuations in the embedded *extratropical cyclones* with their associated frontal systems. See NAO Index, Box 2.5.

Northern Annular Mode (NAM) A winter fluctuation in the amplitude of a pattern characterised by low surface pressure in the Arctic and strong mid-latitude westerlies. The NAM has links with the northern polar vortex into the *stratosphere*. Its pattern has a bias to the North Atlantic and its index has a large correlation with the *North Atlantic Oscillation* index. See NAM Index, Box 2.5.

Ocean acidification Ocean acidification refers to a reduction in the *pH* of the ocean over an extended period, typically decades or longer, which is caused primarily by *uptake* of *carbon dioxide* from the *atmosphere*, but can also be caused by other chemical additions or subtractions from the ocean. *Anthropogenic ocean acidification* refers to the component of pH reduction that is caused by human activity (IPCC, 2011, p. 37).

Ocean heat uptake efficiency This is a measure ($\text{W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$) of the rate at which heat storage by the global ocean increases as *global mean surface temperature* rises. It is a useful parameter for *climate change* experiments in which the *radiative forcing* is changing monotonically, when it can be compared with the *Climate Feedback Parameter* to gauge the relative importance of climate response and ocean heat *uptake* in determining the rate of climate change. It can be estimated from such an experiment as the ratio of the rate of increase of ocean heat content to the global mean surface air temperature change.

Organic aerosol Component of the *aerosol* that consists of organic compounds, mainly carbon, hydrogen, oxygen and lesser amounts of other elements. See also *Carbonaceous aerosol*.

Outgoing longwave radiation Net outgoing radiation in the infrared part of the spectrum at the top of the *atmosphere*. See also *Terrestrial radiation*.

Outlet glacier A *glacier*, usually between rock walls, that is part of, and drains an *ice sheet*. See also *Ice stream*.

Ozone Ozone, the triatomic form of oxygen (O_3), is a gaseous atmospheric constituent. In the *troposphere*, it is created both naturally and by photochemical reactions involving gases resulting from human activities (*smog*). Tropospheric ozone acts as a *greenhouse gas*. In the *stratosphere*, it is created by the interaction between solar ultraviolet radiation and molecular oxygen (O_2). Stratospheric ozone plays a dominant role in the stratospheric radiative balance. Its concentration is highest in the *ozone layer*.

Ozone hole See *Ozone layer*.

Ozone layer The *stratosphere* contains a layer in which the concentration of *ozone* is greatest, the so-called ozone layer. The layer extends from about 12 to 40 km above the Earth's surface. The ozone concentration reaches a maximum between about 20 and 25 km. This layer has been depleted by human emissions of chlorine and bromine compounds. Every year, during the Southern Hemisphere spring, a very strong depletion of the ozone layer takes place over the Antarctic, caused by *anthropogenic* chlorine and bromine compounds in combination with the specific meteorological conditions of that *region*. This phenomenon is called the *Ozone hole*. See also *Montreal Protocol*.

Pacific Decadal Oscillation (PDO) The pattern and time series of the first empirical orthogonal function of *sea surface temperature* over the North Pacific north of 20°N . The PDO broadened to cover the whole Pacific Basin is known as the Inter-decadal Pacific Oscillation. The PDO and IPO exhibit similar temporal evolution. See also *Pacific Decadal Variability*.

Pacific decadal variability Coupled decadal-to-inter-decadal variability of the atmospheric circulation and underlying ocean in the Pacific Basin. It is most prominent in the North Pacific, where fluctuations in the strength of the winter Aleutian Low pressure system co-vary with North Pacific *sea surface temperatures*, and are linked to decadal variations in atmospheric circulation, sea surface temperatures and ocean circulation throughout the whole Pacific Basin. Such fluctuations have the effect of modulating the *El Niño-Southern Oscillation* cycle. Key measures of Pacific decadal variability are the *North Pacific Index (NPI)*, the *Pacific Decadal Oscillation (PDO)* index and the *Inter-decadal Pacific Oscillation (IPO)* index, all defined in Box 2.5.

Pacific-North American (PNA) pattern An atmospheric large-scale wave pattern featuring a sequence of tropospheric high and low pressure anomalies stretching from the subtropical west Pacific to the east coast of North America. See PNA pattern index, Box 2.5.

Paleoclimate *Climate* during periods prior to the development of measuring instruments, including historic and geologic time, for which only *proxy* climate records are available.

Parametrization In *climate models*, this term refers to the technique of representing processes that cannot be explicitly resolved at the spatial or temporal *resolution* of the model (sub-grid scale processes) by relationships between model-resolved larger-scale variables and the area- or time-averaged effect of such subgrid scale processes.

