5.3.3.2 LGM Constraints on Equilibrium Climate Sensitivity

Temperature change recorded in proxies results from various feedback processes, and external forcings vary before equilibrium of the whole Earth system is reached. Nevertheless, the equilibrium climate sensitivity (ECS) can be estimated from past temperatures by explicitly counting the slow components of the processes (e.g., ice sheets) as forcings, rather than as feedbacks (PALAEOSSENS Project Members, 2012). This is achieved in three fundamentally different ways (Edwards et al., 2007); see also Section 9.7.3.2 and Section 10.8.2.4.

In the first approach, ECS is estimated by scaling the reconstructed global mean temperature change in the past with the radiative forcing difference of the past and $2 \times \text{CO}_2$ (Hansen et al., 2008; Köhler et al., 2010) (Table 5.3). The results are subject to uncertainties in the estimate of global mean surface temperature based on proxy records of incomplete spatial coverage (see Section 5.3.3.1). Additional uncertainty is introduced when the sensitivity to LGM forcing is scaled to the sensitivity to $2 \times \text{CO}_2$ forcing, as some but not all (Brady et al., 2013) models show that these sensitivities differ due to the difference in cloud feedbacks (Crucifix, 2006; Hargreaves et al., 2007; Yoshimori et al., 2011) (Figure 5.5a-b).

In the second approach, an ensemble of LGM simulations is carried out using a single climate model in which each ensemble member differs in model parameters and the ensemble covers a range of ECS (Annan et al., 2005; Schneider von Deimling et al., 2006; Holden et al., 2010a; Schmittner et al., 2011) (Table 5.3). Model parameters are then constrained by comparison with LGM temperature proxy information, generating a probability distribution of ECS. While EMICs are often used in order to attain sufficiently large ensemble

size, the uncertainty arising from asymmetric cloud feedbacks cannot be addressed because they are parameterized in the EMICs.

In the third approach, multiple GCM simulations are compared to proxy data, and performance of the models and indirectly their ECSs are assessed (Otto-Bliesner et al., 2009; Braconnot et al., 2012b). Because the cross-model correlation between simulated LGM global cooling and ECS is poor (Figure 5.5a), ECS cannot be constrained by the LGM global mean cooling. Models that show weaker sensitivity to LGM forcing than $4 \times \text{CO}_2$ forcing in Figure 5.5a tend to show weaker shortwave cloud feedback and hence weaker total feedback under LGM forcing than $4 \times \text{CO}_2$ forcing (Figure 5.5b), consistent with previous studies (Crucifix, 2006). The relation found between simulated LGM tropical cooling and ECS across multi-GCM (Hargreaves et al., 2012; Figure 5.5c) has been used to constrain the ECS with the reconstructed LGM tropical cooling (Table 5.3). Again, the main caveats of this approach are the uncertainties in proxy reconstructions and missing dust and vegetation effects which may lead to underestimated LGM cooling in the simulations.

Based on these different approaches, estimates of ECS yield low probability for values outside the range 1°C – 5°C (Table 5.3). Even though there is some uncertainty in these studies due to problems in both the paleoclimate data and paleoclimate modelling as discussed in this section, it is *very likely* that ECS is greater than 1°C , and *very unlikely* that ECS exceeds 6°C .

Table 5.3 Summary of ECS estimates based on LGM climate. Uncertainty ranges are 5–95% confidence intervals, with the exception of MARGO Project Members (2009) where the published interval is reported here.

Method (number follows the “approach” in the text)	ECS Estimate ($^\circ\text{C}$)	Reference and Model Name
1. Proxy data	1.0–3.6	MARGO Project Members (2009)
	1.4–5.2	Köhler et al. (2010)
2. Single-model ensemble constrained by proxy data	<6	Annan et al. (2005), MIROC3.2 AOGCM
	1.2–4.3	Schneider von Deimling et al. (2006), CLIMBER-2
	2.0–5.0	Holden et al. (2010a), GENIE-1
	1.4–2.8	Schmittner et al. (2011), UVic
3. Multi-GCM ensemble constrained by proxy data	~3.6	Fyke and Eby (2012), UVic
	1.2–4.2	Hargreaves et al. (2012), updated with addition of PMIP3/CMIP5 AOGCMs
	1.6–4.5	Hargreaves et al. (2012), updated with addition of PMIP3/CMIP5 AOGCMs ^a

Notes:

(a) Temperature constraints in the tropics were lowered by 0.4°C according to Annan and Hargreaves (2013).

[INSERT FIGURE 5.5 HERE]

Figure 5.5: (a) Relation between equilibrium climate sensitivity (ECS) estimated from LGM simulations and that estimated from equilibrium $2 \times \text{CO}_2$ or abrupt $4 \times \text{CO}_2$ experiments. All experiments are referenced to pre-industrial simulations. FGOALS1, IPSL4, MPI5, and ECBILT of PMIP2 models stand for FGOALS-1.0g, IPSL-CM4-V1-MR, ECHAM53-MPIOM127-LPJ, and ECBILTCLIO, respectively. FGOALS2, IPSL5, MIROCE, MPIE, MRI3, and CNRM5 of PMIP3 models stand for FGOALS-g2, IPSL-CM5A-LR, MIROC-ESM, MPI-ESM-P, MRI-CGCM3, and CNRM-CM5, respectively. ECS based on LGM simulations (abscissa) was derived by multiplying the LGM global mean temperature anomaly (ΔT_{LGM}) and the ratio of radiative forcing between $2 \times \text{CO}_2$ and LGM (ΔF_{ratio}). ΔF_{ratio} for three PMIP2 models (CCSM3, HadCM3, and IPSL4) were taken from Crucifix (2006), and it was taken from Yoshimori et al. (2009) for MIROC3. Its range, -0.80 to -0.56 , with a mean of -0.69 was used for other PMIP2 and all PMIP3 models. ECS of PMIP2 models (ordinate) was taken from Hargreaves et al. (2012). ECS of PMIP3 models was taken from Andrews et al. (2012) and Brady et al. (2013), or computed using the method of Andrews et al. (2012) for FGOALS2. Also plotted is a one-to-one line. (b) Strength of individual feedbacks for the PMIP3/CMIP5 abrupt $4 \times \text{CO}_2$ (131–150 years) and LGM (stable states) experiments following the method in Yoshimori et al. (2011). “WV+LR”, “A”, “C_{SW}”, “C_{LW}” denote water vapour plus lapse-rate, surface albedo, shortwave cloud, and longwave cloud feedbacks, respectively. “All” denotes the sum of all feedbacks except for the Planck response. Feedback parameter here is defined as the change in net radiation at the top of the atmosphere due to the change in individual fields, such as water vapour, with respect to the pre-industrial simulations. It was normalized by the global mean surface air temperature change. Positive (negative) value indicates that the feedback amplifies (damp) the initial temperature

response. Only models with all necessary data available for the analysis are displayed. (c) Relation between LGM tropical (20°S–30°N) surface air temperature anomaly from pre-industrial simulations and ECS across models. A dark blue bar represents a 90% confidence interval for the estimate of reconstructed temperature anomaly of Annan and Hargreaves (2013). A light blue bar represents the same with additional 0.4°C anomaly increase according to the result of the sensitivity experiment conducted in Annan and Hargreaves (2013), in which additional 1°C lowering of tropical SST proxy data was assumed. (d) Same as in c but for the average of East Antarctica ice core sites of Dome F, Vostok, EDC and EDML. A dark blue bar represents a range of reconstructed temperature anomaly based on stable isotopes at these core sites (Stenni et al., 2010; Uemura et al., 2012). A value below zero is not displayed (the result of CNRM5). Note that the Antarctic ice sheet used for PMIP3 simulations, based on several different methods (Tarasov and Peltier, 2007; Argus and Peltier, 2010; Lambeck et al., 2010) differs in elevation from that used in PMIP2 (panel d).

5.3.4 Past Interglacials

Past interglacials are characterized by different combinations of orbital forcing (Section 5.2.1.1), atmospheric composition (Section 5.2.2.1) and climate responses (Tzedakis et al., 2009; Lang and Wolff, 2011). Documenting natural interglacial climate variability in the past provides a deeper understanding of the physical climate responses to orbital forcing. This section reports on interglacials of the past 800 kyr, with emphasis on the Last Interglacial (LIG, Table 5.1) which has more data and modelling studies for assessing regional and global temperature changes than earlier interglacials. The LIG sea level responses are assessed in Section 5.6.2. Section 5.5 is devoted to the current interglacial, the Holocene.

The phasing and strengths of the precessional parameter and obliquity varied over past interglacials (Figure 5.3b,c), influencing their timing, duration, and intensity (Tzedakis et al., 2012b; Yin and Berger, 2012) (Figure 5.3e,f,h). Since 800 ka, atmospheric CO₂ concentrations during interglacials were systematically higher than during glacial periods. Prior to ~430 ka, ice cores from Antarctica record lower interglacial CO₂ concentrations than for the subsequent interglacial periods (Section 5.2.2.1; Figure 5.3d). While LIG WMGHG concentrations were similar to the pre-industrial Holocene values, orbital conditions were very different with larger latitudinal and seasonal insolation variations. Large eccentricity and the phasing of precession and obliquity (Figure 5.3a-c) during the LIG resulted in July 65°N insolation peaking at ~126 ka and staying above the Holocene maximum values from ~129 to 123 ka. The high obliquity (Figure 5.3b) contributed to small, but positive annual insolation anomalies at high latitudes in both hemispheres and negative anomalies at low latitudes.

New data and syntheses from marine and terrestrial archives, with updated age models, have provided an expanded view of temperature patterns during interglacials since 800 ka (Masson-Delmotte et al., 2010a; Lang and Wolff, 2011; Rohling et al., 2012). There is currently no consensus on whether interglacials changed intensity after ~430 ka. EPICA Dome C Antarctic ice cores record warmer temperatures after this transition (Jouzel et al., 2007) and marine records of deep-water temperatures are characterized by generally higher values during later interglacials than earlier interglacials (Lang and Wolff, 2011). In contrast, similar interglacial magnitudes are observed across the ~430 ka boundary in some terrestrial archives from Eurasia (Prokopenko et al., 2002; Tzedakis et al., 2006; Candy et al., 2010). Simulations with an EMIC relate global and southern high latitude mean annual surface temperature variations to changes in CO₂ variations, while orbital forcing and associated feedbacks of vegetation and sea ice have a major impact on the simulated northern high-latitude mean annual surface temperature (Yin and Berger, 2012). The highest and lowest interglacial temperatures occur in models when WMGHG concentrations and local insolation reinforce each other (Yin and Berger, 2010; Herold et al., 2012; Yin and Berger, 2012).

At the time of the AR4, a compilation of Arctic records and two AOGCM simulations allowed an assessment of LIG summer temperature changes. New quantitative data syntheses (Figure 5.6a) now allow estimation of maximum annual surface temperatures around the globe for the LIG (Turney and Jones, 2010; McKay et al., 2011). A caveat is that these data syntheses assume that the warmest phases were globally synchronous (see Figure 5.6 legend for details). However, there is *high confidence* that warming in the Southern Ocean (Cortese et al., 2007; Schneider Mor et al., 2012) and over Antarctica (Masson-Delmotte et al., 2010b) occurred prior to peak warmth in the North Atlantic, Nordic Seas, and Greenland (Bauch et al., 2011; Govin et al., 2012; NEEM community members, 2013). Overall, higher annual temperatures than pre-industrial are reconstructed for high latitudes of both hemispheres. At ~128 ka, East Antarctic ice cores record early peak temperatures ~5°C above the present, (Jouzel et al., 2007; Sime et al., 2009; Stenni et al., 2010). Higher temperatures are derived for northern Eurasia and Alaska, with sites near the Arctic coast in Northeast

Siberia indicating warming of more than 10°C as compared to late Holocene (Velichko et al., 2008). Greenland warming of 8°C ± 4°C at 126 ka is estimated from the new Greenland NEEM ice core, after accounting for ice sheet elevation changes (NEEM community members, 2013). Seasonally open waters off northern Greenland and in the central Arctic are recorded during the LIG (Nørgaard-Pedersen et al., 2007; Adler et al., 2009). Changes in Arctic sea ice cover (Sime et al., 2013) may have affected the Greenland water stable isotope – temperature relationship, adding some uncertainty to LIG Greenland temperature reconstructions. Marine proxies from the Atlantic indicate warmer than late Holocene year-round SSTs north of 30°N, while SST changes were more variable south of this latitude (McKay et al., 2011).

Transient LIG simulations with EMICs and low-resolution AOGCMs display peak NH summer warmth between 128 ka and 125 ka in response to orbital and WMGHG forcings. This warming is delayed when NH ice sheets are allowed to evolve (Bakker et al., 2013). Time-slice climate simulations run by 13 modelling groups with a hierarchy of climate models forced with orbital and WMGHG changes for 128–125 ka (Figure 5.6b) simulate the reconstructed pattern of NH annual warming (Figure 5.6a). Positive feedbacks with the cryosphere (sea ice and snowcover) provide the memory that allows simulated NH high-latitude warming, annually as well as seasonally, in response to the seasonal orbital forcing (Schurgers et al., 2007; Yin and Berger, 2012). The magnitude of observed NH annual warming though is only reached in summer in the simulations (Lunt et al., 2013) (Figure 5.6c,d). The reasons for this discrepancy are not yet fully determined. Error bars on temperature reconstructions vary significantly between methods and regions, due to the effects of seasonality and resolution (Kienast et al., 2011; McKay et al., 2011; Tarasov et al., 2011). Differences may also be related to model representations of cloud and sea ice processes (Born et al., 2010; Fischer and Jungclaus, 2010; Kim et al., 2010; Otto-Bliesner et al., 2013), and that most LIG simulations set the vegetation and ice sheets to their pre-industrial states (Schurgers et al., 2007; Holden et al., 2010b; Bradley et al., 2013). Simulations accounting for the bipolar seesaw response to persistent iceberg melting at high northern latitudes (Govin et al., 2012) and disintegration of the WAIS (Overpeck et al., 2006) (see Section 5.6.2.3) are better able to reproduce the early LIG Antarctic warming (Holden et al., 2010b).

From data synthesis, the LIG global mean annual surface temperature is estimated to be ~1°C–2°C warmer than pre-industrial (Turney and Jones, 2010; Otto-Bliesner et al., 2013), albeit proxy reconstructions may overestimate the global temperature change. In response to orbital forcing and WMGHG concentration changes, time slice simulations for 128–125ka exhibit global mean annual surface temperature changes of 0.0°C ± 0.5°C as compared to pre-industrial. Data and models suggest a land-ocean contrast in the responses to the LIG forcing (Figure 5.6c,d). Peak global annual SST warming is estimated from data to be 0.7°C ± 0.6°C (*medium confidence*) (McKay et al., 2011). Models give more confidence to the lower bound. The ensemble of climate model simulations gives a large range of global annual land temperature change relative to pre-industrial, –0.4°C to 1.7°C, when sampled at the data locations and cooler than when averaged for all model land areas, pointing to difficulties in estimating global mean annual surface temperature with current spatial data coverage (Otto-Bliesner et al., 2013).

[INSERT FIGURE 5.6 HERE]

Figure 5.6: Changes in surface temperature for the LIG as reconstructed from data and simulated by an ensemble of climate model experiments in response to orbital and WMGHG forcings. (a) Proxy data syntheses of annual surface temperature anomalies as published by Turney and Jones (2010) and McKay et al. (2011). McKay et al., (2011) calculated an annual anomaly for each record as the average SST of the 5-kyr period centred on the warmest temperature between 135 ka and 118 ka and then subtracting the average SST of the late Holocene (last 5 kyr). Turney and Jones (2010) calculated the annual temperature anomalies relative to 1961–1990 by averaging the LIG temperature estimates across the isotopic plateau in the marine and ice records and the period of maximum warmth in the terrestrial records (assuming globally synchronous terrestrial warmth). (b) Multi-model average of annual surface air temperature anomalies simulated for the LIG computed with respect to pre-industrial. The results for the LIG are obtained from 16 simulations for 128–125 ka conducted by 13 modelling groups (Lunt et al., 2013). (c) Seasonal SST anomalies. Multi-model zonal averages are shown as solid line with shaded bands indicating 2 standard deviations. Plotted values are the respective seasonal multi-mean global average. Symbols are individual proxy records of seasonal SST anomalies from McKay et al., 2011. (d) Seasonal terrestrial surface temperature anomalies. As in (c) but with symbols representing terrestrial proxy records as compiled from published literature (Table 5.A.5). Observed seasonal terrestrial anomalies larger than 10°C or less than –6°C are not shown.

5.3.5 Temperature Variations During the Last 2000 Years

The last two millennia allow comparison of instrumental records with multidecadal-to-centennial variability arising from external forcings and internal climate variability. The assessment benefits from high-resolution proxy records and reconstructions of natural and anthropogenic forcings back to at least 850 (Section 5.2), used as boundary conditions for transient GCM simulations. Since AR4, expanded proxy data networks and better understanding of reconstruction methods have supported new reconstructions of surface temperature changes during the last 2000 years (Section 5.3.5.1) and their associated uncertainties (Section 5.3.5.2), and supported more extensive comparisons with GCM simulations (Section 5.3.5.3).

5.3.5.1 Recent Warming in the Context of New Reconstructions

New paleoclimate reconstruction efforts since AR4 (Figure 5.7; Table 5.4; Table 5.A.1) have provided further insights into the characteristics of the Medieval Climate Anomaly (MCA; Table 5.1) and the Little Ice Age (LIA; Table 5.1). The timing and spatial structure of the MCA and LIA are complex (see Box 6.4 in AR4 and Diaz et al., 2011) (and section 5.5), with different reconstructions exhibiting warm and cold conditions at different times for different regions and seasons. The median of the NH temperature reconstructions (Figure 5.7) indicates mostly warm conditions from ca. 950–1250 and colder conditions from ca. 1450–1850; these time intervals are chosen here to represent the MCA and the LIA, respectively.

Based on multiple lines of evidence (using different statistical methods or different compilations of proxy records; see Appendix 5.A.1 for a description of reconstructions and selection criteria), published reconstructions and their uncertainty estimates indicate, with *high confidence*, that the mean NH temperature of the last 30 or 50 years *very likely* exceeded any previous 30- or 50-year mean during the past 800 years (Table 5.4). The timing of warm and cold periods is mostly consistent across reconstructions (in some cases this is because they use similar proxy compilations) but the magnitude of the changes is clearly sensitive to the statistical method and to the target domain (land or land and sea; the full hemisphere or only the extra-tropics; Figure 5.7a). Even accounting for these uncertainties, almost all reconstructions agree that each 30-year (50-year) period from 1200 to 1899 was *very likely* colder in the NH than the 1983–2012 (1963–2012) instrumental temperature.

NH reconstructions covering part or all of the first millennium suggest that some earlier 50-year periods might have been as warm as the 1963–2012 mean instrumental temperature, but the higher temperature of the last 30 years appear to be at least likely the warmest 30-year period in all reconstructions (Table 5.4). However, the confidence in this finding is lower prior to 1200, because the evidence is less reliable and there are fewer independent lines of evidence. There are fewer proxy records, thus yielding less independence among the reconstructions while making them more susceptible to errors in individual proxy records. The published uncertainty ranges do not include all sources of error (Section 5.3.5.2), and some proxy records and uncertainty estimates do not fully represent variations on timescales as short as the 30 years considered in Table 5.4. Considering these caveats, there is *medium confidence* that the last 30 years were *likely* the warmest 30-year period of the last 1400 years.