Percentile The set of partition values which divides the total population of a distribution into one hundred equal parts, the 50th percentile corresponding to the *median* of the population.

Permafrost Ground (soil or rock and included ice and organic material) that remains at or below 0°C for at least two consecutive years.

pH pH is a dimensionless measure of the acidity of water (or any solution) given by its concentration of hydrogen ions (H⁺). pH is measured on a logarithmic scale where $\text{pH} = -\log_{10}(\text{H}^+)$. Thus, a pH decrease of 1 unit corresponds to a 10-fold increase in the concentration of H⁺, or acidity.

Photosynthesis The process by which plants take *carbon dioxide* from the air (or bicarbonate in water) to build carbohydrates, releasing oxygen in the process. There are several pathways of photosynthesis with different responses to atmospheric carbon dioxide concentrations. See also *Carbon dioxide fertilization*.

Plankton Microorganisms living in the upper layers of aquatic systems. A distinction is made between *phytoplankton*, which depend on *photosynthesis* for their energy supply, and *zooplankton*, which feed on phytoplankton.

Pleistocene The Pleistocene Epoch is the earlier of two epochs in the *Quaternary* System, extending from 2.59 Ma to the beginning of the *Holocene* at 11.65 ka.

Pliocene The Pliocene Epoch is the last epoch of the *Neogene* System and extends from 5.33 Ma to the beginning of the *Pleistocene* at 2.59 Ma.

Pollen analysis A technique of both relative dating and environmental *reconstruction*, consisting of the identification and counting of pollen types preserved in peat, lake sediments and other deposits. See also *Proxy*.

Precipitable water The total amount of atmospheric water vapour in a vertical column of unit cross-sectional area. It is commonly expressed in terms of the height of the water if completely condensed and collected in a vessel of the same unit cross section.

Precursors Atmospheric compounds that are not *greenhouse gases* or *aerosols*, but that have an effect on greenhouse gas or aerosol concentrations by taking part in physical or chemical processes regulating their production or destruction rates.

Predictability The extent to which future states of a system may be predicted based on knowledge of current and past states of the system. Since knowledge of the *climate system*'s past and current states is generally imperfect, as are the models that utilise this knowledge to produce a *climate prediction*, and since the climate system is inherently *nonlinear* and *chaotic*, predictability of the climate system is inherently limited. Even with arbitrarily accurate models and observations, there may still be limits to the predictability of such a nonlinear system (AMS, 2000).

Prediction quality/skill Measures of the success of a *prediction* against observationally-based information. No single measure can summarize all aspects of forecast quality and a suite of *metrics* is considered. Metrics will differ for forecasts given in deterministic and probabilistic form. See also *Climate prediction*.

Pre-industrial See *Industrial Revolution*.

Probability Density Function (PDF) A probability density function is a function that indicates the relative chances of occurrence of different outcomes of a variable. The function integrates to unity over the domain for which it is defined and has the property that the integral over a sub-domain equals the probability that the outcome of the variable lies within that sub-domain. For example, the probability that a temperature anomaly defined in a particular way is greater than zero is obtained from its PDF by integrating the PDF over all possible temperature anomalies greater than zero. Probability density functions that describe two or more variables simultaneously are similarly defined.

Process Based Model Theoretical concepts and computational methods that represent and simulate the behaviour of real-world systems derived from a set of functional components and their interactions with each other and the system environment, through physical and mechanistic processes occurring over time. See also *Climate model*.

Projection A projection is a potential future evolution of a quantity or set of quantities, often computed with the aid of a model. Unlike predictions, projections are conditional on assumptions concerning, for example, future socioeconomic and technological developments that may or may not be realised. See also *Climate prediction* and *Climate projection*.

Proxy A proxy *climate* indicator is a record that is interpreted, using physical and biophysical principles, to represent some combination of climate-related variations back in time. Climate-related data derived in this way are referred to as proxy data. Examples of proxies include *pollen analysis*, *tree ring* records, speleothems, characteristics of corals and various data derived from marine sediments and *ice cores*. Proxy-data can be calibrated to provide quantitative climate information.

Quasi-Biennial Oscillation (QBO) A near-periodic oscillation of the equatorial zonal wind between easterlies and westerlies in the tropical *stratosphere* with a mean period of around 28 months. The alternating wind maxima descend from the base of the mesosphere down to the *tropopause*, and are driven by wave energy that propagates up from the *troposphere*.

Quaternary The Quaternary System is the latter of three systems that make up the *Cenozoic Era* (65 Ma to present), extending from 2.59 Ma to the present, and includes the *Pleistocene* and *Holocene* epochs.

Radiative effect The impact on a radiation flux or heating rate (most commonly, on the downward flux at the top of *atmosphere*) caused by the interaction of a particular constituent with either the *infrared* or *solar radiation* fields through absorption, scattering and emission, relative to an otherwise identical atmosphere free of that constituent. This quantifies the impact of the constituent on the *climate system*. Examples include the *aerosol-radiation interactions*, *cloud radiative effect*, and *greenhouse effect*. In this report, the portion of any top-of-atmosphere radiative effect that is due to *anthropogenic* or other external influences (for example, volcanic eruptions or changes in the sun) is termed the *instantaneous radiative forcing*.

Radiative forcing Radiative forcing is the change in the net, downward minus upward, irradiance (expressed in W m^{-2}) at the *tropopause* or top of *atmosphere* due to a change in an external driver of *climate change*, such as, for example, a change in the concentration of *carbon dioxide* or the output of the Sun. Sometimes internal drivers are still treated as forcings even though they result from the alteration in *climate*, for example *aerosol* or *greenhouse gas* changes in *paleoclimates*. The traditional radiative forcing is computed with all tropospheric properties held fixed at their unperturbed values, and after allowing for stratospheric temperatures, if perturbed, to readjust to radiative-dynamical equilibrium. Radiative forcing is called *instantaneous* if no change in stratospheric temperature is accounted for. The radiative forcing once *rapid adjustments* are accounted for is termed the *effective radiative forcing*. For the purposes of this report, radiative forcing is further defined as the change relative to the year 1750 and, unless otherwise noted, refers to a global and annual average value. Radiative forcing is not to be confused with *cloud radiative forcing*, which describes an unrelated measure of the impact of clouds on the irradiance at the top of the atmosphere.

Rapid adjustment The response to an agent perturbing the *climate system* that is driven directly by the agent, independently of any change in the *global mean surface temperature*. For example *carbon dioxide* and *aerosols*, by altering internal heating and cooling rates within the *atmosphere*, can each cause changes to cloud cover and other variables thereby producing a *radiative effect* even in the absence of any surface warming or cooling. Adjustments are *rapid* in the sense that they begin to occur right away, before *climate feedbacks* which are driven by warming (although some adjustments may still take significant time to proceed to completion, for example those involving vegetation or *ice sheets*). It is also called the *rapid response* or *fast adjustment*. For further explanation on the concept, see Sections 7.1 and 8.1.

Rapid climate change See *Abrupt climate change*.

Rapid dynamical change (of glaciers or ice sheets) Changes in *glacier* or *ice sheet* mass controlled by changes in flow speed and *discharge* rather than by *accumulation* or *ablation*. This can result in a rate of mass change larger than that due to any imbalance between accumulation and ablation. Rapid dynamical change may be initiated by a climatic trigger, such as incursion of warm ocean water beneath an *ice shelf*, or thinning of a grounded tidewater terminus, which may lead to reactions within the glacier system, that may result in rapid ice loss. See also *Mass balance/budget (of glaciers or ice sheets)*.

Reanalysis Reanalyses are estimates of historical atmospheric temperature and wind or oceanographic temperature and current, and other quantities, created by processing past meteorological or oceanographic data using fixed state-of-the-art weather forecasting or ocean circulation models with data assimilation techniques. Using fixed data assimilation avoids effects from the changing analysis system that occur in operational analyses. Although continuity is improved, global reanalyses still suffer from changing coverage and biases in the observing systems.

Rebound effect: When CO_2 is removed from the *atmosphere*, the CO_2 concentration gradient between atmospheric and land/ocean carbon *reservoirs* is reduced. This leads to a reduction or reversal in subsequent inherent rate of removal of CO_2 from the atmosphere by natural *carbon cycle* processes on land and ocean.

Reconstruction (of climate variable) Approach to reconstructing the past temporal and spatial characteristics of a climate variable from predictors. The predictors can be instrumental data if the reconstruction is used to infill missing data or *proxy* data if it is used to develop *paleoclimate* reconstructions. Various techniques have been developed for this purpose: linear multivariate regression based methods and non-linear *Bayesian* and analog methods.

Reforestation Planting of *forests* on lands that have previously contained forests but that have been converted to some other use. For a discussion of the term *forest* and related terms such as *afforestation*, *reforestation* and *deforestation*, see the IPCC Report on Land Use, Land-Use Change and Forestry (IPCC, 2000). See also the Report on Definitions and Methodological Options to Inventory Emissions from Direct Human-induced Degradation of Forests and Devegetation of Other Vegetation Types (IPCC, 2003).