Increasing numbers of proxy records and regional reconstructions are being developed for the SH (see Section 5.5), but few reconstructions of SH or global mean temperatures have been published (Figure 5.7b,c). The SH and global reconstructions with published uncertainty estimates indicate that each 30- or 50-year interval during the last four centuries was *very likely* colder than the warmest 30- or 50-year interval after 1900 (Table 5.4). However, there is only limited proxy evidence and therefore *low confidence* that the recent warming has exceeded the range of reconstructed temperatures for the SH and global scales.

[INSERT FIGURE 5.7 HERE]

Figure 5.7: Reconstructed (a) Northern Hemisphere and (b) Southern Hemisphere, and (c) global annual temperatures during the last 2000 years. Individual reconstructions (see Appendix 5.A.1 for further information about each one) are shown as indicated in the legends, grouped by colour according to their spatial representation (red: land-only all latitudes; orange: land-only extra-tropical latitudes; light blue: land and sea extra-tropical latitudes; dark blue: land and sea all latitudes) and instrumental temperatures shown in black (HadCRUT4 land and sea, and CRUTEM4 land-only; Morice et al., 2012). All series represent anomalies (°C) from the 1881–1980 mean (horizontal dashed line) and have been smoothed with a filter that reduces variations on timescales less than ~50 years.

Table 5.4: Comparison of recent hemispheric and global temperature estimates with earlier reconstructed values, using published uncertainty ranges to assess likelihood of unusual warmth. Each reconstructed *N*-year mean temperature within the indicated period is compared with both the warmest *N*-year mean reconstructed after 1900 and with the most recent *N*-year mean instrumental temperature, for *N* = 30 and *N* = 50 years. Blue symbols indicate the periods and reconstructions where the reconstructed temperatures are *very likely* cooler than the post-1900 reconstruction (■), or otherwise *very likely* (*) or *likely* (⊠) cooler than the most recent instrumental temperatures; □ indicates that some reconstructed temperatures were as likely warmer or colder than recent temperatures.

Notes:

Symbols indicate the likelihood (based on the published multi-decadal uncertainty ranges) that each *N*-year mean of the reconstructed temperature during the indicated period was colder than the warmest *N*-year mean after 1900. A reconstructed mean temperature *X* is considered to be likely (very likely) colder than a modern temperature *Y* if $X + aE < Y$, where *E* is the reconstruction standard error and *a* = 0.42 (1.29) corresponding to a 66% (90%) one-tailed confidence interval assuming the reconstruction error is normally distributed. Symbols indicate that the reconstructed temperatures were either:

⊠ likely colder than the 1983–2012 or 1963–2012 mean instrumental temperature;

* very likely colder than the 1983–2012 or 1963–2012 mean instrumental temperature;

■ very likely colder than the 1983–2012 or 1963–2012 mean instrumental temperature and additionally very likely colder than the warmest 30- or 50-year mean of the post-1900 reconstruction (which is typically not as warm as the end of the instrumental record);

□ indicates that at least one *N*-year reconstructed mean is about as likely colder or warmer than the 1983–2012 or 1963–2012 mean instrumental temperature.

No symbol is given where the reconstruction does not fully cover the indicated period.

Identification and further information for each study is given in Table 5.A.6 of Appendix 5.A.1:

1=Mo05wave; 2=Ma08eivf; 3=Ma09regm; 4=Ju07cvm; 5=LM08ave; 6=Ma08cpsl; 7=Ma08eivl; 8=Sh13pcar; 9=LO2012; 10=Lj10cps; 11=CL12loc; 12=He07tls; 13=Da06treecps; 14=Fr07treecps; 15=PS04bore.

5.3.5.2 Reconstruction Methods, Limitations and Uncertainties

Reconstructing NH, SH or global-mean temperature variations over the last 2000 years remains a challenge due to limitations of spatial sampling, uncertainties in individual proxy records and challenges associated with the statistical methods used to calibrate and integrate multi-proxy information (Hughes and Ammann, 2009; Jones et al., 2009; Frank et al., 2010a). Since AR4, new assessments of the statistical methods used to reconstruct either global/hemispheric temperature averages or spatial fields of past temperature anomalies have been published. The former include approaches for simple compositing and scaling of local or regional

proxy records into global and hemispheric averages using uniform or proxy-dependent weighting (Hegerl et al., 2007; Juckes et al., 2007; Mann et al., 2008; Christiansen and Ljungqvist, 2012). The latter correspond to improvements in climate field reconstruction methods (Mann et al., 2009; Smerdon et al., 2011) that apply temporal and spatial relationships between instrumental and proxy records to the pre-instrumental period. New developments for both reconstruction approaches include implementations of Bayesian inference (Li et al., 2010a; Tingley and Huybers, 2010; McShane and Wyner, 2011; Tingley and Huybers, 2013; Werner et al., 2013). In particular, Bayesian hierarchical models enable a more explicit representation of the underlying processes that relate proxy (and instrumental) records to climate, allowing a more systematic treatment of the multiple uncertainties that affect the climate reconstruction process. This is done by specifying simple parametric forms for the proxy-temperature relationships that are then used to estimate a probability distribution of the reconstructed temperature evolution that is compatible with the available data (Tingley et al., 2012).

An improved understanding of potential uncertainties and biases associated with reconstruction methods has been achieved, particularly by using millennial GCM simulations as a surrogate reality in which pseudo-proxy records are created and reconstruction methods are replicated and tested (Smerdon, 2012). A key finding is that the methods used for many published reconstructions can underestimate the amplitude of the low-frequency variability (Lee et al., 2008; Christiansen et al., 2009; Smerdon et al., 2010). The magnitude of this amplitude attenuation in real-world reconstructions is uncertain, but for affected methods the problem will be larger: (i) for cases with weaker correlation between instrumental temperatures and proxies (Lee et al., 2008; Christiansen et al., 2009; Smerdon et al., 2011); (ii) if errors in the proxy data are not incorporated correctly (Hegerl et al., 2007; Ammann et al., 2010); or (iii) if the data are detrended in the calibration phase (Lee et al., 2008; Christiansen et al., 2009). The 20th-century trends in proxies may contain relevant temperature information (Ammann and Wahl, 2007) but calibration with detrended or undetrended data has been an issue of debate (von Storch et al., 2006; Wahl et al., 2006; Mann et al., 2007) because trends in proxy records can be induced by other (non-temperature) climate and non-climatic influences (Jones et al., 2009; Gagen et al., 2011). Recent developments mitigate the loss of low-frequency variance in global and hemispheric reconstructions by increasing the correlation between proxies and temperature through temporal smoothing (Lee et al., 2008) or by correctly attributing part or all of the temperature-proxy differences to imperfect proxy data (Hegerl et al., 2007; Juckes et al., 2007; Mann et al., 2008). Pseudoproxy experiments have shown that the latter approach used with a site-by-site calibration (Christiansen, 2011; Christiansen and Ljungqvist, 2012) can also avoid attenuation of low-frequency variability, though it is debated whether it might instead inflate the variability and thus constitute an upper bound for low-frequency variability (Moberg, 2013). Even those field reconstruction methods that do not attenuate the low-frequency variability of global or hemispheric means may still suffer from attenuation and other errors at regional scales (Smerdon et al., 2011; Annan and Hargreaves, 2012; Smerdon, 2012; Werner et al., 2013).

The fundamental limitations for deriving past temperature variability at global/hemispheric scales are the relatively short instrumental period and the number, temporal and geographical distribution, reliability and climate signal of proxy records (Jones et al., 2009). The database of high-resolution proxies has been expanded since AR4 (Mann et al., 2008; Wahl et al., 2010; Neukom and Gergis, 2011; PAGES 2k Consortium, 2013), but data are still sparse in the tropics, SH and over the oceans (see new developments in Section 5.5). Integration of low-resolution records (e.g., marine or some lake sediment cores and some speleothem records) with high-resolution tree-ring, ice core and coral records in global/hemispheric reconstructions is still challenging. Dating uncertainty, limited replication and the possibility of temporal lags in low-resolution records (Jones et al., 2009) make regression-based calibration particularly difficult (Christiansen et al., 2009) and can be potentially best addressed in the future with Bayesian hierarchical models (Tingley et al., 2012). The short instrumental period and the paucity of proxy data in specific regions may preclude obtaining accurate estimates of the covariance of temperature and proxy records (Juckes et al., 2007), impacting the selection and weighting of proxy records in global/hemispheric reconstructions (Bürger, 2007; Osborn and Briffa, 2007; Emile-Geay et al., 2013b) and resulting in regional errors in climate field reconstructions (Smerdon et al., 2011).

Two further sources of uncertainty have been only partially considered in the published literature. First, some studies have used multiple statistical models (Mann et al., 2008) or generated ensembles of reconstructions by sampling parameter space (Frank et al., 2010b), but this type of structural and parameter uncertainty needs further examination (Christiansen et al., 2009; Smerdon et al., 2011). Second, proxy-

temperature relationships may change over time due to the effect of other climate and non-climate influences on a proxy, a prominent example being the divergence between some tree-ring width and density chronologies and instrumental temperature trends during the last decades of the 20th century (Briffa et al., 1998). In cases that do show divergence, a number of factors may be responsible, such as direct temperature or drought stress on trees, delayed snowmelt, changes in seasonality and reductions in solar radiation (Lloyd and Bunn, 2007; D'Arrigo et al., 2008; Porter and Pisaric, 2011). However, this phenomenon does not affect all tree-ring records (Wilson et al., 2007; Esper and Frank, 2009) and in some cases where divergence is apparent it may arise from the use of inappropriate statistical standardization of the data (Melvin and Briffa, 2008; Briffa and Melvin, 2011) and not due to a genuine change in the proxy–temperature relationship. For the European Alps and Siberia, (Büntgen et al., 2008; Esper et al., 2010) demonstrate that divergence can be avoided by careful selection of sites and standardization methods together with large sample replication.

Limitations in proxy data and reconstruction methods suggest that published uncertainties will underestimate the full range of uncertainties of large-scale temperature reconstructions (see Section 5.3.5.1). While this has fostered debate about the extent to which proxy-based reconstructions provide useful climate information (e.g., McShane and Wyner, 2011 and associated comments and rejoinder), it is well established that temperature and external forcing signals are detectable in proxy reconstructions (Sections 5.3.5.3; 10.7.2). Recently, model experiments assuming a nonlinear sensitivity of tree-rings to climate (Mann et al., 2012) have been used to suggest that the tree-ring response to volcanic cooling may be attenuated and lagged. Tree-ring data and additional tree-growth model assessments (Anchukaitis et al., 2012; Esper et al., 2013) have challenged this interpretation and analyses of instrumental data suggest hemispheric temperature reconstructions agree well with the degree of volcanic cooling during early 19th-century volcanic events (Brohan et al., 2012; see Section 5.3.5.3). These lines of evidence leave the representation of volcanic events in tree-ring records and associated hemispheric scale temperature reconstructions as an emerging area of investigation.

5.3.5.3 Comparing Reconstructions and Simulations

The number of GCM simulations of the last millennium has increased since AR4 (Fernández-Donado et al., 2013). The simulations have used different estimates of natural and anthropogenic forcings (Table 5.A.1). In particular, the PMIP3/CMIP5 simulations are driven by smaller long-term changes in TSI (Section 5.2.1; Figure 5.1b): TSI increases by $\leq 0.10\%$ from the Late Maunder Minimum (LMM; 1675–1715) to the late 20th century (Schmidt et al., 2011), while most previous simulations use increases between 0.23% and 0.29% (Fernández-Donado et al., 2013). Simulated NH temperatures during the last millennium lie mostly within the uncertainties of the available reconstructions (Figure 5.8a). This agreement between GCM simulations and reconstructions provides neither strong constraints on forcings nor on model sensitivities because internal variability and uncertainties in the forcings and reconstructions are considerable factors.

Data have also been assimilated into climate models (see Sections 5.5 and 10.7, Figure 10.18) by either nudging simulations to follow local or regional proxy-based reconstructions (Widmann et al., 2010) or by selecting simulations from decade-by-decade ensembles to obtain the closest match to reconstructed climate patterns (Annan and Hargreaves, 2012; Goosse et al., 2012a). The resulting simulations provide insight into the relative roles of internal variability and external forcing (Goosse et al., 2012b), and processes that may account for the spatial distribution of past climate anomalies (Crespin et al., 2009; Palastanga et al., 2011).

Figure 5.8b-d provides additional tests of model-data agreement by compositing the temperature response to a number of distinct forcing events. The models simulate a significant NH cooling in response to volcanic events (Figure 5.8b; peaks between 0.1°C and 0.5°C depending on model) that lasts 3 to 5 years, overlapping with the signal inferred from reconstructions with annual resolution (0.05°C–0.3°C). CMIP5 simulations tend to overestimate cooling following the major 1809 and 1815 eruptions relative to early instrumental data (Brohan et al., 2012). Such differences could arise from uncertainties in volcanic forcing (Section 5.2.1.3) and its implementation in climate models (Joshi and Jones, 2009) or from errors in the reconstructions (Section 5.3.5.2). Since many reconstructions do not have annual resolution, similar composites (Figure 5.8c) are formed to show the response to changes in multidecadal volcanic forcings (representing clusters of eruptions). Both the simulated and reconstructed responses are significant and comparable in magnitude, although simulations show a faster recovery (<5 years) than reconstructions. Solar forcing estimated over the last millennium shows weaker variations than volcanic forcing (Figure 5.8d), even at multidecadal

timescales. Compositing the response to multidecadal fluctuations in solar irradiance shows cooling in simulations and reconstructions of NH temperature between 0.0°C and 0.15°C. In both cases, the cooling may be partly a response to concurrent variations in volcanic forcing (green line in Figure 5.8d).

Temperature differences between the warmest and coolest centennial or multi-centennial periods provide an additional comparison of the amplitude of NH temperature variations in the reconstructions and simulations: between 950–1250 (nominally the MCA) and 1450–1850 (nominally the LIA; Figures 5.8e; 5.9a–c) and between the LIA and the 20th century (Figures 5.8f; 5.9g–i). Despite similar multi-model and multi-reconstruction means for the warming from the LIA to the present, the range of individual results is very wide (see Sections 9.5.3.1 and 10.7.1 for a comparison of reconstructed and simulated variability across various frequency ranges) and there is no clear difference between runs with weaker or stronger solar forcing (Figure 5.8f; Section 10.7.2.2). The difference between the MCA and LIA temperatures, however, has a smaller range for the model simulations than the reconstructions, and the simulations (especially those with weaker solar forcing) lie within the lower half of the reconstructed range of temperature changes (Figure 5.8e). Recent studies have assessed the consistency of model simulations and temperature reconstructions at the hemispheric scale. Hind and Moberg (2012) found closer data-model agreement for simulations with 0.1% TSI increase than 0.24% TSI increase, but the result is sensitive to the reconstruction uncertainty and the climate sensitivity of the model. Simulations with an EMIC using a much stronger solar forcing (0.44% TSI increase from LMM to present, Shapiro et al., 2011) appear to be incompatible with most temperature reconstructions (Feulner, 2011).

The spatial distributions of simulated and reconstructed (Mann et al., 2009; Ljungqvist et al., 2012) temperature changes between the MCA, LIA and 20th century are shown in Figure 5.9. Simulated changes tend to be larger, particularly with stronger TSI forcing, over the continents and ice/snow-covered regions, showing polar amplification (see Box 5.1). The largest simulated and reconstructed changes are between the LIA and present, with reconstructions (Figure 5.9i) indicating widespread warming except for the cooling south of Greenland. Models also simulate overall warming between the MCA and present (Figure 5.9d,e), whereas the reconstructions indicate significant regional cooling (in the North Atlantic, southeastern North America, and the mid-latitudes of the Pacific Ocean). This is not surprising because greater regional variability is expected in the reconstructions compared with the mean of multiple model simulations, though reconstructed changes for such areas with few or no proxy data (Figure 5.9i) should also be interpreted with caution (Smerdon et al., 2011). The reconstructed temperature differences between MCA and LIA (Figure 5.9c) indicate higher medieval temperatures over the NH continents in agreement with simulations (Figure 5.9a,b). The reconstructed MCA warming is higher than in the simulations, even for stronger TSI changes and individual simulations (Fernández-Donado et al., 2013). Simulations with proxy assimilation show that this pattern of change is compatible with a direct response to a relatively weak solar forcing and internal variability patterns similar to a positive Northern Annular Mode (NAM) phase and northward shifts of the Kuroshio and Gulf Stream currents (Goosse et al., 2012b). For the tropical regions, an enhanced zonal SST gradient produced by either a warmer Indian Ocean (Graham et al., 2011) or a cooler eastern Pacific (La Niña-like state) (Seager et al., 2007; Mann et al., 2009) could explain the reconstructed MCA patterns (Figure 5.9c). However, the enhanced gradients are not reproduced by model simulations (Figure 5.9a,b) and are not robust when considering the reconstruction uncertainties and the limited proxy records in these tropical ocean regions (Emile-Geay et al., 2013b) (Sections 5.4.1, 5.5.1). This precludes an assessment of the role of external forcing and/or internal variability in these reconstructed patterns.

[INSERT FIGURE 5.8 HERE]

Figure 5.8: Comparisons of simulated and reconstructed NH temperature changes. (a) Changes over the last millennium. (b) Response to individual volcanic events. (c) Response to multidecadal periods of volcanic activity. (d) Response to multidecadal variations in solar activity. (e) Mean change from MCA to LIA. (f) Mean change from 20th century to LIA. Note that some reconstructions represent a smaller spatial domain than the full NH or a specific season, while annual temperatures for the full NH mean are shown for the simulations. (a) Simulations shown by coloured lines (thick lines: multi-model-mean; thin lines: multi-model 90% range; red/blue lines: models forced by stronger/weaker solar variability, though other forcings and model sensitivities also differ between the red and blue groups); overlap of reconstructed temperatures shown by grey shading; all data are expressed as anomalies from their 1500–1850 mean and smoothed with a 30-year filter. Superposed composites (time segments from selected periods positioned so that the years with peak negative forcing are aligned) of the forcing and temperature response to: (b) 12 of the strongest individual volcanic forcing events after 1400 (the data shown are not smoothed); (c) multidecadal changes in volcanic activity; (d) multidecadal changes in solar irradiance. Upper panels show volcanic or solar forcing for the individual

selected periods together with the composite mean (thick line); in (d), the composite mean of volcanic forcing (green) during the solar composite is also shown. Lower panels show the NH temperature composite means and 90% range of spread between simulations (red line, pink shading) or reconstructions (grey line and shading), with overlap indicated by darker shading. Mean NH temperature difference between (e) MCA (950–1250) and LIA (1450–1850) and (f) 20th century (1900–2000) and LIA, from reconstructions (grey), multi-reconstruction mean and range (dark grey), multi-model mean and range and individual simulations (red/blue for models forced by stronger/weaker solar variability). Where an ensemble of simulations is available from one model, the ensemble mean is shown in solid and the individual ensemble members by open circles. Results are sorted into ascending order and labelled. Reconstructions, models and further details are given in Appendix 5.A.1 and Tables 5.A.1 and 5.A.6.