Region A region is a territory characterised by specific geographical and climatological features. The *climate* of a region is affected by regional and local scale features like topography, *land use* characteristics and lakes, as well as remote influences from other regions. See also *Teleconnection*.

Regional Climate Model (RCM) A *climate model* at higher *resolution* over a limited area. Such models are used in *downscaling* global *climate* results over specific regional domains.

Relative humidity The relative humidity specifies the ratio of actual water vapour pressure to that at saturation with respect to liquid water or ice at the same temperature. See also *Specific humidity*.

Relative sea level Sea level measured by a *tide gauge* with respect to the land upon which it is situated. See also *Mean sea level* and *Sea level change*.

Representative Concentration Pathways Scenarios that include time series of emissions and concentrations of the full suite of *greenhouse gases* and *aerosols* and chemically active gases, as well as *land use/land cover* (Moss et al., 2008). The word *representative* signifies that each RCP provides only one of many possible scenarios that would lead to the specific *radiative forcing* characteristics. The term *pathway* emphasizes that not only the long-term concentration levels are of interest, but also the trajectory taken over time to reach that outcome. (Moss et al., 2010).

RCPs usually refer to the portion of the concentration pathway extending up to 2100, for which Integrated Assessment Models produced corresponding *emission scenarios*. *Extended Concentration Pathways (ECPs)* describe extensions of the RCPs from 2100 to 2500 that were calculated using simple rules generated by stakeholder consultations, and do not represent fully consistent scenarios.

Four RCPs produced from Integrated Assessment Models were selected from the published literature and are used in the present IPCC Assessment as a basis for the *climate predictions* and *projections* presented in Chapters 11 to 14:

RCP8.5 One high pathway for which radiative forcing reaches $>8.5 \text{ W m}^{-2}$ by 2100 and continues to rise for some amount of time (the corresponding ECP assuming constant emissions after 2100 and constant concentrations after 2250);

RCP6.0 and RCP4.5 Two intermediate *stabilization pathways* in which radiative forcing is stabilized at approximately 6 W m^{-2} and 4.5 W m^{-2} after 2100 (the corresponding ECPs assuming constant concentrations after 2150);

RCP2.6 One pathway where radiative forcing peaks at approximately 3 W m^{-2} before 2100 and then declines (the corresponding ECP assuming constant emissions after 2100).

For further description of future scenarios, see Box 1.2.

Reservoir A component of the *climate system*, other than the *atmosphere*, which has the capacity to store, accumulate or release a substance of concern, for example, carbon, a *greenhouse gas* or a *precursor*. Oceans, soils and *forests* are examples of reservoirs of carbon. *Pool* is an equivalent term (note that the definition of pool often includes the atmosphere). The absolute quantity of the substance of concern held within a reservoir at a specified time is called the *stock*.

Resolution In *climate models*, this term refers to the physical distance (metres or degrees) between each point on the grid used to compute the equations. *Temporal resolution* refers to the time step or time elapse between each model computation of the equations.

Respiration The process whereby living organisms convert organic matter to *carbon dioxide*, releasing energy and consuming molecular oxygen.

Response time The response time or *adjustment time* is the time needed for the *climate system* or its components to re-equilibrate to a new state, following a forcing resulting from external processes. It is very different for various components of the climate system. The response time of the *troposphere* is relatively short, from days to weeks, whereas the *stratosphere* reaches equilibrium on a time scale of typically a few months. Due to their large heat capacity, the oceans have a much longer response time: typically decades, but up to centuries or millennia. The response time of the strongly coupled surface-troposphere system is, therefore, slow compared to that of the stratosphere, and mainly determined by the oceans. The *biosphere* may respond quickly (e.g., to *droughts*), but also very slowly to imposed changes. See *lifetime* for a different definition of response time pertinent to the rate of processes affecting the concentration of trace gases.

Return period An estimate of the average time interval between occurrences of an event (e.g. flood or extreme rainfall) of (or below/above) a defined size or intensity. See also *Return value*.

Return value The highest (or, alternatively, lowest) value of a given variable, on average occurring once in a given period of time (e.g., in 10 years). See also *Return period*.

River discharge See *Streamflow*.

Runoff That part of precipitation that does not evaporate and is not transpired, but flows through the ground or over the ground surface and returns to bodies of water. See also *Hydrological cycle*.

Scenario A plausible description of how the future may develop based on a coherent and internally consistent set of assumptions about key driving forces (e.g., rate of technological change, prices) and relationships. Note that scenarios are neither predictions nor forecasts, but are useful to provide a view of the implications of developments and actions. See also *Climate scenario*, *Emission scenario*, *Representative Concentration Pathways* and *SRES scenarios*.

Sea ice Ice found at the sea surface that has originated from the freezing of seawater. Sea ice may be discontinuous pieces (ice floes) moved on the ocean surface by wind and currents (pack ice), or a motionless sheet attached to the coast (land-fast ice). *Sea ice concentration* is the fraction of the ocean covered by ice. Sea ice less than one year old is called *first-year ice*. *Perennial ice* is sea ice that survives at least one summer. It may be subdivided into *second-year ice* and *multi-year ice*, where multiyear ice has survived at least two summers.

Sea level change Sea level can change, both globally and locally due to (i) changes in the shape of the ocean basins, (ii) a change in ocean volume as a result of a change in the mass of water in the ocean, and (iii) changes in ocean volume as a result of changes in ocean-water density. Global *mean sea level* change resulting from change in the mass of the ocean is called *barystatic*. The amount of barystatic sea level change due to the addition or removal of a mass of water is called its *sea level equivalent (SLE)*. Sea level changes, both globally and locally, resulting from changes in water density are called *steric*. Density changes induced by temperature changes only are called *thermosteric*, while density changes induced by salinity changes are called *halosteric*. Barystatic and steric sea level changes do not include the effect of changes in the shape of ocean basins induced by the change in the ocean mass and its distribution. See also *Relative Sea Level* and *Thermal expansion*.

Sea level equivalent (SLE) The sea level equivalent of a mass of water (ice, liquid or vapour) is that mass, converted to a volume using a density of 1000 kg m^{-3} , and divided by the present-day ocean surface area of $3.625 \times 10^{14} \text{ m}^2$. Thus, 362.5 Gt of water mass added to the ocean will cause 1 mm of global *mean sea level* rise. See also *Sea level change*.

Seasonally frozen ground See *Frozen ground*.

Sea surface temperature (SST) The sea surface temperature is the subsurface bulk temperature in the top few metres of the ocean, measured by ships, buoys and drifters. From ships, measurements of water samples in buckets were mostly switched in the 1940s to samples from engine intake water. Satellite measurements of *skin temperature* (uppermost layer; a fraction of a millimetre thick) in the infrared or the top centimetre or so in the microwave are also used, but must be adjusted to be compatible with the bulk temperature.

Semi-direct (aerosol) effect See *Aerosol-radiation interaction*.

Semi-empirical model Model in which calculations are based on a combination of observed associations between variables and theoretical considerations relating variables through fundamental principles (e.g., conservation of energy). For example, in sea level studies, semi-empirical models refer specifically to transfer functions formulated to project future global *mean sea level change*, or contributions to it, from future *global mean surface temperature* change or *radiative forcing*.

Sensible heat flux The turbulent or conductive flux of heat from the Earth's surface to the *atmosphere* that is not associated with phase changes of water; a component of the surface *energy budget*.

Sequestration See *Uptake*.

Shortwave radiation See *Solar radiation*.

Significant wave height The average trough-to-crest height of the highest one third of the wave heights (sea and swell) occurring in a particular time period.

Sink Any process, activity or mechanism that removes a *greenhouse gas*, an *aerosol* or a *precursor* of a greenhouse gas or aerosol from the *atmosphere*.

Slab-ocean model A simplified representation in a *climate model* of the ocean as a motionless layer of water with a depth of 50 to 100 m. Climate models with a slab ocean can only be used for estimating the equilibrium response of *climate* to a given forcing, not the transient evolution of climate. See also *Equilibrium and transient climate experiment*.

Snow cover extent The areal extent of snow covered ground.

Snow water equivalent (SWE) The depth of liquid water that would result if a mass of snow melted completely.

Soil moisture Water stored in the soil in liquid or frozen form.

Soil temperature The temperature of the soil. This can be measured or modelled at multiple levels within the depth of the soil.

Solar activity General term describing a variety of magnetic phenomena on the Sun such as *sunspots*, *faculae* (bright areas), and flares (emission of high-energy particles). It varies on time scales from minutes to millions of years. See also *Solar cycle*.

Solar ('11 year') cycle A quasi-regular modulation of *solar activity* with varying amplitude and a period of between 8 and 14 years.

Solar radiation Electromagnetic radiation emitted by the Sun with a spectrum close to the one of a black body with a temperature of 5770 K. The radiation peaks in visible wavelengths. When compared to the *terrestrial radiation* it is often referred to as *shortwave radiation*. See also *Insolation* and *Total solar irradiance (TSI)*.