[INSERT FIGURE 5.9 HERE]

Figure 5.9: Simulated and reconstructed temperature changes for key periods in the last millennium. Annual temperature differences for: (a) to (c) MCA (950–1250) minus LIA (1450–1850); (d) to (f) present (1950–2000) minus MCA; (g) to (i) present minus LIA. Model temperature differences (left and middle columns) are average temperature changes in the ensemble of available model simulations of the last millennium, grouped into those using stronger (TSI change from the LMM to present $>0.23\%$; left column; SS in Table 5.A.1) or weaker solar forcing changes (TSI change from the LMM to present $<0.1\%$; middle column; SW in Table 5.A.1). Right column panels (c, f, i) show differences (shading) for the Mann et al. (2009) field reconstruction. In (c), dots represent additionally proxy differences from Ljungqvist et al. (2012), scaled by 0.5 for display purposes. The distribution, type and temporal span of the input data used in the field reconstruction of Mann et al. (2009) are shown in (j); proxy types are included in the legend, acronyms stand for: tree-ring maximum latewood density (MXD); tree-ring width (TRW); regional TRW composite (TRW-RC); and multi-proxy climate field reconstruction (CFR). Dotted grid-cells indicate non-significant differences (<0.05 level) in reconstructed fields (right) or that $<80\%$ of the simulations showed significant changes of the same sign (left and middle). For simulations starting after 950, the period 1000–1250 was used to estimate MCA values. Grid-cells outside the domain of the Mann et al. (2009) reconstruction are shaded grey in the model panels to enable easier comparison, though contours (interval 0.2 K) illustrate model output over the complete global domain. Only simulations spanning the whole millennium and including at least solar, volcanic and greenhouse gas forcing have been used (Table 5.A.1): BCC-csm1-1 (1), CCSM3 (1), CCSM4 (1), CNRM-CM3.3, CSIRO-mk3L-1-2 (4), CSM1.4 (1), ECHAM5-MPIOM (8), ECHO-G (1), MPI-ESM-P (1), FGOALS-g1 (1), GISS-E2-R (3), HadCM3 (1), IPSL-CM5A-LR (1). Averages for each model are calculated first, to avoid models with multiple simulations having greater influence on the ensemble means shown here.

5.4 Modes of Climate Variability

Since AR4, new proxy reconstructions and model simulations have provided additional insights into the forced and unforced behaviour of modes of climate variability. This section focuses only on the interannual ENSO, the NAM and NAO, the Southern Annular Mode (SAM) and longer term variability associated with the Atlantic Multidecadal Oscillation (AMO) (see Glossary and Chapter 14 for definitions and illustrations and Box 2.5). It is organized from low to high latitudes and from interannual to decadal-scale modes of variability.

5.4.1 Tropical Modes

During the MPWP, climate conditions in the equatorial Pacific were characterized by weaker zonal (Wara et al., 2005) and cross-equatorial (Steph et al., 2010) SST gradients, consistent with the absence of an eastern equatorial cold tongue. This state still supported interannual variability, according to proxy records (Scroxton et al., 2011; Watanabe et al., 2011). These results together with recent GCM experiments (Haywood et al., 2007) indicate (*medium confidence*) that interannual ENSO variability existed, at least sporadically, during the warm background state of the Pliocene (Section 5.3.1).

LGM GCM simulations display wide ranges in the behaviour of ENSO and the eastern equatorial Pacific annual cycle of SST with little consistency (Liu et al., 2007a; Zheng et al., 2008) (Figure 5.10). Currently ENSO variance reconstructions for the LGM are too uncertain to help constrain the simulated responses of the annual cycle and ENSO to LGM boundary conditions. GCMs show that a reduced AMOC, *very likely* induces intensification of ENSO amplitude and for the majority of climate models also a reduction of the amplitude of the SST annual cycle in the eastern equatorial Pacific (Timmermann et al., 2007; Merkel et al., 2010; Braconnot et al., 2012a) (Figure 5.10). About 75% of the PMIP2 and PMIP3/CMIP5 mid-Holocene simulations exhibit a weakening of interannual SST amplitude in the eastern equatorial Pacific relative to pre-industrial conditions. More than 87% of these simulations also show a concomitant substantial weakening in the amplitude of the annual cycle of eastern equatorial Pacific SST. Model results are

consistent with a reduction of total variance of $\delta^{18}\text{O}$ variations of individual foraminifera in the eastern equatorial Pacific, indicative of an orbital effect on eastern equatorial Pacific SST variance (Koutavas and Joanides, 2012). In contrast to these findings, a recent proxy study using sub-annually resolved $\delta^{18}\text{O}$ from central equatorial Pacific coral segments (Cobb et al., 2013) reveals no evidence for orbitally-induced changes in interannual ENSO amplitude throughout the last 7 ka, but an ENSO system that experienced very large internal variance changes on decadal and centennial timescales. This latter finding is also confirmed by the analysis of ~ 2000 years of annually varved lake sediments (Wolff et al., 2011) in the ENSO-teleconnected region of equatorial East Africa. Furthermore, Cobb et al. (2013) identify the late 20th century as a period of anomalously high, although not unprecedented, ENSO variability relative to the average reconstructed variance over the last 7000 years.

Reconstructions of ENSO for the last millennium also document multidecadal-to-centennial variations in the amplitude of reconstructed interannual eastern equatorial Pacific SST anomalies (McGregor et al., 2010; Wilson et al., 2010; Li et al., 2011; Emile-Geay et al., 2013a). Statistical efforts to determine ENSO variance changes in different annually resolved ENSO proxies (D'Arrigo et al., 2005; Braganza et al., 2009; McGregor et al., 2010; Fowler et al., 2012; Hereid et al., 2013) and from documentary sources (Garcia-Herrera et al., 2008; Gergis and Fowler, 2009) reveal (*medium confidence*) extended periods of low ENSO activity during parts of the LIA compared to the 20th century. Direct TSI effects on reconstructed multidecadal ENSO variance changes cannot be identified (McGregor et al., 2010). According to reconstructions of volcanic events (Section 5.2.1.3) and some ENSO proxies, a slightly increased probability exists (*medium confidence*) for the occurrence of El Niño events 1-2 years after major volcanic eruptions (Adams et al., 2003; McGregor et al., 2010; Wilson et al., 2010). This response is not captured robustly by GCMs (McGregor and Timmermann, 2010; Ohba et al., 2013).

5.4.2 Extratropical Modes

Robust evidence from LGM simulations indicates a weakening of the NAM variability, connected with stronger planetary wave activity (Lü et al., 2010). A significant but model-dependent distortion of the simulated LGM NAO pattern may result from the strong topographic ice sheet forcing (Justino and Peltier, 2005; Handorf et al., 2009; Pausata et al., 2009; Riviere et al., 2010). A multimodel analysis of NAO behaviour in mid-Holocene GCM simulations (Gladstone et al., 2005) reveals an NAO structure, similar to its pre-industrial state, but a tendency for more positive NAO values during the early Holocene (Rimbu et al., 2003), with no consistent change in its interannual variability. Robust proxy evidence to test these model-based results has not yet been established. A new 5,200-year-long lake sediment record from southwestern Greenland (Olsen et al., 2012) suggests that around 4,500 and 650 years ago variability associated with the NAO changed from generally positive to variable, intermittently negative conditions. Since AR4, a few cold-season NAO reconstructions for the last centuries have been published. They are based on long instrumental pressure series (Cornes et al., 2012), a combination of instrumental and ship log-book data (Küttel et al., 2010) and two proxy records (Trouet et al., 2009). Whereas these and earlier NAO reconstructions (Cook et al., 2002; Luterbacher et al., 2002; Timm et al., 2004; Pinto and Raible, 2012) differ in several aspects, and taking into consideration associated reconstruction uncertainties, they demonstrate with *high confidence* that the strong positive NAO phases of the early 20th century and the mid-1990s are not unusual in the context of the past half millennium. Trouet et al. (2009) presented a winter NAO reconstruction that yielded a persistent positive phase during the MCA in contrast to higher frequency variability during the LIA. This is not consistent with the strong NAO imprint in Greenland ice core data (Vinther et al., 2010) and recent results from transient model simulations that neither support such a persistent positive NAO during the MCA, nor a strong NAO phase shift during the LIA (Lehner et al., 2012; Yiou et al., 2012). A recent pseudo-proxy-based assessment of low-frequency NAO behaviour (Lehner et al., 2012) infers weaknesses in the reconstruction method used by Trouet et al. (2009). Last millennium GCM simulations reveal no significant response of the NAO to solar forcing (Yiou et al., 2012), except for the GISS-ER coupled model which includes ozone photochemistry, extends into the middle atmosphere and exhibits changes in NAO that are weak during the MCA compared to the LIA (Mann et al., 2009).

Changes in the SAM modulate the strength and position of the mean SH westerlies, and leave an important signature on SH present-day surface climate (Gillett et al., 2006) past tree-ring growth (e.g., Urrutia et al., 2011), wildfires (Holz and Veblen, 2011) as well as on LGM climate (Justino and Peltier, 2008). A first hemispheric-wide, tree-ring-based reconstruction of the austral summer SAM (Villalba et al., 2012) indicates

with *medium confidence* that the late 20th century positive trend may have been anomalous in the context of the last 600 years, thus supporting earlier South American proxy evidence (e.g., Lara et al., 2008) and GCM (Wilmes et al., 2012) studies.

The AMO (Delworth and Mann, 2000; Knight et al., 2005) (see also Sections 9.5.3.3.2 and 14.7.6) has been reconstructed using marine (Black et al., 2007; Kilbourne et al., 2008; Sicre et al., 2008; Chiessi et al., 2009; Saenger et al., 2009) and terrestrial proxy records (Gray et al., 2004; Shanahan et al., 2009) from different locations. Correlations among different AMO reconstructions decrease rapidly prior to 1900 (Winter et al., 2011). An 8000-year long AMO reconstruction (Knudsen et al., 2011) shows no correlation with TSI changes, and is interpreted as internally generated ocean-atmosphere variability. However, GCM experiments (Waple et al., 2002; Ottera et al., 2010) using solar and/or volcanic forcing reconstructions indicate that external forcings may have played a role in driving or at least acting as pacemaker for AMO variations.

[INSERT FIGURE 5.10 HERE]

Figure 5.10: Relative changes in amplitude of the annual cycle of SST in Niño 3 region (average over 5°S–5°N and 150°W–90°W) (left) and in amplitude of interannual SST anomalies in the Niño 3.4 region (average over 5°S–5°N and 170°W–120°W) (right) simulated by an ensemble of climate model experiments in response to external forcing. Left: Multi-model average of relative changes (%) in amplitude of the mean seasonal cycle of Niño 3 SST for mid Holocene (MH) and LGM time-slice experiments and for freshwater perturbation experiments (Hosing) that lead to a weakening of the AMOC by more than 50%. Bars encompass the 25 and 75 percentiles, with the red horizontal lines indicating the median in the respective multi-model ensemble, red crosses are values in the upper and lower quartile of the distribution; Right: same as left, but for the SST anomalies in the Niño 3.4 region, representing ENSO variability. The MH ensemble includes 4 experiments performed by models participating in PMIP2 (FGOALS1.0g, IPSL-CM4, MIROC3.2 medres, CCSM3.0) and 7 experiments (mid-Holocene) performed by models participating in PMIP3/CMIP5 (CCSM4.0, CSIRO-Mk3-6-0, HadGEM2-CC, HadGEM2-ES, MIROC-ESM, MPI-ESM-P, MRI-CGCM3). The LGM ensemble includes 5 experiments performed by models participating in PMIP2 (FGOALS1.0g, IPSL-CM4, MIROC3.2 medres, CCSM3.0, HadCM3) and 5 experiments (LGM) performed by models participating in PMIP3/CMIP5 (CCSM4, GISS-E2-R, IPSL-CM5A-LR, MIROC-ESM, and MPI-ESM-P). The changes in response to MH and LGM forcing are computed with respect to the pre-industrial control simulations coordinated by PMIP2 and PMIP3/CMIP5. The results for Hosing are obtained from freshwater perturbation experiments conducted with CCSM2.0, CCSM3.0, HadCM3, ECHAM5-MPIOM, GFDL-CM2.1 (Timmermann et al., 2007), CSM1.4 (Bozbiyik et al., 2011) for pre-industrial or present-day conditions and with CCSM3 for glacial conditions (Merkel et al., 2010). The changes in response to fresh water forcing are computed with respect the portion of simulations when the AMOC is high.

5.5 Regional Changes During the Holocene

Reconstructions and simulations of regional changes that have emerged since AR4 are assessed. Most emphasis is on the last 2000 years, which has the best data coverage.

5.5.1 Temperature

5.5.1.1 Northern Hemisphere Mid-to-High Latitudes

New studies confirm the spatial patterns of SAT and SST distribution as summarised in AR4 (Jansen et al., 2007). According to a recent compilation of proxy data, the global mean annual temperatures around 8–6 ka were about 0.7°C higher, and extratropical NH temperatures were about 1°C higher than for pre-industrial conditions (Marcott et al., 2013). Spatial variability in the temperature anomalies and the timing of the thermal maximum implicate atmospheric or oceanic dynamical feedbacks including effects from remaining ice sheets (e.g., Wanner et al., 2008; Leduc et al., 2010; Bartlein et al., 2011; Renssen et al., 2012). The peak early-to-mid-Holocene North Atlantic and sub-Arctic SST anomalies are reconstructed and simulated to primarily occur in summer and in the stratified uppermost surface-ocean layer (Hald et al., 2007; Andersson et al., 2010). Terrestrial MH (~6 ka, Table 5.1) summer-season temperatures were higher than modern in the mid-to-high latitudes of the NH, consistent with minimum glacier extents (Section 5.5.3) and PMIP2 and PMIP3/CMIP5 simulated responses to orbital forcing (Figure 5.11) (Braconnot et al., 2007; Bartlein et al., 2011; Izumi et al., 2013). There is also robust evidence for warmer MH winters compared to the late 20th century (e.g., Wanner et al., 2008; Sundqvist et al., 2010; Bartlein et al., 2011) (Figure 5.11), but the simulated high latitude winter warming is model dependent and is sensitive to ocean and sea-ice changes (Otto et al., 2009; Zhang et al., 2010). Overall, models underestimate the reduction in the latitudinal gradient

of European winter temperatures during the MH (Brewer et al., 2007). There is a general, gradual NH cooling after ~5 ka, linked to orbital forcing, and increased amplitude of millennial-scale variability (Wanner et al., 2008; Vinther et al., 2009; Kobashi et al., 2011; Marcott et al., 2013).

Since AR4, regional temperature reconstructions have been produced for the last 2 kyr (Figure 5.12; PAGES 2k Consortium, 2013). A recent multi-proxy 2000-year Arctic temperature reconstruction shows that temperatures during the first centuries were comparable or even higher than during the 20th century (Hanhijärvi et al., 2013; PAGES 2k Consortium, 2013). During the MCA, portions of the Arctic and sub-Arctic experienced periods warmer than any subsequent period, except for the most recent 50 years (Figure 5.12) (Kaufman et al., 2009; Kobashi et al., 2010; Vinther et al., 2010; Kobashi et al., 2011; Spielhagen et al., 2011). Tingley and Huybers (2013) provided a statistical analysis of northern high-latitude temperature reconstructions back to 1400 and found that recent extreme hot summers are unprecedented over this time span. Marine proxy records indicate anomalously high SSTs north of Iceland and the Norwegian Sea from 900 to 1300, followed by a generally colder period that ended in the early 20th century. Modern SSTs in this region may still be lower than the warmest intervals of the 900–1300 period (Cunningham et al., 2013). Further north, in Fram Strait, modern SSTs from Atlantic Water appear warmer than those reconstructed from foraminifera for any prior period of the last 2000 years (Spielhagen et al., 2011). However, different results are obtained using dinocysts from the same sediment core (Bonnet et al. (2010) showing a cooling trend over the last 2000 years without a 20th century rise, and warmest intervals entered at years 100 and 600.

Tree-ring data and lake sediment information from the North American treeline (McKay et al., 2008; Bird et al., 2009; D'Arrigo et al., 2009; Anchukaitis et al., 2012) suggest common variability between different records during the last centuries. An annually resolved, tree-ring based 800-year temperature reconstruction over temperate North America (PAGES 2k Consortium, 2013) and a 1500-year long pollen-based temperature estimate (Viau et al., 2012) show cool periods 500–700 and 1200–1900 as well as a warm period between 750 and 1100. The generally colder conditions until 1900 are in broad agreement with other pollen, tree-ring and lake-sediment evidence from northwest Canada, the Canadian Rockies and Colorado (Luckman and Wilson, 2005; Salzer and Kipfmüller, 2005; Loso, 2009; MacDonald et al., 2009; Thomas and Briner, 2009). It is *very likely* that the most recent decades have been, on average, the warmest across mid-latitude western and temperate North America over at least 500 years (Wahl and Smerdon, 2012; PAGES 2k Consortium, 2013; Figure 5.12).

[INSERT FIGURE 5.11 HERE]

Figure 5.11: Model-data comparison of surface temperature anomalies for the mid-Holocene (6 ka). MTCO is the mean temperature of the coldest month; MTWA is the mean temperature of the warmest month. Top panels are pollen-based reconstructions of Bartlein et al., (2011) with anomalies defined as compared to modern, which varies among the records. The bulk of the records fall within the range of 5.5–6.5 ka, with only 3.5% falling outside this range. Middle panels are corresponding surface temperature anomalies simulated by the PMIP2 and PMIP3/CMIP5 models for 6 ka as compared to pre-industrial. Bottom panels contain boxplots for reconstructions (grey), for model ensembles and for the individual CMIP5 models interpolated to the locations of the reconstructions. Included are OA (Ocean-Atmosphere), OAV (Ocean-Atmosphere-Vegetation), and OAC (Ocean-Atmosphere-Carbon cycle) models. The boxes are drawn using the 25th, 50th and 75th percentiles (bottom, middle and top of the box, respectively), and whiskers extend to the 5th and 95th percentiles of data or model results within each area. The northern extratropics are defined as 30°N–90°N and the tropics as 30°S–30°N. For additional model-data comparisons for the mid-Holocene, see Section 9.4.1.4 and Figures 9.11 and 9.12.

New warm-season temperature reconstructions (PAGES 2k Consortium, 2013; Figure 5.12) covering the past 2 millennia show that warm European summer conditions were prevalent during 1st century, followed by cooler conditions from the 4th to the 7th century. Persistent warm conditions also occurred during the 8th–11th centuries, peaking throughout Europe during the 10th century. Prominent periods with cold summers occurred in the mid-15th and early 19th centuries. There is *high confidence* that northern Fennoscandia from 900 to 1100 was as warm as the mid-to-late 20th century (Helama et al., 2010; Linderholm et al., 2010; Büntgen et al., 2011a; Esper et al., 2012a; Esper et al., 2012b; McCarroll et al., 2013; Melvin et al., 2013). The evidence also suggests warm conditions during the 1st century, but comparison with recent temperatures is restricted because long-term temperature trends from tree-ring data are uncertain (Esper et al., 2012a). In the European Alps region, tree-ring based summer temperature reconstructions (Büntgen et al., 2005; Büntgen et al., 2006; Nicolussi et al., 2009; Corona et al., 2010; Büntgen et al., 2011b; Corona et al., 2011)

show higher temperatures in the last decades than during any time in the MCA, while reconstructions based on lake sediments (Larocque-Tobler et al., 2010; Larocque-Tobler et al., 2012; Trachsel et al., 2012) show as high, or slightly higher temperatures during parts of the MCA compared to most recent decades. The longest summer temperature reconstructions from parts of the Alps show several intervals during Roman and earlier times as warm (or warmer) than most of the 20th century (Büntgen et al., 2011b; Stewart et al., 2011).

Since AR4, new temperature reconstructions have also been generated for Asia. A tree-ring based summer temperature reconstruction for temperate East Asia back to 800 indicates warm conditions during the period 850–1050, followed by cooler conditions during 1350–1880 and a subsequent 20th century warming (Cook et al., 2012; PAGES 2k Consortium, 2013; Figure 5.12). Tree-ring reconstructions from the western Himalayas, Tibetan Plateau, Tianshan Mountains and western High Asia depict warm conditions from the 10th to the 15th centuries, lower temperature afterwards and a 20th century warming (Esper et al., 2007a; Zhu et al., 2008; Zhang et al., 2009; Yadav et al., 2011). Taking associated uncertainties into consideration, 20th century temperatures in those regions were *likely* not higher than during the first part of the last millennium. In different regions of China, temperatures appear higher during recent decades than during earlier centuries, although with large uncertainties (e.g., Ge et al., 2006; Wang et al., 2007; Holmes et al., 2009; Yang et al., 2009; Zhang et al., 2009; Ge et al., 2010; Cook et al., 2012). In northeast China, an alkenone-based reconstruction indicates that the growing season temperature during the periods 480–860, 1260–1300, 1510–1570 and 1800–1900 was about 1°C lower compared with the 20th century (Chu et al., 2011). These reconstructed NH regional temperature evolutions appear consistent with last millennium GCM simulations using a range of solar forcing estimates (Figure 5.12).

There is *high confidence* that in the extratropical NH, both regionally and on a hemispheric basis, the surface warming of the 20th century reversed the long term cooling trend due to orbital forcing.

[INSERT FIGURE 5.12 HERE]

Figure 5.12: Regional temperature reconstructions, comparison with model simulations over the past millennium (950–2010). Temperature anomalies (thick black line), and uncertainty estimated provided by each individual reconstruction (grey envelope). Uncertainties: Arctic: 90% confidence bands. Antarctica, Australasia, North American pollen and South America: ± 2 standard deviation. Asia: ± 2 root mean square error. Europe: 95% confidence bands. North American trees: upper/lower 5% bootstrap bounds. Simulations are separated into 2 groups: High solar forcing (red thick line), and weak solar forcing (blue thick line). For each model subgroup, uncertainty is shown as 1.645 times sigma level (light red and blue lines). For comparison with instrumental record, the CRUTEM4 dataset is shown (yellow line). Green bars in rectangles on top of each panel indicate the 30 warmest years in the 950–1250 period (left rectangle) and 1800–2010 period (right rectangle). All lines are smoothed by applying a 30 year moving average. Map at bottom right shows the individual regions for each reconstruction, and in bars the MCA (950–1250) – LIA (1450–1850) differences over those regions. Reconstructions: from PAGES 2k Consortium (2013). Models used: simulations with strong solar forcing (mostly pre-PMIP3 simulations): CCSM3 (1), CNRM-CM3.3 (1), CSM1.4 (1), CSIRO-MK3L-1-2 (3), ECHAM5/MPIOM (3), ECHO-G (1) IPSLCM4 (1), FGOALS-g1 (1). Simulations with weak solar forcing (mostly PMIP3/CMIP5 simulations): BCC-csm1-1 (1), CCSM4 (1), CSIRO-MK3L-1-2 (1), GISS-E2-R (3, ensemble members 121, 124, 127), HadCM3 (1), MPI-ESM, ECHAM5/MPIOM (5), IPSL-CM5A-LR (1). In parenthesis are the number of simulations used for each model. All simulations are treated individually, in the timeseries as well as in the MCA–LIA bars. More information about forcings used in simulations and corresponding references are given in Table 5.A.1.

5.5.1.2 Tropics

Marcott et al. (2013) provide a compilation of tropical SST reconstructions, showing a gradual warming of about 0.5°C until 5 ka and little change thereafter. Holocene tropical SST trends are regionally heterogeneous and variable in magnitude. Alkenone records from the eastern tropical Pacific, western tropical Atlantic, and the Indonesian archipelago document a warming trend of $\sim 0.5^\circ\text{C}$ to 2°C from the early Holocene to present (Leduc et al., 2010), consistent with local insolation. In contrast, regional trends of planktonic foraminiferal Mg/Ca records are heterogeneous, and imply smaller magnitude SST changes (Leduc et al., 2010; Schneider et al., 2010). Foraminiferal Mg/Ca records in the Indo-Pacific warm-pool region show cooling trends with varying magnitudes (Stott et al., 2004; Linsley et al., 2010). When comparing SST records from different paleoclimate proxies it is important to note that they can have different, and also regionally varying, seasonal biases (Schneider et al., 2010).

Terrestrial temperature reconstruction efforts have mostly focussed on Africa and to some extent on southeast Asia (Figure 5.11), with a lack of syntheses from South America and Australia (Bartlein et al., 2011). The PMIP2 and PMIP3/CMIP5 MH simulations show summer cooling compared to pre-industrial conditions and a shorter growing season in the tropical monsoon regions of Africa and southeast Asia (Figure 5.11), attributed to increased cloudiness and local evaporation (Braconnot et al., 2007). In contrast, MH simulations and reconstructions for the entire tropics (30°S–30°N) show generally higher mean temperature of the warmest month and lower mean temperature of the coldest month than for the mid-20th century.

5.5.1.3 Southern Hemisphere Mid-to-High Latitudes

In the high latitude Southern Ocean, Holocene SST trends follow the decrease in austral summer duration, with a cooling trend from the early Holocene into the late Holocene (Kaiser et al., 2008; Shevenell et al., 2011). Similar cooling trends are found in the Australian-New Zealand region (Bostock et al., 2012). Increased amplitude of millennial-to-centennial scale SST variability between 5 ka and 4 ka is recorded in several locations, possibly due to variations in the position and strength of the westerlies (Moros et al., 2009; Euler and Ninnemann, 2010; Shevenell et al., 2011). The Holocene land-surface temperature history in the SH is difficult to assess. Individual reconstructions generally track the trends registered by Antarctic ice-core records with peak values at around 12–10 ka (Masson-Delmotte et al., 2011b; Marcott et al., 2013; Mathiot et al., 2013). Pollen-based records indicate positive MH temperature anomalies in southern South Africa that are not reproduced in the PMIP3/CMIP5 simulations (Figure 5.11).

Indices for the position of Southern Ocean fronts and the strength and position of the westerlies diverge (Moros et al., 2009; e.g., Shevenell et al., 2011). For the mid-to-late-Holocene, climate models of different complexity consistently show a poleward shift and intensification of the SH westerlies in response to orbital forcing (Varma et al., 2012). However, the magnitude, spatial pattern and seasonal response vary significantly among the models.

New high-resolution, climate reconstructions for the last millennium are based on tree-ring records from the subtropical and central Andes, northern and southern Patagonia, Tierra del Fuego, New Zealand and Tasmania (Cook et al., 2006; Boninsegna et al., 2009; Villalba et al., 2009), ice cores, lake and marine sediments and documentary evidence from southern South America (Prieto and García Herrera, 2009; Vimeux et al., 2009; von Gunten et al., 2009; Tierney et al., 2010; Neukom et al., 2011), terrestrial and shallow marine geological records from eastern Antarctica (Verleyen et al., 2011), ice cores from Antarctica (Goosse et al., 2012c; Abram et al., 2013; Steig et al., 2013), boreholes from western Antarctica (Orsi et al., 2012) and coral records from the Indian and Pacific Oceans (Linsley et al., 2008; Zinke et al., 2009; Lough, 2011; DeLong et al., 2012). There is *medium confidence* that southern South America (Neukom et al., 2011) austral summer temperatures during 950–1350 were warmer than the 20th century. A 1000-year temperature reconstruction for land and ocean representing Australasia indicates a warm period during 1160–1370 though this reconstruction is based on only three records before 1430 (PAGES 2k Consortium, 2013). In Australasia, 1971–2000 temperatures were *very likely* higher than any other 30-year period over the last 580 years (PAGES 2k Consortium, 2013).

Antarctica was *likely* warmer than 1971–2000 during the late 17th century, and during the period from approximately the mid-2nd century to 1250 (PAGES 2k Consortium, 2013).

In conclusion, continental scale surface temperature reconstructions from 950 to 1250 show multidecadal intervals that were in some regions as warm as in the mid-20th century and in others as warm as in the late 20th century (*high confidence*). These intervals were not as synchronous across seasons and regions as the warming since the mid-20th century (*high confidence*).

5.5.2 Sea Ice

Since AR4 several new Holocene sea-ice reconstructions for the Arctic and sub-Arctic have been made available that resolve multidecadal to century-scale variability. Proxies of sea-ice extent have been further developed from biomarkers in deep sea sediments (e.g., IP25, Belt et al., 2007; Müller et al., 2011) and from sea-ice biota preserved in sediments (e.g., Justwan and Koç, 2008). Indirect information on sea-ice

conditions based on drift wood and beach erosion has also been compiled (Funder et al., 2011). In general, these sea-ice reconstructions parallel regional SST, yet they display spatial heterogeneity, and differences between the methods, making it difficult to provide quantitative estimates of past sea-ice extent. Summer sea-ice cover was reduced compared to late 20th century levels both in the Arctic Ocean and along East Greenland between 8 ka and 6.5 ka (e.g., Moros et al., 2006; Polyak et al., 2010; Funder et al., 2011), a feature which is captured by some MH simulations (Berger et al., 2013). The response of this sea-ice cover to summer insolation warming was shown to be central for explaining the reconstructed warmer winter temperatures over the adjacent land (Otto et al., 2009; Zhang et al., 2010). During the last 6 kyr available records show a long-term trend of a more extensive Arctic sea-ice cover driven by the orbital forcing (e.g., Polyak et al., 2010), but punctuated by strong century-to-millennial scale variability. Consistent with Arctic temperature changes (see Section 5.5.1), sea-ice proxies indicate relatively reduced sea-ice cover from 800 to 1200 followed by a subsequent increase during the LIA (Polyak et al., 2010). Proxy reconstructions document the 20th-century ice-loss trend, which is also observed in historical sea-ice data sets with a decline since the late 19th century (Divine and Dick, 2006). There is *medium confidence* that the current ice loss and increasing SSTs in the Arctic are anomalous at least in the context of the last two millennia (England et al., 2008; Kinnard et al., 2008; Kaufman et al., 2009; Macias Fauria et al., 2010; Polyakov et al., 2010; Kinnard et al., 2011; Spielhagen et al., 2011). Fewer high-resolution records exist from the Southern Ocean. Data from the Indian Ocean sector document an increasing sea-ice trend during the Holocene, with a rather abrupt increase between 5 ka and 4 ka, consistent with regional temperatures (see Section 5.5.1.3) (Denis et al., 2010).

5.5.3 Glaciers

Due to the response time of glacier fronts, glacier length variations resolve only decadal- to centennial-scale climate variability. Since AR4 new and improved chronologies of glacier size variations were published (Anderson et al., 2008; Joerin et al., 2008; Yang et al., 2008; Jomelli et al., 2009; Licciardi et al., 2009; Menounos et al., 2009; Schaefer et al., 2009; Wiles et al., 2011; Hughes et al., 2012). Studies of sediments from glacier-fed lakes and marine deposits have allowed new continuous reconstructions of glacier fluctuations (Matthews and Dresser, 2008; Russell et al., 2009; Briner et al., 2010; Bowerman and Clark, 2011; Larsen et al., 2011; Bertrand et al., 2012; Vasskog et al., 2012). Reconstructions of the history of ice-shelves and ice sheets/caps have also emerged (Antoniades et al., 2011; Hodgson, 2011; Simms et al., 2011; Smith et al., 2011; Kirshner et al., 2012). New data confirm a general increase of glacier extent in the NH and decrease in the SH during the Holocene (Davis et al., 2009; Menounos et al., 2009), consistent with the local trends in summer insolation and temperatures. Some exceptions exist (e.g., in the eastern Himalayas), where glaciers were most extensive in the early Holocene (Gayer et al., 2006; Seong et al., 2009), potentially due to monsoon changes (Rupper et al., 2009). Due to dating uncertainties, incompleteness and heterogeneity of most existing glacial chronologies, it is difficult to compare glacier variations between regions at centennial and shorter time scales (Heyman et al., 2011; Kirkbride and Winkler, 2012). There are no definitive conclusions regarding potential inter-hemispheric synchronicity of sub-millennial scale glacier fluctuations (Wanner et al., 2008; Jomelli et al., 2009; Licciardi et al., 2009; Schaefer et al., 2009; Winkler and Matthews, 2010; Wanner et al., 2011).

Glacial chronologies for the last 2 kyr are better constrained (Yang et al., 2008; Clague et al., 2010; Wiles et al., 2011; Johnson and Smith, 2012). Multi-centennial glacier variability has been linked with variations in solar activity (Holzhauser et al., 2005; Wiles et al., 2008), volcanic forcing (Anderson et al., 2008) and changes in North Atlantic circulation (Linderholm and Jansson, 2007; Nesje, 2009; Marzeion and Nesje, 2012). Glacier response is more heterogeneous and complex during the MCA than the uniform global glacier recession observed at present (see Section 4.3). Glaciers were smaller during the MCA than in the early 21st Century in the western Antarctic Peninsula (Hall et al., 2010) and Southern Greenland (Larsen et al., 2011). However, prominent advances occurred within the MCA in the Alps (Holzhauser et al., 2005), Patagonia (Luckman and Villalba, 2001), New Zealand (Schaefer et al., 2009), East Greenland (Lowell et al., 2013) and SE Tibet (Yang et al., 2008). Glaciers in northwestern North America were similar in size during the MCA compared to the peak during the LIA, probably driven by increased winter precipitation (Koch and Clague, 2011).

There is *high confidence* that glaciers at times have been smaller than at the end of the 20th century in the Alps (Joerin et al., 2008; Ivy-Ochs et al., 2009; Goehring et al., 2011), Scandinavia (Nesje et al., 2011), Altai

in Central Asia (Agatova et al., 2012), Baffin Island (Miller et al., 2005), Greenland (Larsen et al., 2011; Young et al., 2011), Spitsbergen (Humlum et al., 2005), but the precise glacier extent in the previous warm periods of the Holocene is often difficult to assess. While early-to-mid-Holocene glacier minima can be attributed to high summer insolation (see Section 5.5.1.1), the current glacier retreat, however, occurs within a context of orbital forcing that would be favourable for NH glacier growth. If retreats continue at current rates, most extratropical NH glaciers will shrink to their minimum extent, that existed between 8 ka and 6 ka (e.g., Anderson et al., 2008); and ice shelves on the Antarctic peninsula will retreat to an extent unprecedented through Holocene (Hodgson, 2011; Mulvaney et al., 2012).

5.5.4 Monsoon Systems and Convergence Zones

This subsection focuses on internally and externally driven variability of monsoon systems during the last millennium. Abrupt monsoon changes associated with Dansgaard–Oeschger and Heinrich events (Figure 5.4b,e,h) are further assessed in Section 5.7.1. Orbital-scale monsoon (Figure 5.4a,d,g) changes are evaluated in Section 5.3.2.3.

Hydrological proxy data characterizing the intensity of the East Asian monsoon (South American monsoon) show decreased (increased) hydrological activity during the LIA as compared to the MCA (*medium confidence*) (Figure 5.4f,i) (Zhang et al., 2008; Bird et al., 2011; Vuille et al., 2012). These shifts were accompanied by changes in the occurrence of megadroughts (*high confidence*) in parts of the Asian monsoon region (Buckley et al., 2010; Cook et al., 2010a) (Figure 5.13). Lake-sediment data from coastal eastern Africa document dry conditions in the late MCA, a wet LIA, and return toward dry conditions in the 18th or early 19th century (Verschuren et al., 2000; Stager et al., 2005; Verschuren et al., 2009; Tierney et al., 2011; Wolff et al., 2011), qualitatively similar to the South American monsoon proxies in Figure 5.4i, whereas some inland and southern African lakes suggest dry spells during the LIA (Garcin et al., 2007; Anchukaitis and Tierney, 2013). Rainfall patterns associated with the Pacific ITCZ also shifted southward during the MCA/LIA transition in the central equatorial Pacific (Sachs et al., 2009). Extended intervals of monsoon failures and dry spells have been reconstructed for the last few millennia for west Africa (Shanahan et al., 2009), east Africa (Wolff et al., 2011), northern Africa (Esper et al., 2007b; Touchan et al., 2008; Touchan et al., 2011), India and southeastern Asia (Zhang et al., 2008; Berkelhammer et al., 2010; Buckley et al., 2010; Cook et al., 2010a) and Australia (Mohtadi et al., 2011).

On multidecadal-to-centennial timescales, influences of North Atlantic SST variations have been demonstrated for the North and South African monsoon, and the Indian and East Asian summer monsoons (see Figure 5.4c for monsoon regions), both using proxy reconstructions (Feng and Hu, 2008; Shanahan et al., 2009) and GCM simulations (Lu et al., 2006; Zhang and Delworth, 2006; Wang et al., 2009; Luo et al., 2011). These simulations suggest that solar and volcanic forcing (Fan et al., 2009; Liu et al., 2009a; Man et al., 2012) may exert only weak regional influences on monsoon systems (Figure 5.4f,i). A five-member multi-model ensemble mean of PMIP3/CMIP5 simulations (Table 5.A.1) exhibits decreased standardized monsoon rainfall accompanying periods of reduced solar forcing during the LIA in the East Asian monsoon regions (Figure 5.4f). There is, however, a considerable inter-model spread in the simulated annual mean precipitation response to solar forcing with the multi-model mean, explaining on average only $\sim 25 \pm 15\%$ (1 standard deviation) of the variance of the individual model simulations. An assessment of the pre-instrumental response of monsoon systems to volcanic forcing using paleo-proxy data has revealed wetter conditions over southeast Asia in the year of a major volcanic eruption and drier conditions in central Asia (Anchukaitis et al., 2010), in contrast to GCM simulations (Oman et al., 2005; Brovkin et al., 2008; Fan et al., 2009; Schneider et al., 2009).

5.5.5 Megadroughts and Floods

Multiple lines of proxy evidence from tree rings, lake sediments, and speleothems indicate with *high confidence* that decadal or multidecadal episodes of drought have been a prominent feature of North American Holocene hydroclimate (e.g., Axelson et al., 2009; St. George et al., 2009; Cook et al., 2010a; Cook et al., 2010b; Shuman et al., 2010; Woodhouse et al., 2010; Newby et al., 2011; Oswald and Foster, 2011; Routson et al., 2011; Stahle et al., 2011; Stambaugh et al., 2011; Laird et al., 2012; Ault et al., 2013). During the last millennium, western North America drought reconstructions based on tree ring information (Figure 5.13) show longer and more severe droughts than today, particularly during the MCA in the

southwestern and central United States (Meko et al., 2007; Cook et al., 2010b). The mid-14th century cooling coincides in southwestern North America with a shift towards overall wetter conditions (Cook et al., 2010a; Cook et al., 2010b). In the Pacific Northwest, contrasting results emerge from lake sediment records, indicating wetter conditions during the MCA (Steinman et al., 2013), and tree-ring data showing no substantial change (Zhang and Hebda, 2005; Cook et al., 2010a). In Scandinavia, new tree-ring based reconstructions show a multi-centennial summer drought phase during Medieval times (900–1350) (Helama et al., 2009), while lake-sediment proxies from the same region suggest wetter winters (Luoto et al., 2013). New tree-ring reconstructions from the southern-central (Wilson et al., 2013) and southeastern British Isles (Cooper et al., 2013) do not reveal multi-centennial drought during medieval times, but rather alternating multidecades of dry and wet periods. Wilson et al. (2013) reconstructed drier conditions between ~1300 and the early 16th century. Büntgen et al. (2011b) identified exceptionally dry conditions in central Europe from 200 to 350 and between 400 and 600. Numerous tree-ring records from the eastern Mediterranean testify to the regular occurrence of droughts in the past few millennia (e.g., Akkemik et al., 2008; Nicault et al., 2008; Luterbacher et al., 2012). In northern Africa, Esper et al. (2007b) and Touchan et al. (2008; 2011) show severe drought events through the last millennium, particularly prior to 1300, in the 1400s, between 1700 and 1900, and in the most recent instrumental data. Using multiple proxies from Chile, Boucher et al. (2011) inferred wetter conditions during 1000–1250, followed by much drier period until 1400 and wetter conditions similar to present afterwards, while Ledru et al. (2013) reconstructed a dry MCA-LIA transition until 1550. For the South American Altiplano Morales et al. (2012) found periods of drier conditions in the 14th, 16th, and 18th centuries, as well as a modern drying trend.