Solar Radiation Management (SRM) Solar Radiation Management refers to the intentional modification of the Earth's shortwave radiative budget with the aim to reduce *climate change* according to a given *metric* (e.g., *surface temperature*, precipitation, regional impacts, etc). Artificial injection of stratospheric *aerosols* and cloud brightening are two examples of SRM techniques. Methods to modify some fast-responding elements of the longwave radiative budget (such as cirrus clouds), although not strictly speaking SRM, can be related to SRM. SRM techniques do not fall within the usual definitions of *mitigation* and adaptation (IPCC, 2012, p. 2). See also *Solar radiation*, *Carbon Dioxide Removal (CDR)* and *Geoengineering*.

Solubility pump Solubility pump is an important physico-chemical process that transports dissolved inorganic carbon from the ocean's surface to its interior. This process controls the inventory of carbon in the ocean. The solubility of gaseous *carbon dioxide* can alter carbon dioxide concentrations in the oceans and the overlying *atmosphere*. See also *Biological pump*.

Source Any process, activity or mechanism that releases a *greenhouse gas*, an *aerosol* or a *precursor* of a greenhouse gas or aerosol into the *atmosphere*.

Southern Annular Mode (SAM) The leading mode of variability of Southern Hemisphere geopotential height, which is associated with shifts in the latitude of the midlatitude jet. See SAM Index, Box 2.5.

Southern Oscillation See *El Niño-Southern Oscillation (ENSO)*.

Spatial and temporal scales *Climate* may vary on a large range of spatial and temporal scales. Spatial scales may range from local (less than 100 000 km²), through regional (100 000 to 10 million km²) to continental (10 to 100 million km²). Temporal scales may range from seasonal to geological (up to hundreds of millions of years).

South Pacific Convergence Zone (SPCZ) A band of low-level convergence, cloudiness and precipitation ranging from the west Pacific warm pool south-eastwards towards French Polynesia, which is one of the most significant features of subtropical Southern Hemisphere *climate*. It shares some characteristics with the *ITCZ*, but is more extratropical in nature, especially east of the Dateline.

Specific humidity The specific humidity specifies the ratio of the mass of water vapour to the total mass of moist air. See also *Relative humidity*.

SRES scenarios SRES scenarios are *emission scenarios* developed by Nakićenović and Swart (2000) and used, among others, as a basis for some of the *climate projections* shown in Chapters 9 to 11 of IPCC (2001) and Chapters 10 and 11 of IPCC (2007). The following terms are relevant for a better understanding of the structure and use of the set of SRES scenarios:

Scenario family Scenarios that have a similar demographic, societal, economic and technical change storyline. Four scenario families comprise the SRES scenario set: A1, A2, B1 and B2.

Illustrative Scenario A scenario that is illustrative for each of the six scenario groups reflected in the Summary for Policymakers of Nakićenović and Swart (2000). They include four revised *marker scenarios* for the scenario groups A1B, A2, B1, B2, and two additional scenarios for the A1FI and A1T groups. All scenario groups are equally sound.

Marker Scenario A scenario that was originally posted in draft form on the SRES website to represent a given scenario family. The choice of markers was based on which of the initial quantifications best reflected the storyline, and the features of specific models. Markers are no more likely than other scenarios, but are considered by the SRES writing team as illustrative of a particular storyline. They are included in revised form in Nakićenović and Swart (2000). These scenarios received the closest scrutiny of the entire writing team and via the SRES open process. Scenarios were also selected to illustrate the other two scenario groups.

Storyline A narrative description of a scenario (or family of scenarios), highlighting the main scenario characteristics, relationships between key driving forces and the dynamics of their evolution.

Steric See *Sea level change*.

Stock See *Reservoir*.

Storm surge The temporary increase, at a particular locality, in the height of the sea due to extreme meteorological conditions (low atmospheric pressure and/or strong winds). The storm surge is defined as being the excess above the level expected from the tidal variation alone at that time and place.

Storm tracks Originally, a term referring to the tracks of individual cyclonic weather systems, but now often generalised to refer to the main *regions* where the tracks of extratropical disturbances occur as sequences of low (cyclonic) and high (anticyclonic) pressure systems.

Stratosphere The highly stratified region of the *atmosphere* above the *troposphere* extending from about 10 km (ranging from 9 km at high latitudes to 16 km in the tropics on average) to about 50 km altitude.

Streamflow Water flow within a river channel, for example expressed in $\text{m}^3 \text{s}^{-1}$. A synonym for *river discharge*.