[INSERT FIGURE 5.13 HERE]

Figure 5.13: Severity, duration, and frequency of droughts in the Monsoon Asia (Cook et al., 2010b) and North American (Cook et al., 2004) Drought Atlases. The box in (a) and (d) indicates the region over which the tree-ring reconstructed Palmer Drought Severity Index (PDSI) values have been averaged to form the regional mean time series shown in (c) and (f), respectively. Solid black lines in (c) and (f) are a 9-year Gaussian smooth on the annual data shown by the red and blue bars. The covariance of drought (PDSI <0) duration and cumulative severity for each region is shown in panels (b) and (e) by the red circles (corresponding to the left y-axes), along with the respective marginal frequency histograms for each quantity. Not shown in b) is an outlier with an apparent duration of 24 years, corresponding to the 'Strange Parallels' drought identified in Cook et al. (2010b). Return intervals for droughts of given durations are shown in the same panels and are estimated as the mean interval between their occurrence, with the minimum and maximum reconstructed intervals indicated (corresponding to the right y-axes, shown as connected lines and their corresponding range). No range is given if there is only a single observation of a drought of that duration. The period of analysis is restricted by the availability of tree-ring data to the period 1300–1989 for Monsoon Asia, following Cook et al. (2010a), and from 800 to 1978 for southwestern North America, following Cook et al. (2004).

Reconstruction of past flooding from sedimentary, botanical and historical records (Brázdil et al., 2006; Baker, 2008; Brázdil et al., 2012) provides a means to compare recent large, rare floods, and to analyse links between flooding and climate variability. During the last few millennia, flood records reveal strong decadal to secular variability and non-stationarity in flood frequency and clustering of paleofloods, which varied among regions. In Europe, modern flood magnitudes are not unusual within the context of the last 1000 years (e.g., Brázdil et al., 2012). In Central Europe, the Elbe and the Oder/Odra rivers show a decrease in the frequency of winter floods during the last 80 to 150 years compared to earlier centuries, while summer floods indicate no significant trend (Mudelsee et al., 2003) (Figure 5.14f-i). In the Alps, paleoflood records derived from lake sediments have shown a higher flood frequency during cool and/or wet phases (Stewart et al., 2011; Giguët-Covex et al., 2012; Wilhelm et al., 2012), a feature also found in Central Europe (Starkel et al., 2006) and the British Isles (Macklin et al., 2012). In the western Mediterranean, winter floods were more frequent during relatively cool and wet climate conditions of the LIA (Benito et al., 2003b; Piccarreta et al., 2011; Luterbacher et al., 2012; Figure 5.14a), whereas autumn floods reflect multidecadal variations (Benito et al., 2010; Machado et al., 2011; Figure 5.14b-c). In China, extraordinary paleoflood events in the Yellow, Weihe and Qishuihe rivers, occurred synchronously with severe droughts and dust accumulations coinciding with a monsoonal shift, the most severe floods dated at 3.1 ka (Zha et al., 2009; Huang et al., 2012). In India, flood frequencies since 1950 are the largest for the last several hundred years for eight rivers, interpreted as a strengthening of the monsoon conditions after the LIA (Kale, 2008). In southwestern United States, increased frequency of high-magnitude paleofloods coincide with periods of cool, wet climate, whereas warm intervals including the MCA, corresponded with significant decreases in the number of large floods (Ely et al., 1993). In the Great Plains of North America, the frequency of large floods increased significantly around 850 with magnitudes roughly 2–3 times larger than those of the 1972 flood (Harden et al., 2011).

South America large flooding in the Atacama and Peruvian desert streams originated in the highland Altiplano and were particularly intense during El Niño events (Magilligan et al., 2008). In the winter rainfall zone of southern Africa, the frequency of large floods decreased during warmer conditions (e.g., from 1425 to 1600 and after 1925) and increased during wetter, colder conditions (Benito et al., 2011).

In summary, there is *high confidence* that past floods larger than recorded since the 20th century have occurred during the past 500 years in northern and central Europe, western Mediterranean region, and eastern Asia. There is, however, *medium confidence* that in the Near East, India, central North America, modern large floods are comparable to or surpass historical floods in magnitude and/or frequency.

[INSERT FIGURE 5.14 HERE]

Figure 5.14: Flood frequency from paleofloods, historical and instrumental records in selected European rivers. Depicted is the number of floods exceeding a particular discharge threshold or flood height over periods of 20 years (bidecadal). Flood categories include rare or catastrophic floods (CAT) associated with high flood discharge or severe damages, and extraordinary floods (EXT) causing inundation of the floodplain with moderate-to-minor damages. Legend at each panel indicates for each category the period of record in years, number of floods (n) over the period, and the average occurrence interval (T in years). (a) Tagus River combined paleoflood, historical and instrumental flood records from Aranjuez and Toledo with thresholds of 100–400 m³ s⁻¹ (EXT) and >400 m³ s⁻¹ (CAT) (data from Benito et al., 2003a; 2003b). (b) Segura River Basin (SE Spain) documentary and instrumental records at Murcia (Barriendos and Rodrigo, 2006; Machado et al., 2011). (c) Gardon River combined discharges from paleofloods at La Baume (Sheffer et al., 2008), documented floods (since the 15th century) and historical and daily water stage readings at Anduze (1741–2005; Neppel et al., 2010). Discharge thresholds referred to Anduze are 1000–3000 m³ s⁻¹ (EXT), >3000 m³ s⁻¹ (CAT). At least five floods larger than the 2002 flood (the largest in the gauged record) occurred in the period 1400–1800 (Sheffer et al., 2008). (d) Tiber River floods in Rome from observed historical stages (since 1100; Camuffo and Enzi, 1996; Calenda et al., 2005) and continuous stage readings (1870 to present) at the Ripetta landing (Calenda et al., 2005). Discharge thresholds set at 2300–2900 m³ s⁻¹ (EXT) and >2900 m³ s⁻¹ (CAT); >17 m stage at Ripetta). Recent flooding is difficult to evaluate in context due to river regulation structures. (e) River Ouse at York combined documentary and instrumental flood record (Macdonald and Black, 2010). Discharge thresholds for large floods were set at 500 m³ s⁻¹ (CAT) and 350–500 m³ s⁻¹ (EXT). (f) Vltava River combined documentary and instrumental flood record at Prague (Brázdil et al., 2005) discharge thresholds: CAT, flood index 2 and 3 or discharge >2900 m³ s⁻¹; EXT flood index 1 or discharge 2000–2900 m³ s⁻¹. (g) Elbe River combined documentary and instrumental flood record (Mudelsee et al., 2003). Classes refer to Mudelsee et al. (2003) strong (EXT) and exceptionally strong (CAT) flooding. (h) Oder River combined documentary and instrumental flood record (Mudelsee et al., 2003). The map shows the location of rivers used in the flood frequency plots. Note that flood frequencies obtained from historical sources may be down biased in the early part of the reported periods owing to document loss.

5.6 Past Changes in Sea Level

This section discusses evidence for global mean sea level (GMSL) change from key periods. The MPWP (Table 5.1) has been selected as a period of higher than present sea level (Section 5.6.1), warmer temperature (Section 5.3.1) and 350–450 ppm atmospheric CO₂ concentration (Section 5.2.2.2). Of the recent interglacial periods with evidence for higher than present sea level, the LIG has the best-preserved record (Section 5.6.2). For testing glacio-isostatic adjustment (GIA) models, the principal characteristics of Termination I, including Meltwater Pulse-1A (Section 5.6.3) is assessed. For the Holocene, the emphasis is on the last 6000 years when ice volumes stabilized near present-day values, providing the baseline for discussion of anthropogenic contributions.

5.6.1 Mid-Pliocene Warm Period (MPWP)

Estimates of peak sea levels during the MPWP (Table 5.1, Section 5.3.1) based on a variety of geological records are consistent in suggesting higher-than-present sea levels, but they range widely (10–30 m; Miller et al., 2012a), and are each subject to large uncertainties. For example, coastal records (shorelines, continental margin sequences) are influenced by GIA, with magnitudes of the order of 5 m to 30 m for sites in the far and near fields of ice sheets, respectively (Raymo et al., 2011), and global mantle dynamic processes (Moucha et al., 2008; Müller et al., 2008) may contribute up to an additional ±10 m. Consequently, both signals can be as large as the sea level estimate itself and current estimates of their amplitudes are uncertain.

Benthic δ¹⁸O records are better dated than many coastal records and provide a continuous time series, but the δ¹⁸O signal reflects ice volume, temperature and regional hydrographic variability. During the mid-Pliocene

warm interval, the 0.1–0.25‰ anomalies recorded in the LR04 benthic $\delta^{18}\text{O}$ stack (Lisiecki and Raymo, 2005) would translate into ~12–31 m higher than present GMSL, if they reflected only ice volume. Conversely, these anomalies could be explained entirely by warmer deep-water temperatures (Dowsett et al., 2009). Attempts to constrain the temperature component in benthic $\delta^{18}\text{O}$ records conclude higher than present GMSL during the MPWP with large uncertainties (± 10 m) (Dwyer and Chandler, 2009; Naish and Wilson, 2009; Sosdian and Rosenthal, 2009; Miller et al., 2012a).

The first appearance of ice-rafted debris across the entire North Atlantic indicates that continental-scale ice sheets in North America and Eurasia did not develop until ~2.7 Ma (Kleiven et al., 2002). This suggests that MPWP high sea levels were due to mass loss from the GIS, the WAIS and possibly the East Antarctic Ice sheet (EAIS). Sedimentary record from the Ross Sea indicates that the WAIS and the marine margin of EAIS retreated periodically during obliquity-paced interglacial periods of MPWP (Naish et al., 2009a). Reconstructed SSTs for the ice free seasons in the Ross Sea range from 2°C–8°C (McKay et al., 2012b), with mean values $>5^\circ\text{C}$ being, according to one ice sheet model, above the stability threshold for ice shelves and marine portions of the WAIS and EAIS (Pollard and DeConto, 2009; see also Section 5.8.1). A synthesis of the geological evidence from the coastal regions of the Transantarctic Mountains (Barrett, 2013) and an iceberg-rafted debris record offshore of Prydz Bay (Passchier, 2011) also supports coastal thinning and retreat of the EAIS between ~5–2.7 Ma. In response to Pliocene climate, ice-sheet models consistently produce near-complete deglaciation of GIS (+7 m) and WAIS (+4 m) and retreat of the marine margins of EAIS (+3 m) (Lunt et al., 2008; Pollard and DeConto, 2009; Hill et al., 2010), altogether corresponding to a GMSL rise of up to 14m.

In summary, there is *high confidence* that GMSL was above present, due to deglaciation of GIS, WAIS and areas of EAIS, and that sea level was not higher than 20 m above present during the interglacials of the MPWP.

5.6.2 The Last Interglacial (LIG)

Proxy indicators of sea level, including emergent shoreline deposits (Blanchon et al., 2009; Thompson et al., 2011; Dutton and Lambeck, 2012) and foraminiferal $\delta^{18}\text{O}$ records (Siddall et al., 2003; Rohling et al., 2008a; Grant et al., 2012) are used to reconstruct LIG sea levels. Implicit in these reconstructions is that geophysical processes affecting the elevation of the sea level indicators (uplift, subsidence, GIA) have been properly modelled and/or that the sea level component of the stable isotope signal has been properly isolated. Particularly important issues with regard to the LIG are (1) the ongoing debate on its initiation and duration (cf. 130–116 ka, Stirling et al., 1998; 124–119 ka, Thompson and Goldstein, 2005), due to coral geochronology issues; (2) the magnitude of its maximum rise; and (3) sea level variability within the interval. Foraminiferal $\delta^{18}\text{O}$ records can constrain (2) and possibly (3). Emergent shorelines on tectonically active coasts can constrain (1) and (3) and possibly (2) if vertical tectonic rates are independently known. Shorelines on tectonically stable coasts can constrain all three issues. Here evidence from emergent shorelines that can be dated directly is emphasized.

5.6.2.1 Magnitude of LIG Sea Level Rise

AR4 assessed that global sea level was *likely* between 4 and 6 m higher during the LIG than in the 20th century. Since AR4, two studies (Kopp et al., 2009; Dutton and Lambeck, 2012) have addressed GIA effects from observations of coastal sites.

Kopp et al. (2009) obtained a probabilistic estimate of GMSL based on a large and geographically broadly distributed database of LIG sea level indicators (Figure 5.15a). Their analysis accounted for GIA effects as well as uncertainties in geochronology, the interpretation of sea level indicators, and regional tectonic uplift and subsidence. They concluded that GMSL was *very likely* +6.6 m and *likely* +8.0 m relative to present, and that it is *unlikely* to have exceeded +9.4 m, although some of the most rapid and sustained rates of change occur in the early period when GMSL was still below present (Figure 5.15a).

Dutton and Lambeck (2012), used data from two tectonically stable far-field areas (areas far from the former centres of glaciation), Australia and the Seychelles islands. At these sites, in contrast to sites near the former ice margins, the isostatic signals are less sensitive to the choice of parameters defining the Earth rheology

and the glacial ice sheets (Lambeck et al., 2012). On the west coast of Australia, the highest LIG reef elevations are at +3.5 m and the inferred paleo-sea level, allowing for possible reef erosion, is about +5.5 m relative to present. In the Seychelles, LIG coral reefs occur from 0 m to 6 m, but also possibly as high as ~9 m (Israelson and Wohlfarth, 1999, and references therein). Ten of the eleven LIG coral samples from the Seychelles used in Dutton and Lambeck (2012) have reef elevation estimates ranging from +2.1 to +4 m relative to present; whereas a single LIG coral sample has a reef elevation estimate of +6 m. Additional results are needed to support an estimate of a maximum LIG sea level at the Seychelles of +9 m relative to present.

In conclusion, there is *very high confidence* that the maximum GMSL during the LIG was at least 5 m higher than present but that GMSL at this time did not exceed 10 m (*high confidence*). The best estimate from the two available studies is 6 m higher than present.

5.6.2.2 Evidence for LIG Sea Level Variability

Since AR4, there is evidence for meter-scale variability in local LIG sea level between 126 ka and 120 ka (Thompson and Goldstein, 2005; Hearty et al., 2007; Rohling et al., 2008a; Kopp et al., 2009; Thompson et al., 2011). However, there are considerable differences in the timing and amplitude of the reported fluctuations due to regional sea level variability and uncertainties in sea level proxies and their ages.

Two episodes of reef building during the LIG have been reported on the Yucatan coast (Blanchon et al., 2009) and in the Bahamas (Chen et al., 1991; Thompson et al., 2011). Blanchon et al. (2009) provide evidence of Yucatan reef growth early in the LIG at a relative sea level of +3 m, followed by a later episode at +6 m. Thompson et al. (2011) inferred a +4 m relative sea level at ~123 ka, followed by a fall to near present, and finally a rise to +6 m at ~119 ka. This yields a rate of sea level change in the Bahamas of ~2.6 m kyr⁻¹, although the higher estimate at the end of the interval may reflect GIA effects that result in a rise in relative sea level at these locations (Dutton and Lambeck, 2012).

LIG sea level rise rates of between 1.1 and 2.6 m per century have been estimated based on a foraminiferal $\delta^{18}\text{O}$ record from the Red Sea (Rohling et al., 2008a). However, the original Red-Sea chronology was based on a short LIG duration of 124–119 ka, after Thompson and Goldstein (2005). The longer LIG duration of 130–116 ka indicated by the coral data (Stirling et al., 1998) reduces these rates to 0.4–0.9 m per century, and a revised chronology of the Red Sea sea level record adjusted to ages from Soreq Cave yields estimates of sea level rise rates of up to 0.7 m per century when sea level was above present level during the LIG (Grant et al., 2012).

In their probabilistic assessment of LIG sea level, Kopp et al. (2013) concluded that it was extremely likely that there were at least two peaks in sea level during the LIG. They further concluded that during the interval following the initial peak at ~126 ka (Figure 5.15a) it is likely that there was a period in which GMSL rose at an average rate exceeding 3 m ky⁻¹, but unlikely that this rate exceeded 7 m ky⁻¹.

In summary, there is evidence for two intra-LIG sea level peaks (high confidence) during which sea level varied by up to 4 m (medium confidence). The millennial-scale rate of sea level rise during these periods exceeded 2 m kyr⁻¹ (high confidence).

[INSERT FIGURE 5.15 HERE]

Figure 5.15: Sea level during the Last Interglacial period. (a) Proxy-derived estimate of global mean sea level anomaly from Kopp et al. (2013). Mean GMSL (red line), 67% confidence limits (blue dashed lines) and 95% confidence limits (green dashed lines). The chronology is based on open-system U/Th dates. (b) Local LIG relative sea level reconstructions from Western Australia based on in-situ coral elevations (red) that pass diagenetic screening (Dutton and Lambeck, 2012). Age error bars correspond to 2 standard deviation uncertainties. All elevations have been normalised to the upper growth limit of corals corresponding to mean low water spring or mean low sea level. The blue line indicates the simplest interpretation of local sea level consistent with reef stratigraphy and should be considered as lower limits by an amount indicated by the blue upper limit error bars. The chronology is based on closed system U/Th dates. (c) Predicted sea levels for selected sites in the Caribbean and North Atlantic in the absence of tectonics with the assumption that ice volumes during the interval from 129–116 ka are equal to those of today (Lambeck et al., 2012) illustrating the spatial variability expected across the region due to glacio-isostatic effects of primarily the MIS-6 and MIS-2 deglaciations (see also Raymo and Mitrovica, 2012). The reference ice-volume model for the LIG interval (blue

shaded), earth rheology and ice sheet parameters are based on rebound analyses from different regions spanning the interval from Marine Isotope Stage 6 to the present (c.f. Lambeck et al., 2006). LIG sea level observations from these sites contain information on these ice histories and on GMSL. (d) Same as (c) but for different sites along the Western Australia coast contributing to the data set in (b). The dependence on details of the ice sheet and on Earth-model parameters is less important at these sites than for those in (c). Thus data from these locations, assuming tectonic stability, is more appropriate for estimating GMSL. (e) The Western Australian reconstructed evidence (blue) from (b), compared with the model-predicted result (red) for a reference site midway between the northern and southern most localities. The difference between the reconstructed and predicted functions provides an estimate of GMSL (green). Uncertainties in this estimate (67% confidence limits) include the observational uncertainties from (b) and model uncertainties (see e.g., Lambeck et al., 2004a, for a treatment of model errors). (f) Simulated contribution of GIS to GMSL change (black, Q, Quiquet et al. (2013); red, R, Robinson et al. (2011); blue, S, Stone et al. (2013), The Q, R, S correspond to the labels in Figure 5.16). (g) Simulated total GMSL contribution from the GIS (Q, R, S as in panel (f)) and the Antarctic ice sheet contribution (PD) according to Pollard and DeConto (2009). (h) Central Greenland surface-air temperature anomalies for summer (June–August, JJA) used for ice sheet simulations displayed in panel (f) and in Figure 5.16. Anomalies in all panels are calculated relative to present.