Subduction Ocean process in which surface waters enter the ocean interior from the surface mixed layer through *Ekman pumping* and lateral *advection*. The latter occurs when surface waters are advected to a region where the local surface layer is less dense and therefore must slide below the surface layer, usually with no change in density.

Sunspots Dark areas on the Sun where strong magnetic fields reduce the convection causing a temperature reduction of about 1500 K compared to the surrounding regions. The number of sunspots is higher during periods of higher *solar activity*, and varies in particular with the *solar cycle*.

Surface layer See *Atmospheric boundary layer*.

Surface temperature See *Global mean surface temperature*, *Land surface air temperature* and *Sea surface temperature*.

Talik A layer of year-round unfrozen ground that lies in *permafrost* areas.

Teleconnection A statistical association between climate variables at widely separated, geographically-fixed spatial locations. Teleconnections are caused by large spatial structures such as basin-wide coupled modes of ocean-*atmosphere* variability, Rossby wave-trains, mid-latitude jets and *storm tracks*, etc. See also *Teleconnection pattern*.

Teleconnection pattern A correlation map obtained by calculating the correlation between variables at different spatial locations and a *climate index*. It is the special case of a *climate pattern* obtained for standardised variables and a standardised climate index i.e., the variables and index are each centred and scaled to have zero mean and unit variance. One-point teleconnection maps are made by choosing a variable at one of the locations to be the climate index. See also *Teleconnection*.

Terrestrial radiation Radiation emitted by the Earth's surface, the *atmosphere* and the clouds. It is also known as *thermal infrared* or *longwave radiation*, and is to be distinguished from the near-infrared radiation that is part of the solar spectrum. *Infrared radiation*, in general, has a distinctive range of wavelengths (*spectrum*) longer than the wavelength of the red light in the visible part of the spectrum. The spectrum of terrestrial radiation is almost entirely distinct from that of shortwave or *solar radiation* because of the difference in temperature between the Sun and the Earth-atmosphere system. See also *Outgoing longwave radiation*.

Thermal expansion In connection with sea level, this refers to the increase in volume (and decrease in density) that results from warming water. A warming of the ocean leads to an expansion of the ocean volume and hence an increase in sea level. See also *Sea level change*.

Thermocline The layer of maximum vertical temperature gradient in the ocean, lying between the surface ocean and the abyssal ocean. In subtropical regions, its source waters are typically surface waters at higher latitudes that have *subducted* (see *Subduction*) and moved equatorward. At high latitudes, it is sometimes absent, replaced by a *halocline*, which is a layer of maximum vertical salinity gradient.

Thermohaline circulation (THC) Large-scale circulation in the ocean that transforms low-density upper ocean waters to higher-density intermediate and deep waters and returns those waters back to the upper ocean. The circulation is asymmetric, with conversion to dense waters in restricted regions at high latitudes and the return to the surface involving slow upwelling and diffusive processes over much larger geographic regions. The THC is driven by high densities at or near the surface, caused by cold temperatures and/or high salinities, but despite its suggestive though common name, is also driven by mechanical forces such as wind and tides. Frequently, the name THC has been used synonymously with *Meridional Overturning Circulation*.

Thermokarst The process by which characteristic landforms result from the thawing of ice-rich *permafrost* or the melting of massive ground ice.

Thermosteric See *Sea level change*.

Tide gauge A device at a coastal or deep-sea location that continuously measures the level of the sea with respect to the adjacent land. Time averaging of the sea level so recorded gives the observed secular changes of the *relative sea level*.

Tipping point In *climate*, a hypothesized critical threshold when global or regional *climate changes* from one stable state to another stable state. The tipping point event may be irreversible. See also *Irreversibility*.

Total solar irradiance (TSI) The total amount of *solar radiation* in Watt per square metre received outside the Earth's *atmosphere* on a surface normal to the incident radiation, and at the Earth's mean distance from the Sun.

Reliable measurements of solar radiation can only be made from space and the precise record extends back only to 1978. The generally accepted value is 1368 W m^{-2} with an accuracy of about 0.2%. It has recently been estimated to $1360.8 \pm 0.5 \text{ W m}^{-2}$ for the solar minimum of 2008. Variations of a few tenths of a percent are common, usually associated with the passage of *sunspots* across the solar disk. The *solar cycle* variation

of TSI is of the order of 0.1% (AMS, 2000). Changes in the ultraviolet part of the spectrum during a solar cycle are comparatively larger (percent) than in TSI. See also *Insolation*.

Transient climate response See *Climate sensitivity*.

Transient climate response to cumulative CO₂ emissions (TCRE) The transient global average *surface temperature* change per unit cumulated CO₂ emissions, usually 1000 PgC. TCRE combines both information on the *airborne fraction* of cumulated CO₂ emissions (the fraction of the total CO₂ emitted that remains in the *atmosphere*), and on the *transient climate response* (TCR).

Tree rings Concentric rings of secondary wood evident in a cross-section of the stem of a woody plant. The difference between the dense, small-celled late wood of one season and the wide-celled early wood of the following spring enables the age of a tree to be estimated, and the ring widths or density can be related to climate parameters such as temperature and precipitation. See also *Proxy*.

Trend In this report, the word *trend* designates a change, generally monotonic in time, in the value of a variable.

Tropopause The boundary between the *troposphere* and the *stratosphere*.

Troposphere The lowest part of the *atmosphere*, from the surface to about 10 km in altitude at mid-latitudes (ranging from 9 km at high latitudes to 16 km in the tropics on average), where clouds and weather phenomena occur. In the troposphere, temperatures generally decrease with height. See also *Stratosphere*.

Turnover time See *Lifetime*.

Uncertainty A state of incomplete knowledge that can result from a lack of information or from disagreement about what is known or even knowable. It may have many types of sources, from imprecision in the data to ambiguously defined concepts or terminology, or uncertain *projections* of human behaviour. Uncertainty can therefore be represented by quantitative measures (e.g., a *probability density function*) or by qualitative statements (e.g., reflecting the judgment of a team of experts) (see Moss and Schneider, 2000; Manning et al., 2004; Mastrandrea et al., 2010). See also *Confidence* and *Likelihood*.

United Nations Framework Convention on Climate Change (UNFCCC) The Convention was adopted on 9 May 1992 in New York and signed at the 1992 Earth Summit in Rio de Janeiro by more than 150 countries and the European Community. Its ultimate objective is the ‘stabilisation of *greenhouse gas* concentrations in the *atmosphere* at a level that would prevent dangerous *anthropogenic* interference with the *climate system*’. It contains commitments for all Parties. Under the Convention, Parties included in Annex I (all OECD countries and countries with economies in transition) aim to return greenhouse gas emissions not controlled by the *Montreal Protocol* to 1990 levels by the year 2000. The convention entered in force in March 1994. In 1997, the UNFCCC adopted the *Kyoto Protocol*.

Uptake The addition of a substance of concern to a *reservoir*. The uptake of carbon containing substances, in particular *carbon dioxide*, is often called (carbon) *sequestration*.

Urban heat island (UHI) The relative warmth of a city compared with surrounding rural areas, associated with changes in *runoff*, effects on heat retention, and changes in surface *albedo*.

Ventilation The exchange of ocean properties with the atmospheric *surface layer* such that property concentrations are brought closer to equilibrium values with the *atmosphere* (AMS, 2000), and the processes that propagate these properties into the ocean interior.

Volatile Organic Compounds (VOC) Important class of organic chemical air pollutants that are volatile at ambient air conditions. Other terms used to represent VOCs are *hydrocarbons* (HCs), *reactive organic gases* (ROGs) and *non-methane volatile organic compounds* (NMVOCs). NMVOCs are major contributors (together with NO_x and CO) to the formation of photochemical oxidants like *ozone*.

Walker Circulation Direct thermally driven zonal overturning circulation in the *atmosphere* over the tropical Pacific Ocean, with rising air in the western and sinking air in the eastern Pacific.

Warm days/warm nights Days where maximum temperature, or nights where minimum temperature, exceeds the 90th *percentile*, where the respective temperature distributions are generally defined with respect to the 1961-1990 *reference* period. For the corresponding indices, see Box 2.4.

Warm spell A period of abnormally hot weather. For the corresponding indices, see Box 2.4. See also *Heat wave*.

Water cycle See *Hydrological cycle*.

Water mass A body of ocean water with identifiable properties (temperature, salinity, density, chemical tracers) resulting from its unique formation process. Water masses are often identified through a vertical or horizontal extremum of a property such as salinity. North Pacific Intermediate Water (NPIW) and Antarctic Intermediate Water (AAIW) are examples of water masses.

Weathering The gradual removal of atmospheric CO_2 through dissolution of silicate and carbonate rocks. Weathering may involve physical processes (*mechanical weathering*) or chemical activity (*chemical weathering*).

Well-mixed greenhouse gas See *Greenhouse gas*.

Younger Dryas A period 12.85 to 11.65 ka (thousand years before 1950), during the *deglaciation*, characterised by a temporary return to colder conditions in many locations, especially around the North Atlantic.