5.6.2.3 Implications for Ice Sheet Loss During the LIG

The principal sources for the additional LIG meltwater are the GIS, WAIS and the low elevation, marine-based margins of the EAIS. An upper limit for the contributions from mountain glaciers is $\sim 0.42 \pm 0.11$ m if all present-day mountain glaciers melted (cf. Section 4.3). The estimated LIG ocean thermal expansion contribution is 0.4 ± 0.3 m (McKay et al., 2011).

Sedimentological evidence indicates that southern Greenland was not ice-free during the LIG (Colville et al., 2011). Since AR4, the evidence for LIG ice layers in Greenland ice cores, which was ambiguous from Dye 3 and unequivocal from Summit and NGRIP ice cores (summarised in Masson-Delmotte et al., 2011a), has been strengthened. Data from the new NEEM ice core (NEEM community members, 2013; see Figure 5.16 for locations) point to an unequivocal existence of ice throughout the LIG with elevations differing a few hundred meter from present, possibly decreasing in elevation by $\sim 400 \text{ m} \pm 350 \text{ m}$ between 128 and 122 ka BP. GIS simulations give an average contribution of ~ 2.3 m to LIG GMSL (1.5 m, 1.9 m, 1.4 m and 4.3 m respectively for four models illustrated in Figure 5.16). Each model result has been selected from a series of runs within a range of parameter uncertainties that yield predictions consistent with the occurrence of ice at NEEM and the elevation of that ice reconstructed from the ice core record. In summary, the GIS simulations that are consistent with elevation changes from the ice-core analysis show limited ice retreat during this period such that this ice sheet *very likely* contributed between 1.4 and 4.3 m sea level equivalent.

One model of WAIS glacial-interglacial variability shows very little difference in ice volumes between the LIG and present (Pollard and DeConto, 2009) (Figure 5.15g), when the surface climate and ocean melt term were parameterised using the global benthic $\delta^{18}\text{O}$ record for the last 5 Ma. Direct geological evidence of fluctuations in the extent of WAIS margin during the LIG is equivocal due to inadequate age control on two sediment cores which imply that open-water conditions existed in the southeastern sector of the Ross Ice Shelf at some time in the last 1 Ma (Scherer et al., 1998; McKay et al., 2011; Vaughan et al., 2011) and in the vicinity of the northwestern Ross Ice Shelf within the last 250,000 years during MIS 7 or LIG (McKay et al., 2012a). Ackert et al. (2011) dated glacial erratics and moraines across the Ohio Mountain Range of the Transantarctic Mountains and concluded that the ice elevations were similar during the LIG and today, but such results cannot be extrapolated beyond this region. East Antarctic ice core LIG data may reflect the impact of a reduced WAIS due to climatic effects (Holden et al., 2010b) but not through isostatic effects (Bradley et al., 2012). Modelling and ice core data suggest EAIS may have retreated in the Wilkes Basin (Bradley et al., 2012).

In summary, no reliable assessment of the contribution of the Antarctic ice volume to LIG sea level is currently possible. The only available transient ice-sheet model simulation (Pollard and DeConto, 2009) does not have realistic boundary conditions, not enough is known about the subsurface temperatures and there are few direct observational constraints on the location of ice margins during this period. If the above inference of the contribution to GMSL from the GIS (5.6.2.1) is correct, the full GMSL change (section 5.6.2.2) implies significantly less LIG ice in Antarctica than today, but as yet this cannot be supported by the observational and model evidence.

[INSERT FIGURE 5.16 HERE]

Figure 5.16: Simulated GIS elevation at the LIG in transient (Q, R, S) and constant-forcing experiments (B). (Q) GRISLI ice sheet model with transient climate forcing derived from IPSL simulations and paleoclimate reconstructions (Quiquet et al., 2013). (R) Simulation, most consistent with independent evidence from ice cores, from ensemble runs SICOPOLIS ice sheet model driven by transient LIG climate simulations downscaled from CLIMBER2 with the regional model REMBO (Robinson et al., 2011). (S) As R but from ensemble simulations with the Glimmer ice sheet model forced with transient climate forcing from 135 to 120 ka with HadCM3 (Stone et al., 2013). (B) SICOPOLIS ice sheet model forced with a constant Eemian climate simulation of IPSL (at 126 ka), running for 6000 years starting from fully glaciated present-day GIS (Born and Nisancioglu, 2012). White squares in each panel show the locations of ice core sites: GRIP/GISP from the summit (G), NGRIP (NG), NEEM (NE), Camp Century (C), and Dye3 (D). For ice sheet simulations using transient climate forcing, the minimum in ice volume is illustrated. All panels use original model resolution and grids. Below each panel, maximum contribution to global mean sea level rise and time of minimum ice volume are denoted together with information on experimental design (either "transient" run of the Interglacial period starting from the former glacial or "equilibrium" run of a time slice at the peak interglacial). The differences in model outputs regarding timing and ice elevations result from different methodologies (e.g., transient climate change or equilibrium climate, with the latter assumption leading to the highest estimate of the four models), melt schemes (van de Berg et al., 2011), and the reference climate input (Quiquet et al., 2013).

5.6.3 Last Glacial Termination and Holocene

The onset of melting of the LGM ice sheets occurred at approximately 20 ka and was followed by a GMSL rise of ~130 m in ~13 kyr (Lambeck et al., 2002b). Coeval with the onset of the Bølling warming in the NH, a particularly rapid rise of ~20 m occurred within ~340 years (Meltwater Pulse 1A, MWP-1A), as most recently documented by (Deschamps et al., 2012) from a new Tahiti coral record. At this location sea level rose between 14 and 18 m at a rate approaching 5 m per century. The source of MWP-1A continues to be widely debated with most attention being on scenarios in which the Antarctic ice sheet contributed either significantly (Clark et al., 2002; Bassett et al., 2005; Clark et al., 2009) or very little (Bentley et al., 2010; Mackintosh et al., 2011). Evidence of rapid WAIS retreat at around the time of MWP-1A is also indicated by analysis of marine sediment cores (e.g., Kilfeather et al., 2011; Smith et al., 2011).

If the Antarctic ice sheet was the major contributor to MWP-1A then it must have contained at least $7 \cdot 10^6$ km³ more ice than at present (equivalent to ~17 m GMSL), which is about twice the difference in Antarctic ice volume between the LGM and present found by Whitehouse et al. (2012). Because of the Earth-ocean (including gravitational, deformational and rotational) response to rapid changes in ice volume, the amplitude of the associated sea level change is spatially variable (Clark et al., 2002) and can provide insight into the source region. Based on the comparison of the new Tahiti record with records from Barbados (Fairbanks, 1989) and the Sunda Shelf (Hanebuth et al., 2011), Deschamps et al. (2012) conclude that a significant meltwater contribution to GMSL, of at least 7 m, originated from Antarctica. From ice sheet modelling, Gregoire et al. (2012) argued that the separation of the North American Laurentide and Cordilleran ice sheets may in part be the cause of MWP-1A, contributing ~9 m in 500 years. Another ice sheet modelling study Carlson et al. (2012) suggests a contribution of 6–8 m in 500 years from the Laurentide at the onset of the Bølling warming over North America. These studies indicate that there are no glaciological impediments to a major North American contribution to MWP-1A. In contrast, there are as yet no modelling results that show a rapid retreat or partial collapse of the Antarctic ice sheet at that time.

Since AR4, high-resolution sea level records from different localities suggest further periods of rapid ice-mass loss. For example, records from Singapore indicate a rise of ~14 m from ~9.5 to 8.0 ka followed by a short interval of a smaller rise centred on about 7.2 ka (Bird et al., 2010, for Singapore) and records from the US Atlantic (Cronin et al., 2007) and North Sea coasts (Hijma and Cohen, 2010) suggest a rise at around ~9.0–7.5 ka that is possibly punctuated by one or two short intervals of higher rates. These and similar rapid events have to be interpreted against a background of rapid rise that is spatially variable because of the residual isostatic response to the last deglaciation (Milne and Mitrovica, 2008). Different explanations of these short-duration events have been proposed: a multi-stage draining of glacial Lake Agassiz (Hijma and Cohen, 2010), although estimates of the amount of water stored in this lake are less than the required amount; a rapid melting of the Labrador and Baffin ice domes (Carlson et al., 2007; Gregoire et al., 2012); or to Antarctic ice-sheet decay (Bird et al., 2007; Cronin et al., 2007).

Ocean volume between about 7 ka and 3 ka is *likely* to have increased by an equivalent sea level rise of 2–3 m (Lambeck et al., 2004b; Lambeck et al., 2010) (Figure 5.17). About 10% of this increase can be attributed to a mid-to-late-Holocene ice reduction over Marie Byrd Land, West Antarctica (Stone et al., 2003).

Elevation histories derived from central Greenland ice core data (Vinther et al., 2009; Lecavalier et al., 2013) have presented evidence for thinning from 8 ka to 6 ka but no integrated observation-based estimate for the total ice sheet is available. Contributions from mountain glaciers for this interval are unknown.

Resolving decimeter-scale sea level fluctuations is critical for understanding the causes of sea level change during the last few millennia. Three types of proxies have this capability: salt-marsh plants and microfauna (foraminifera and diatoms) that form distinctive elevation zones reflecting variations in tolerances to the frequency and duration of tidal inundation (Donnelly et al., 2004; Horton and Edwards, 2006; Gehrels et al., 2008; Kemp et al., 2009; Long et al., 2012); coral microatolls found in intertidal environments close to lowest spring tides (Woodroffe and McLean, 1990; Smithers and Woodroffe, 2001; Goodwin and Harvey, 2008); and coastal archaeological features constructed with direct (e.g., fish ponds and certain harbour structures) or indirect (e.g., changes in water-table level in ancient wells) relationships to sea level (Lambeck et al., 2004b; Sivan et al., 2004; Auriemma and Solinas, 2009; Anzidei et al., 2011). Of these, the salt-marsh records are particularly important because they have been validated against regional tide-gauge records and because they can provide near-continuous records. The most robust signal captured in the salt-marsh proxy sea level records from both the NH and SH is an acceleration, late in the 19th or in the early 20th century (Figure 5.17), that marks a transition from relatively low rates of change during the late Holocene (order tenths of mm yr^{-1}) to modern rates (order mm yr^{-1}) (see also FAQ 5.2). Variability in both the magnitude and the timing (1840–1920) of this acceleration has been reported (Gehrels et al., 2006; Gehrels et al., 2008; Kemp et al., 2009; Gehrels et al., 2011; Kemp et al., 2011), but Gehrels and Woodworth (2013) have concluded that these mismatches can be reconciled within the observational uncertainties. Combined with the instrumental evidence (see Section 3.7) and with inferences drawn from archaeological evidence from 2000 years ago (Lambeck et al., 2004b), rates of sea level rise exceeded the late Holocene background rate after about 1900 (Figure 5.17).

Regionally, as along the US Atlantic coast and Gulf of Mexico coast, the salt-marsh records reveal some consistency in multidecadal and centennial timescales deviations from the linear trends expected from the GIA signal (see e.g., panels (a) and (b) in Figure 5.17) (van de Plassche et al., 1998; González and Törnqvist, 2009; Kemp et al., 2011) but they have not yet been identified as truly global phenomena. For the past 5 millennia the most complete sea level record from a single location consists of microatoll evidence from Christmas Island (Pacific Ocean) (Woodroffe et al., 2012) that reveals with *medium confidence* that amplitudes of any fluctuations in GMSL during this interval did not exceed approximately ± 25 cm on time scales of a few hundred years. Proxy data from other localities with quasi-continuous records for parts of this pre-industrial period, likewise, do not identify significant global oscillations on centennial time scales (Figure 5.17).

[INSERT FIGURE 5.17 HERE]

Figure 5.17: Observational evidence for sea level change in the recent and late Holocene. Left panels (a-d): High-resolution, relative sea level results from salt-marsh data at representative sites, without corrections for glacial isostatic movement of land and sea surfaces. Locations are given on the map. The North Carolina (a) result is based on two nearby locations, Tump Point (dark blue) and Sand Point (light blue). They are representative of other North American Atlantic coast locations (e.g., b; Kemp et al., 2011). The rate of change occurring late in the 19th century are seen in all high resolution salt-marsh records—e.g., in New Zealand (c) (Gehrels et al., 2008; Gehrels and Woodworth, 2013) and in Spain (d) (Leorri et al., 2008; García-Artola et al., 2009)—that extend into modern time and is consistent with Roman archaeological evidence (Lambeck et al., 2004b). The oscillation in sea level seen in the North Carolina record at about 1000 years ago occurs in some (González and Törnqvist, 2009) but not all records (cf. Gehrels et al., 2011; Kemp et al., 2011). Right hand side panels (g-j): Observational evidence for sea level change from lower resolution but longer period records. All records are uncorrected for isostatic effects resulting in spatially variable near-linear trend in sea level over the 7000 year period. The Kiritimati record (Christmas Island) (g) consists of coral microatoll elevations whose fossil elevations are with respect to the growth position of living microatolls (Woodroffe et al., 2012). The North Queensland record (h) is also based on microatoll evidence from several sites on Orpheus Island (Chappell, 1983; Lambeck et al., 2002a). The data from Mediterranean France (i) is based on biological indicators (Laborel et al., 1994) restricted to three nearby locations between which differential isostatic effects are less than the observational errors (Lambeck and Bard, 2000). The Spanish record (j) from estuarine sedimentary deposits is for two nearby localities; Bilboa (dark blue) and Urdaibai (light blue) (Leorri et al., 2012). The two global records (central panels) are estimates of change in global mean sea level from (i) the instrumental record (Jevrejeva et al., 2008) that overlaps the salt-marsh records, and (j) from a range of geological and archaeological indicators from different localities around the world (Lambeck et al., 2010), with the contributing records corrected individually for the isostatic effects at each location.

5.7 Evidence and Processes of Abrupt Climate Change

Many paleoclimate archives document climate changes that happened at rates considerably exceeding the average rate of change for longer-term averaging periods prior and after this change (see Glossary for other definition of Abrupt Climate Change). A variety of mechanisms have been suggested to explain the emergence of such abrupt climate changes (see Section 12.5.5). Most of them invoke the existence of nonlinearities or, more specifically, thresholds in the underlying dynamics of one or more Earth-system components. Both internal dynamics and external forcings can generate abrupt changes in the climate state. Documentation of abrupt climate changes in the past using multiple sources of proxy evidence can provide important benchmarks to test instability mechanisms in climate models. This assessment of abrupt climate change on timescales of 10–100 years focuses on Dansgaard-Oeschger (DO) events and iceberg/meltwater discharges during Heinrich events, especially the advances since AR4 in reconstructing and understanding their global impacts and in extending the record of millennial-scale variability to ~800 ka.

Twenty-five abrupt DO events (North Greenland Ice Core Project members, 2004) and several centennial-scale events (Capron et al., 2010b) occurred during the last glacial cycle (see Section 5.3.2). DO events in Greenland were marked by an abrupt transition (within a few decades) from a cold phase, referred to as Greenland Stadial (GS) into a warm phase, known as Greenland Interstadial (GI). Subsequently but within a GI, a gradual cooling preceded a rapid jump to GS that lasted for centuries up to millennia. Thermal gas-fractionation methods (Landais et al., 2004; Huber et al., 2006) suggest that for certain DO events Greenland temperatures increased by up to $16^{\circ}\text{C} \pm 2.5^{\circ}\text{C}$ (1 standard deviation) within several decades. Such transitions were also accompanied by abrupt shifts in dust and deuterium excess, indicative of reorganizations in atmospheric circulation (Steffensen et al., 2008; Thomas et al., 2009). Reconstructions from the subtropical Atlantic and Mediterranean reveal concomitant SST changes attaining values up to 5°C (e.g., Martrat et al., 2004; Martrat et al., 2007).

In spite of the visible presence of DO events in many paleoclimate records from both hemispheres, the underlying mechanisms still remain unresolved and range from internally generated atmosphere-ocean-ice sheet events (Timmermann et al., 2003; Ditlevsen and Ditlevsen, 2009), to solar-forced variability (Braun et al., 2008; Braun and Kurths, 2010). However, given the lack of observational evidence for a direct linear modulation of solar irradiance on DO timescales, (Muscheler and Beer, 2006), solar forcing is an improbable candidate to generate DO events. There is robust evidence from multiple lines of paleoceanographic information and modelling that DO variability is often associated with AMOC changes, as suggested by climate models of varying complexity (Ganopolski and Rahmstorf, 2001; Arzel et al., 2009) and marine proxy records (Piotrowski et al., 2005; Kissel et al., 2008; Barker et al., 2010; Roberts et al., 2010); but also potential influences of sea-ice cover (Li et al., 2010b), atmosphere circulation and ice-sheet topography (Wunsch, 2006) have been proposed.

The widespread presence of massive layers of ice-rafted detritus in North Atlantic marine sediments provide robust evidence that some DO GS, known as Heinrich stadials, were associated with iceberg discharges originating from the Northern Hemispheric ice sheets. During these periods global sea level rose by up to several tens of meters (Chappell, 2002; Rohling et al., 2008b; Siddall et al., 2008; Gonzalez and Dupont, 2009; Yokoyama and Esat, 2011), with remaining uncertainties in timing and amplitude of sea level rise, stadial cooling and ocean circulation changes relative to the iceberg discharge (Hall et al., 2006; Arz et al., 2007; Siddall et al., 2008; Gonzalez and Dupont, 2009; Sierro et al., 2009; Hodell et al., 2010). Internal instabilities of the Laurentide ice sheet can cause massive calving and meltwater events similar to those reconstructed from proxy records (Calov et al., 2002; Marshall and Koutnik, 2006; Calov et al., 2010). Alternatively, an initial weakening of the AMOC can lead to subsurface warming in parts of the North Atlantic (Shaffer et al., 2004) and subsequent basal melting of the Labrador ice shelves, and a resulting acceleration of ice streams and iceberg discharge (Alvarez-Solas et al., 2010; Marcott et al., 2011). At present, unresolved dynamics in ice-sheet models and limited proxy information do not allow us to distinguish the two mechanisms with confidence.

Since AR4, climate model simulations (Liu et al., 2009b; Otto-Bliesner and Brady, 2010; Menviel et al., 2011; Kageyama et al., 2013) have further confirmed the finding (*high confidence*) that changes in AMOC strength induce abrupt climate changes with magnitude and patterns resembling reconstructed paleoclimate-proxy data of DO and Heinrich events.

Recent studies have presented a better understanding of the global imprints of DO events and Heinrich events, for various regions. Widespread North Atlantic cooling and sea-ice anomalies during GS induced atmospheric circulation changes (*high confidence*) (Krebs and Timmermann, 2007; Clement and Peterson, 2008; Kageyama et al., 2010; Merkel et al., 2010; Otto-Bliesner and Brady, 2010; Timmermann et al., 2010) which in turn affected inter-hemispheric tropical rainfall patterns, leading to drying in Northern South America (Peterson and Haug, 2006), the Mediterranean (Fletcher and Sánchez Goñi, 2008; Fleitmann et al., 2009), equatorial western Africa and Arabia (Higginson et al., 2004; Ivanochko et al., 2005; Weldeab et al., 2007a; Mulitza et al., 2008; Tjallingii et al., 2008; Itambi et al., 2009; Weldeab, 2012), wide parts of Asia (Wang et al., 2008; Cai et al., 2010) (see Figure 5.4e) as well as in the Australian-Indonesian monsoon region (Mohtadi et al., 2011). Concomitant wetter conditions have been reconstructed for southwestern North America (Asmerom et al., 2010; Wagner et al., 2010) and southern South America (Kanner et al., 2012) (Figure 5.4h). Moreover, atmospheric circulation changes have been invoked (Zhang and Delworth, 2005; Xie et al., 2008; Okumura et al., 2009) to explain temperature variations in the North Pacific that varied in unison with abrupt climate change in the North Atlantic region (Harada et al., 2008; Harada et al., 2012; Pak et al., 2012). Other factors that may have contributed to North Pacific climate anomalies include large-scale Pacific Ocean circulation changes (Saenko et al., 2004; Schmittner et al., 2007; Harada et al., 2009; Okazaki et al., 2010) during phases of a weak AMOC. Recent high-resolution ice-core studies (EPICA Community Members, 2006; Capron et al., 2010b; Capron et al., 2010a; Stenni et al., 2011; Capron et al., 2012) show that Antarctica warmed gradually for most GS, reaching maximum values at the time of GS/GI transitions, which is in agreement with the bipolar seesaw concept (Stocker and Johnsen, 2003; Stenni et al., 2011). A recent global temperature compilation (Shakun et al., 2012), Southern Ocean temperature records (Lamy et al., 2007; Barker et al., 2009; De Deckker et al., 2012), evidence from SH terrestrial records (Kaplan et al., 2010; Putnam et al., 2010) and transient climate model experiments (Menviel et al., 2011) provide multiple lines of evidence for the inter-hemispheric character of millennial-scale variability during the last glacial termination and for DO events (*high confidence*).

Newly available marine records (Martrat et al., 2007; Grützner and Higgins, 2010; Margari et al., 2010; Kleiven et al., 2011), Antarctic WGMHG records (Loulergue et al., 2008; Schilt et al., 2010) and statistical analyses of Antarctic ice core data (Siddall et al., 2010; Lambert et al., 2012) combined with bipolar seesaw modelling (Siddall et al., 2006; Barker et al., 2011) document with *high confidence* that abrupt climate change events, similar to the DO events and Heinrich stadials of the last glacial cycle, occurred during previous glacial periods extending back ~800 ka and, with *medium confidence*, to 1100 ka.

5.8 Paleoclimate Perspective on Irreversibility in the Climate System

For an introduction of the concept of irreversibility see Glossary.

5.8.1 Ice Sheets

Modelling studies suggest the existence of multiple equilibrium states for ice sheets with respect to temperature, CO₂ concentration and orbital forcing phase spaces (DeConto and Pollard, 2003; Calov and Ganopolski, 2005; Ridley et al., 2010). This implies a possibility of irreversible changes in the climate-cryosphere system in the past and future.

The existence of threshold behaviour in the EAIS is consistent with an abrupt increase in Antarctic ice volume at the Eocene/Oligocene boundary, 33 Ma, attributed to gradual atmospheric CO₂ concentration decline on geological time scale (Pagani et al., 2005b; Pearson et al., 2009) (Figure 5.2, Section 5.2.2). Ice-sheet models produce a hysteresis behaviour of the EAIS with respect to CO₂ concentrations, leading to EAIS glaciation when CO₂ concentration declined to 600–900 ppm (DeConto and Pollard, 2003; Langebroek et al., 2009) and deglaciation for CO₂ above 1200 ppm (Pollard and DeConto, 2009). Proxy records suggest that the WAIS might have collapsed during past interglacials (Naish et al., 2009b; Vaughan et al., 2011) and was absent during warm periods of the Pliocene when CO₂ concentration was 350–450 ppm (see Section 5.2.2.2) and global sea level was higher than present (see Section 5.6.1). These reconstructions and one ice-sheet model simulation (Pollard and DeConto, 2009) suggest that WAIS is very sensitive to the subsurface ocean temperature. This implies, with *medium confidence*, that a large part of the WAIS will be eventually

lost if the atmospheric CO₂ concentration stays within, or above, the range of 350–450 ppm for several millennia.

Observational evidence suggest that the GIS was also much smaller than today during the MPWP (see Sections 5.6.1 and 5.2.2), consistent with the results of simulations with ice-sheet models (Dolan et al., 2011; Koenig et al., 2011). Ice-sheet model simulations and proxy records show that the volume of the GIS was also reduced during the past interglacial period (Section 5.6.2). This supports modelling results that indicate temperature or CO₂ thresholds for melting and re-growth of the GIS may lie in close proximity to the present and future levels (Gregory and Huybrechts, 2006; Lunt et al., 2008) (Section 5.6.1) and that the GIS may have multiple equilibrium states under present-day climate state (Ridley et al., 2010).

Therefore, proxy records and results of model simulations indicate with *medium confidence* that the GIS and WAIS could be destabilized by projected climate changes, although the time scales of the ice sheets response to climate change are very long (several centuries to millennia).

5.8.2 Ocean Circulation

Numerous modelling studies demonstrate that increased freshwater flux into the North Atlantic leads to weakening of the AMOC. Results of EMICs (Rahmstorf et al., 2005) and coupled GCMs also suggest that AMOC may have multiple equilibrium states under present or glacial climate conditions (Hawkins et al., 2011; Hu et al., 2012). Experiments with climate models provide evidence that the sensitivity of the AMOC to freshwater perturbation is larger for glacial boundary conditions than for interglacial conditions (Swingedouw et al., 2009) and that the recovery timescale of the AMOC is longer for LGM conditions than for the Holocene (Bitz et al., 2007).

The abrupt climate-change event at 8.2 ka permits the study of the recovery time of the AMOC to freshwater perturbation under near-modern boundary conditions (Rohling and Pälike, 2005). Since AR4, new proxy records and simulations confirm that the pattern of surface-ocean and atmospheric climate anomalies is consistent with a reduction in the strength of the AMOC (Figure 5.18a,b,d). Available proxy records from the North Atlantic support the hypothesis that freshwater input into the North Atlantic reduced the amount of deep and central water-mass formation, Nordic Seas overflows, intermediate water temperatures and the ventilation state of North Atlantic Deep Water (Figure 5.18c,d) (McManus et al., 2004; Ellison et al., 2006; Kleiven et al., 2008; Bamberg et al., 2010). A concomitant decrease of SST and atmospheric temperatures in the North Atlantic and in Greenland has been observed (Figure 5.18a,b) with the climate anomaly associated with the event lasting 100–160 years (Daley et al., 2011). The additional freshwater that entered the North Atlantic during the 8.2-ka event is estimated between $1.6 \cdot 10^{14} \text{ m}^3$ and $8 \cdot 10^{14} \text{ m}^3$ (von Grafenstein et al., 1998; Barber et al., 1999; Clarke et al., 2004). The duration of the meltwater release may have been as short as 0.5 years (Clarke et al., 2004), but new drainage estimates indicate an up to 200 year-duration in two separate stages (Gregoire et al., 2012). A four-model ensemble with a one-year freshwater perturbation of 2.5 Sv only gives temperature anomalies half of what has been reconstructed and with a shorter duration than observed, resulting from unresolved processes in models, imprecise representation of the initial climate state or a too short duration of the freshwater forcing (Morrill et al., 2013a). These marine-based reconstructions consistently show that the recovery timescale of the shallow and deep overturning circulation is on the order of 200 years (Ellison et al., 2006; Bamberg et al., 2010) (Figure 5.18c,d), with one record pointing to a partial recovery on a decadal timescale (Kleiven et al., 2008). Both recovery timescale and sensitivity of the AMOC to the freshwater perturbation are generally consistent with model experiments for the 8.2-ka event using coarse-resolution models, GCMs and eddy permitting models (LeGrande and Schmidt, 2008; Spence et al., 2008; Li et al., 2009). The recovery of temperatures out of the cold anomaly appears overprinted with natural variability in the proxy data, and is more gradual in data than in the AOGCM experiments (Figure 5.18c,d).

The characteristic teleconnection patterns associated with a colder North Atlantic Ocean as described in Section 5.7 are evident for the 8.2-ka event in both, models and proxy data (Figure 5.18e,f).

[INSERT FIGURE 5.18 HERE]

Figure 5.18: Compilation of selected paleoenvironmental and climate model data for the abrupt Holocene cold event at 8.2 ka, documenting temperature and ocean-circulation changes around the event and the spatial extent of climate

anomalies following the event. Published age constraints for the period of release of freshwater from glacier lakes Agassiz and Ojibway are bracketed inside the vertical blue bar. Vertical grey bar denotes the time of the main cold event as found in Greenland ice-core records (Thomas et al., 2007). Thick lines in panel a-d denote 5-pt. running mean of underlying data in thin lines. (a) Black curve: NGRIP $\delta^{18}\text{O}$ (temperature proxy) from Greenland Summit (North Greenland Ice Core Project members, 2004). Red curve: Simulated Greenland temperature in an 8.2-ka event simulation with the ECBilt-CLIO-VECODE model (Wiersma et al., 2011). Blue curve: Simulated Greenland temperature in an 8.2 event simulation with the CCSM3 model (Morrill et al., 2011). (b) North Atlantic/Nordic Seas SST-reconstructions, age models are aligned on the peak of the cold-event (less than 100-year adjustment). Blue curve: Nordic Seas (Risebrobakken et al., 2011). Black curve: Gardar Drift south of Iceland (Ellison et al., 2006). (c) Deep- and intermediate-water records. Black curve: Sortable silt record (overflow strength proxy) from Gardar Drift south of Iceland (Ellison et al., 2006), Atlantic intermediate water temperature reconstruction (Bamberg et al., 2010). (d) Black curve: $\delta^{13}\text{C}$ (deep water ventilation proxy) at 3.4 km water depth south of Greenland (Kleiven et al., 2008). Age model is aligned on the minimum overflow strength in (c) (less than 100-year adjustment). Modelled change in the strength of the AMOC—Green curve: an 8.2 ka event simulation with the GISS model (LeGrande et al., 2006). Red curve: an 8.2 ka event simulation with the ECBilt-CLIO-VECODE (v. 3) model (Wiersma et al., 2011). Blue curve: an 8.2 ka event simulation with the CCSM3 model (Morrill et al., 2011). (e) Spatial distribution of the 4-member ensemble mean annual mean surface temperature anomaly ($^{\circ}\text{C}$) compared with the control experiment from model simulations of the effects of a freshwater release at 8.2 ka (based on Morrill et al., 2013a). White dots indicate regions where less than 3 models agree on the sign of change. Coloured circles show paleoclimate data from records resolving the 8.2 ka event: purple = cold anomaly, yellow = warm anomaly, grey = no significant anomaly. Data source and significance thresholds are as summarized by Morrill et al. (2013b). (f) Same as (e) but for annual mean precipitation anomalies in %. Coloured circles show paleoclimate data from records resolving the 8.2 ka-event: purple = dry anomaly, green = wet anomaly, grey = no significant anomaly.

5.8.3 Next Glacial Inception

Since orbital forcing can be accurately calculated for the future (see Section 5.2.1), efforts can be made to predict the onset of the next glacial period. However, the glaciation threshold depends not only on insolation but also on the atmospheric CO_2 concentration (Archer and Ganopolski, 2005). Models of different complexity have been used to investigate the response to orbital forcing in the future for a range of atmospheric CO_2 levels. These results consistently show that a glacial inception is not expected to happen within the next approximate 50 kyr if either atmospheric CO_2 concentration remains above 300 ppm or cumulative carbon emissions exceed 1000 PgC (Loutre and Berger, 2000; Archer and Ganopolski, 2005; Cochelin et al., 2006). Only if atmospheric CO_2 content was below the pre-industrial level would a glaciation be possible under present orbital configuration (Loutre and Berger, 2000; Cochelin et al., 2006; Kutzbach et al., 2011; Vettoretti and Peltier, 2011; Tzedakis et al., 2012a). Simulations with climate-carbon cycle models show multi-millennial life-time of the anthropogenic CO_2 in the atmosphere (see Box 6.1). Even for the lowest RCP 2.6 scenario, atmospheric CO_2 concentrations will exceed 300 ppm until the year 3000. It is therefore virtually certain that orbital forcing will not trigger a glacial inception before the end of the next millennium.

5.9 Concluding Remarks

The assessments in this chapter are based on a rapidly growing body of new evidence from the peer-review literature. Since AR4, there exists a wide range of new information on past changes in atmospheric composition, sea level, regional climates including droughts and floods, as well as new results from internationally co-ordinated model experiments on past climates (PMIP3/CMIP5). At the regional scale proxy-based temperature estimates are still scarce for key regions such as Africa, India and parts of the Americas. Syntheses of past precipitation changes were too limited to support regional assessments.

Precise knowledge of past changes in atmospheric concentrations in well-mixed greenhouse gases prior to the period for which ice-core records are available remains a strong limitation on assessing longer-term climate change. Key limitations to our knowledge of past climates continues to be associated with uncertainties of the quantitative information derived from climate proxies, in particular due to seasonality effects, the lack of proxy records sensitive to winter temperature, or the precise water depth at which ocean proxies signals form. Moreover, methodological uncertainties associated with regional, hemispheric or global syntheses need to be further investigated and quantified.

Despite progress on developing proxy records of past changes in sea ice it is not yet possible to provide quantitative and spatially coherent assessments of past sea ice cover in both polar oceans.

While this assessment could build on improved reconstructions of abrupt climate changes during glacial periods, key questions remain open regarding the underlying cause of these changes. Large uncertainties remain on the variations experienced by the West and East Antarctic ice sheets over various time scales of the past. Regarding past sea level change, major difficulties are associated with deconvolving changes in ocean geodynamic effects, as well as for inferring global signals from regional reconstructions.

The PMIP3/CMIP5 model framework offers the opportunity to directly incorporate information from paleoclimate data and simulations into assessments of future projections. This is an emerging field for which only preliminary information was available for AR5.

FAQ 5.1: Is the Sun a Major Driver of Recent Changes in Climate?

Total solar irradiance (TSI, Chapter 8) is a measure of the total energy received from the sun at the top of the atmosphere. It varies over a wide range of timescales, from billions of years to just a few days, though variations have been relatively small over the past 140 years. Changes in solar irradiance are an important driver of climate variability (Chapter 1; Figure 1.1) along with volcanic emissions and anthropogenic factors. As such, they help explain the observed change in global surface temperatures during the instrumental period (FAQ 5.1, Figure 1; Chapter 10) and over the last millennium. While solar variability may have had a discernible contribution to changes in global surface temperature in the early 20th century, it cannot explain the observed increase since TSI started to be measured directly by satellites in the late 1970s (Chapters 8, 10).

The Sun's core is a massive nuclear fusion reactor that converts hydrogen into helium. This process produces energy that radiates throughout the solar system as electromagnetic radiation. The amount of energy striking the top of Earth's atmosphere varies depending on the generation and emission of electromagnetic energy by the Sun and on the Earth's orbital path around the Sun.

Satellite-based instruments have directly measured TSI since 1978, and indicate that on average, $\sim 1361 \text{ W m}^{-2}$ reaches the top of the Earth's atmosphere. Parts of the Earth's surface and air pollution and clouds in the atmosphere act as a mirror and reflect about 30% of this power back into space. Higher levels of TSI are recorded when the Sun is more active. Irradiance variations follow the roughly 11-year sunspot cycle: during the last cycles, TSI values fluctuated by an average of around 0.1%.

For pre-satellite times, TSI variations have to be estimated from sunspot numbers (back to 1610), or from radioisotopes that are formed in the atmosphere, and archived in polar ice and tree rings. Distinct 50- to 100-year periods of very low solar activity—such as the Maunder Minimum between 1645 and 1715—are commonly referred to as grand solar minima. Most estimates of TSI changes between the Maunder Minimum and the present day are in the order of 0.1%, similar to the amplitude of the 11-year variability.

How can solar variability help explain the observed global surface temperature record back to 1870? To answer this question, it is important to understand that other climate drivers are involved, each producing characteristic patterns of regional climate responses. However, it is the combination of them all that causes the observed climate change. Solar variability and volcanic eruptions are natural factors. Anthropogenic (human-produced) factors, on the other hand, include changes in the concentrations of greenhouse gases, and emissions of visible air pollution (aerosols) and other substances from human activities. 'Internal variability' refers to fluctuations within the climate system, for example, due to weather variability or phenomena like the El Niño Southern Oscillation.

The relative contributions of these natural and anthropogenic factors change with time. FAQ 5.1, Figure 1 illustrates those contributions based on a very simple calculation, in which the mean global surface temperature variation represents the sum of four components linearly related to solar, volcanic, and anthropogenic forcing, and to internal variability. Global surface temperature has increased by approximately

0.8°C from 1870 to 2010 (FAQ 5.1, Figure 1a). However, this increase has not been uniform: at times, factors that cool the Earth's surface—volcanic eruptions, reduced solar activity, most anthropogenic aerosol emissions—have outweighed those factors that warm it, such as greenhouse gases, and the variability generated within the climate system has caused further fluctuations unrelated to external influences.

The solar contribution to the record of global surface temperature change is dominated by the 11-year solar cycle, which can explain global temperature fluctuations up to approximately 0.1°C between minima and maxima (FAQ 5.1, Figure 1b). A long-term increasing trend in solar activity in the early 20th century may have augmented the warming recorded during this interval, together with internal variability, greenhouse gas increases and a hiatus in volcanism. However, it cannot explain the observed increase since the late 1970s, and there was even a slight decreasing trend of TSI from 1986 to 2008 (Chapters 8, 10).

Volcanic eruptions contribute to global surface temperature change by episodically injecting aerosols into the atmosphere, which cool the Earth's surface (FAQ 5.1, Figure 1c). Large volcanic eruptions, such as the eruption of Mt. Pinatubo in 1991, can cool the surface by around 0.1°C to 0.3°C for up to three years.

The most important component of internal climate variability is the El Niño Southern Oscillation, which has a major effect on year-to-year variations of tropical and global mean temperature (FAQ 5.1, Figure 1d). Relatively high annual temperatures have been encountered during El Niño events, such as in 1997–1998.

The variability of observed global surface temperatures from 1870 to 2010 (Figure 1a) reflects the combined influences of natural (solar, volcanic, internal; FAQ 5.1, Figure 1b-d) factors, superimposed on the multidecadal warming trend from anthropogenic factors (FAQ 5.1, Figure 1e).

Prior to 1870, when anthropogenic emissions of greenhouse gases and aerosols were smaller, changes in solar and volcanic activity and internal variability played a more important role, although the specific contributions of these individual factors to global surface temperatures are less certain. Solar minima lasting several decades have often been associated with cold conditions. However, these periods are often also affected by volcanic eruptions, making it difficult to quantify the solar contribution.

At the regional scale, changes in solar activity have been related to changes in surface climate and atmospheric circulation in the Indo-Pacific, Northern Asia and North Atlantic areas. The mechanisms that amplify the regional effects of the relatively small fluctuations of TSI in the roughly 11-year solar cycle involve dynamical interactions between the upper and the lower atmosphere, or between the ocean sea surface temperature and atmosphere, and have little effect on global mean temperatures (see Box 10.2).

Finally, a decrease in solar activity during the past solar minimum a few years ago (FAQ 5.1, Figure 1b) raises the question of its future influence on climate. Despite uncertainties in future solar activity, there is high confidence that the effects of solar activity within the range of grand solar maxima and minima will be much smaller than the changes due to anthropogenic effects.

[INSERT FAQ 5.1, FIGURE 1 HERE]

FAQ 5.1, Figure 1: Global surface temperature anomalies from 1870 to 2010, and the natural (solar, volcanic, and internal) and anthropogenic factors that influence them. (a) Global surface temperature record (1870–2010) relative to the average global surface temperature for 1961–1990 (black line). A model of global surface temperature change (panel a: red line) produced using the sum of the impacts on temperature of natural (panels b, c, d) and anthropogenic factors (panel e). (b) Estimated temperature response to solar forcing. (c) Estimated temperature response to volcanic eruptions. (d) Estimated temperature variability due to internal variability, here related to the El Niño Southern Oscillation. (e) Estimated temperature response to anthropogenic forcing, consisting of a warming component from greenhouse gases, and a cooling component from most aerosols.

[START FAQ 5.2 HERE]

FAQ 5.2: How Unusual is the Current Sea Level Rate of Change?

The rate of mean global sea level change—averaging $1.7 \pm 0.2 \text{ mm yr}^{-1}$ for the entire 20th century and between 2.8 and 3.6 mm yr^{-1} since 1993 (Chapter 13)—is unusual in the context of centennial-scale variations of the last two millennia. However, much more rapid rates of sea level change occurred during past periods of rapid ice-sheet disintegration, such as transitions between glacial and interglacial periods. Exceptional tectonic effects can also drive very rapid local sea level changes, with local rates exceeding the current global rates of change.

‘Sea level’ is commonly thought of as the point where the ocean meets the land. Earth scientists define sea level as a measure of the position of the sea surface relative to the land, both of which may be moving relative to the center of the Earth. A measure of sea level therefore reflects a combination of geophysical and climate factors. Geophysical factors affecting sea level include land subsidence or uplift and glacial isostatic adjustments—the earth-ocean system’s response to changes in mass distribution on the Earth, specifically ocean water and land ice.

Climate influences include variations in ocean temperatures, which cause sea water to expand or contract, changes in the volume of glaciers and ice sheets, and shifts in ocean currents. Local and regional changes in these climate and geophysical factors produce significant deviations from the global estimate of the mean rate of sea level change. For example, *local* sea level is falling at a rate approaching 10 mm yr^{-1} along the northern Swedish coast (Gulf of Bothnia), due to ongoing uplift caused by continental ice that melted after the last glacial period. In contrast, *local* sea level rose at a rate of $\sim 20 \text{ mm yr}^{-1}$ from 1960 to 2005 in the south of Bangkok, mainly in response to subsidence due to ground water extraction.

For the past ~ 150 years, sea level change has been recorded at tide gauge stations, and for the past ~ 20 years, with satellite altimeters. Results of these two data sets are consistent for the overlapping period. The globally averaged rate of sea level rise of $\sim 1.7 \pm 0.2 \text{ mm yr}^{-1}$ over the 20th century—and about twice that over the past two decades—may seem small compared with observations of wave and tidal oscillations around the globe that can be orders of magnitude larger. However, if these rates persist over long time intervals, the magnitude carries important consequences for heavily populated, low-lying coastal regions, where even a small increase in sea level can inundate large land areas.

Prior to the instrumental period, local rates of sea level change are estimated from indirect measures recorded in sedimentary, fossil and archaeological archives. These proxy records are spatially limited and reflect both local and global conditions. Reconstruction of a global signal is strengthened, though, when individual proxy records from widely different environmental settings converge on a common signal. It is important to note that geologic archives—particularly those before $\sim 20,000$ years ago—most commonly only capture millennial-scale changes in sea level. Estimates of century-scale rates of sea level change are therefore based on millennial-scale information, but it must be recognised that such data do not necessarily preclude more rapid rates of century-scale changes in sea level.

Sea level reconstructions for the last two millennia offer an opportunity to use proxy records to overlap with, and extend beyond, the instrumental period. A recent example comes from salt-marsh deposits on the Atlantic Coast of the United States, combined with sea level reconstructions based on tide-gauge data and model predictions, to document an average rate of sea level change since the late 19th century of $2.1 \pm 0.2 \text{ mm yr}^{-1}$. This century-long rise exceeds any other century-scale change rate in the entire 2,000-year record for this same section of coast.

On longer timescales, much larger rates and amplitudes of sea level changes have sometimes been encountered. Glacial-interglacial climate cycles over the past 500,000 years resulted in global sea level changes of up to about 120 to 140 m. Much of this sea level change occurred in 10,000 to 15,000 years, during the transition from a full glacial period to an interglacial period, at average rates of 10 to 15 mm yr^{-1} . These high rates are only sustainable when the Earth is emerging from periods of extreme glaciation, when large ice sheets contact the oceans. For example, during the transition from the last glacial maximum (about 21,000 years ago) to the present interglacial (Holocene, last 11,650 years), fossil coral reef deposits indicate that global sea level rose abruptly by 14 to 18 m in less than 500 years. This event is known as Meltwater Pulse 1a, in which the rate of sea level rise reached more than 40 mm yr^{-1} .

These examples from longer timescales indicate rates of sea level change greater than observed today, but it should be remembered that they all occurred in special circumstances: at times of transition from full glacial to interglacial condition; at locations where the long-term after-effects of these transitions are still occurring; at locations of major tectonic upheavals or in major deltas, where subsidence due to sediment compaction—sometimes amplified by ground-fluid extraction—dominates.

The instrumental and geologic record support the conclusion that the current rate of mean global sea level change is unusual relative to that observed and/or estimated over the last two millennia. Higher rates have been observed in the geological record, especially during times of transition between glacial and interglacial periods.

[INSERT FAQ 5.2, FIGURE 1 HERE]

FAQ 5.2, Figure 1: (a) Estimates of the average rate of global mean sea level change (in mm yr^{-1}) for five selected time intervals: last glacial-to-interglacial transition; Meltwater Pulse 1a; last 2 millennia; 20th century; satellite altimetry era (1993–2012). Blue columns denote time intervals of transition from a glacial to an interglacial period, whereas orange columns denote the current interglacial period. Black bars indicate the range of likely values of the average rate of global mean sea level change. Note the overall higher rates of global mean sea level change characteristic of times of transition between glacial and interglacial periods. (b) Expanded view of the rate of global mean sea level change during three time intervals of the present interglacial.

Appendix 5.A: Supplementary Material

[INSERT TABLE 5.A.1 HERE]

Table 5.A.1: Summary of the AOGCM simulations available and assessed for Sections 5.3.5 and 5.5.1. Acronyms describing forcings are: SS (solar forcing, stronger variability), SW (solar forcing, weaker variability), V (volcanic activity), G (greenhouse gases concentration), A (aerosols), L (land-use-land-cover), and O (orbital). The table is divided into PMIP3/CMIP5 and non-PMIP3/CMIP5 experiments (Braconnot et al., 2012b; Taylor et al., 2012). Superscript indices in forcing acronyms identify the forcing reconstructions used and are listed in the table footnotes. PMIP3 experiments follow forcing guidelines provided in Schmidt et al (2011; 2012b). See Fernández-Donado et al. (2013) for more information on pre-PMIP3/CMIP5 forcing configurations. See Chapter 8 and Table 9.1 for the forcing and model specifications of the CMIP5 historical runs. The simulations highlighted in grey were excluded from Figures 5.8, 5.9 and 5.12 because they did not include at least solar, volcanic and greenhouse gas forcings, they did not span the whole of the last millennium, or for a reason given in the table notes.

[INSERT TABLE 5.A.2 HERE]

Table 5.A.2: Summary of atmospheric CO₂ proxy methods and confidence assessment of their main assumptions.

[INSERT TABLE 5.A.3 HERE]

Table 5.A.3: Summary of SST proxy methods and confidence assessment of their main assumptions.

[INSERT TABLE 5.A.4 HERE]

Table 5.A.4: Assessment of leads and lags between Antarctic, hemispheric temperatures and atmospheric CO₂ concentration during terminations. Chronological synthesis of publications, main findings, incorporation in IPCC assessments and key uncertainties.

[INSERT TABLE 5.A.5 HERE]

Table 5.A.5: Summary of seasonal estimates of terrestrial surface temperature anomalies (°C) for the Last Interglacial (LIG) plotted in Figure 5.6. *pdf*-method stands for probability-density function method. Dating methods: AMS=Accelerator mass spectrometry; IRSL=Infrared stimulated luminescence; OSL=Optically stimulated luminescence; TL=thermoluminescence.

5.A.1 Supplemental Information to Section 5.3.5

Section 5.3.5 assesses knowledge of changes in hemispheric and global temperature over the last 2 ka from a range of studies, reconstructions and simulations. Tables 5.A.1 and 5.A.6 provide further information about the datasets used in Figures 5.7–5.9 and 5.12, and the construction of Figure 5.8 is described in more detail. All reconstructions assessed in, or published since, AR4 were considered, but those that have been superseded by a related study using an expanded proxy dataset and/or updated statistical methods were excluded.

[INSERT TABLE 5.A.6 HERE]

Table 5.A.6: Hemispheric and global temperature reconstructions assessed in Table 5.4 and used in Figures 5.7–5.9.

Figure 5.8 compares simulated and reconstructed NH temperature changes (see caption). Some reconstructions represent a smaller spatial domain than the full NH or a specific season, while annual temperatures for the full NH mean are shown for the simulations. Multi-model means and estimated 90% multi-model ranges are shown by the thick and thin lines, respectively, for two groups of simulations (Table 5.A.1): those forced by stronger (weaker) solar variability in red (blue). Note that the strength of the solar variability is not the only difference between these groups: the GCMs and the other forcings are also different between the groups. In Figure 5.7, the reconstructions are shown as deviations from their 1881–1980 means, which allows them to be compared with the instrumental record. In Figure 5.8a, all timeseries are expressed as anomalies from their 1500–1850 mean (prior to smoothing with a 30-year Gaussian-weighted filter, truncated 7 years from the end of each series to reduce end-effects of the filter) because the comparison of simulations and reconstructions is less sensitive to errors in anthropogenic aerosol forcing applied to the models when a pre-industrial reference period is used, and less sensitive to different realisations of internal variability with a multi-century reference period. The grey shading represents a measure of the overlapping reconstruction confidence intervals, with scores of 1 and 2 assigned to temperatures within ± 1.645 standard deviation (90% confidence range) or ± 1 standard deviation, respectively, then summed over all reconstructions and scaled so that the maximum score is dark grey, and

minimum score is pale grey. This allows the multi-model ensembles to be compared with the ensemble of reconstructed NH temperatures, taking into account the published confidence intervals.

The superposed composites (time segments from selected periods positioned so that the years with peak negative forcing are aligned; top panels of Figure 5.8b-d) compare the simulated and reconstructed temperatures (bottom panels) associated with (b) individual volcanic forcing events; (c) multi-decadal changes in volcanic activity; (d) multi-decadal changes in solar irradiance. Only reconstructions capable of resolving (b) interannual or (c–d) interdecadal variations are used. The thick green line in Figure 5.8d shows the composite mean of the volcanic forcing, also band-pass filtered, but constructed using the solar composite periods to demonstrate the changes in volcanic forcing that are coincident with solar variability. The composite of individual volcanic events shown in (b) is formed by aligned time segments centred on the 12 years (1442, 1456, 1600, 1641, 1674, 1696, 1816, 1835, 1884, 1903, 1983 and 1992) during 1400–1999 that the Crowley and Unterman (2013) volcanic forcing history exceeds 1.0 W m^{-2} below the 1500–1899 mean volcanic forcing, excluding events within 7 years (before or after) of a stronger event. The composite of multi-decadal changes in volcanic forcing shown in (c) is formed from 80-year periods centred on the five years (1259, 1456, 1599, 1695 and 1814) during 850–1999 when the Crowley and Unterman (2013) volcanic forcing, smoothed with a 40-year Gaussian-weighted filter, exceeds 0.2 W m^{-2} below the 1500–1899 mean volcanic forcing, except that a year is not selected if it is within 39 years of another year that has a larger negative 40-year smoothed volcanic forcing. The composite of the strongest multidecadal changes in the solar forcing shown in (d) is formed from 80-year periods centred on the seven years (1044, 1177, 1451, 1539, 1673, 1801 and 1905) during 850–1999 when the Ammann et al. (2007) solar forcing, band-pass filtered to retain variations on timescales between 20 and 160 years, is reduced by at least 0.1 W m^{-2} over a 40-year period. Reconstructed and simulated temperature timeseries were smoothed with a 40-year Gaussian-weighted filter in (c) or 20-to-160-year band-pass filtered in (d), and each composite was shifted to have zero mean during the (b) 5 or (c–d) 40 years preceding the peak negative forcing.

7 Notes:

8 (a) Also known as Marine Isotopic Stage (MIS) 1 or current interglacial.

9 (b) Also known as Medieval Climate Optimum or the Medieval Warm Period.

- 1 (c) Also known as Termination I or the Last Deglaciation. Based on sea level, Last Glacial Termination occurred between ~19 and ~6 ka.
- 2 (d) Also known as Greenland Stadial GS-1.
- 3 (e) Also known as Greenland Interstadial GI-a-c-e.
- 4 (f) Also known as MIS5e, which overlaps with the Eemian (Shackleton et al., 2003).
- 5 (g) As estimated from the Greenland ice core GICC05 chronology (Rasmussen et al., 2006; Thomas et al., 2007).
- 6 (h) In this chapter, when referring to comparison of radiative forcing or climate variables, pre-industrial refers to 1850 values in accordance with Taylor et al. (2012). Otherwise it
- 7 refers to an extended period of time before 1850 as stated in the text. Note that Chapter 7 uses 1750 as the reference pre-industrial period.
- 8 (i) Different durations are reported in the literature. In Section 5.3.5, time intervals 950–1250 and 1450–1850 are used to calculate Northern Hemisphere temperature anomalies
- 9 representative of the MCA and LIA, respectively.
- 10 (j) Note that CMIP5 “Last Millennium simulations” have been performed for the period 850–1850 (Taylor et al., 2012).
- 11 (k) As dated on Tahiti corals (Deschamps et al., 2012).
- 12 (l) The duration of Heinrich stadial 1 (e.g., Stanford et al., 2011) is longer than the associated Heinrich event, which is indicated by ice-rafted debris in deep sea sediment cores from
- 13 the North Atlantic Ocean (Hemming, 2004).
- 14 (m) Period based on MARGO Project Members (2009). LGM simulations are performed for 21 ka. Note that maximum continental ice extent had already occurred at 26.5 ka (Clark
- 15 et al., 2009).
- 16 (n) Ages are maximum date for the onset and minimum age for the end from tectonically stable sites (cf. Section 5.6.2).
- 17 (o) Dowsett et al. (2012).
- 18 (p) Zachos et al. (2008).
- 19 (q) Westerhold et al. (2007).

Table 5.A.1: Summary of the AOGCM simulations available and assessed for Sections 5.3.5 and 5.5.1. Acronyms describing forcings are: SS (solar forcing, stronger variability), SW (solar forcing, weaker variability), V (volcanic activity), G (greenhouse gases concentration), A (aerosols), L (land-use-land-cover), and O (orbital). The table is divided into PMIP3/CMIP5 and non-PMIP3/CMIP5 experiments (Braconnot et al., 2012b; Taylor et al., 2012). Superscript indices in forcing acronyms identify the forcing reconstructions used and are listed in the table footnotes. PMIP3 experiments follow forcing guidelines provided in Schmidt et al (2011; 2012b). See Fernández-Donado et al. (2013) for more information on pre-PMIP3/CMIP5 forcing configurations. See Chapter 8 and Table 9.1 for the forcing and model specifications of the CMIP5 historical runs. The simulations highlighted in grey were excluded from Figures 5.8, 5.9 and 5.12 because they did not include at least solar, volcanic and greenhouse gas forcings, they did not span the whole of the last millennium, or for a reason given in the table notes.

46 [61] Bretagnon and Francou (1988)

47 [62] Berger and Loutre (1991)

48 [63] Laskar et al. (2004)

49 (b) This simulation was only used in Figure 5.8, using NH temperature adjusted by Osborn et al. (2006).

50 (c) The FGOALS-gl experiment is available in the PMIP3 repository, but the forcing configuration is different from Schmidt et al (2011; 2012b) recommendations so it is included here within the pre-PMIP3 ensemble.

51 (d) The GISS-E2-R experiments with Gao et al. (2008) volcanic forcing were not used in Figures 5.8, 5.9 or 5.12. See [24].

52 (e) This simulation was only used in Figure 5.8, using drift-corrected NH temperature.

53

Table 5.A.2: Summary of atmospheric CO₂ proxy methods and confidence assessment of their main assumptions.

Method	Scientific Rationale	Estimated Applicability	Limitations	Main Assumptions (<i>relative confidence</i>)
Alkenone (phytoplankton biomarker) carbon isotopes	Measurements of carbon isotope ratios of marine sedimentary alkenones (or other organic compounds) allows determination of the isotopic fractionation factor during carbon fixation (ϵ_p) from which pCO ₂ can be calculated.	100– ~4000 ppm; 0–100 Ma	Alkenones are often rare in oligotrophic areas and sometimes absent. Method relies on empirical calibration and $\delta^{13}C$ is sensitive to other environmental factors, especially nutrient-related variables. Method has been used successfully to reconstruct glacial-interglacial changes.	Measured alkenone carbon isotope ratio is accurate and precise (<i>high</i>). Ambient aqueous pCO ₂ has a quantifiable relationship with ϵ_p that can be distinguished from the nutrient-related physiological factors such as algal growth rate, cell size, cell geometry and light-limited growth (<i>medium</i>). Aqueous pCO ₂ is in equilibrium with atmospheric pCO ₂ (<i>medium</i>). Carbon isotope fractionation in modern alkenone-producing species is the same in ancient species and constant through time (<i>medium</i>). Levels of biological productivity (e.g., dissolved phosphate concentrations) can be calculated (<i>high</i>). Carbon isotope ratio of aqueous CO ₂ in the mixed layer can be determined (<i>medium</i>). Sea surface temperature can be determined (<i>high</i>). Atmospheric pO ₂ is known or assumed (<i>medium</i>). Diagenetic effects are minimal, or can be quantified (<i>medium</i>).
Boron isotopes in foraminifera	Boron isotope ratios ($\delta^{11}B$) in foraminifera (or other calcifying organisms) give paleo-pH from which pCO ₂ can be calculated if a value for a second carbonate system parameter (e.g., alkalinity) is assumed.	100– ~4000 ppm; 0–100 Ma	Calculated pCO ₂ is very sensitive to the boron isotope ratio of seawater which is relatively poorly known, especially for the earlier Cenozoic. Effects of foraminiferal preservation are not well understood. Method has been used successfully to reconstruct glacial-interglacial changes.	Measured boron isotope ratio is accurate and precise (<i>high</i>): The equilibrium constant for dissociation of boric acid and boron isotopic fractionation between B(OH) ₃ and B(OH) ₄ ⁻ are well known (<i>high</i>): Boron incorporation into carbonate is predominantly from borate ion (<i>high</i>). Boron isotope ratio of foraminifer calcification reflects ambient surface seawater pH (<i>high</i>). Aqueous pCO ₂ is in equilibrium with atmospheric pCO ₂ (<i>medium</i>) Habitats of extinct species can be determined (<i>high</i>) There is no vital effect fractionation in extinct species, or it can be determined (<i>medium</i>). The boron isotope ratio of seawater ($\delta^{11}B_{sw}$) can be determined (<i>medium</i>). Ocean alkalinity or concentration of Total Dissolved Inorganic Carbon can be determined (<i>high</i>). Sea surface temperature (SST) and salinity (SSS) can be determined (<i>high</i>). Diagenetic effects are minimal or can be quantified (<i>high</i>).
Carbon isotopes in soil carbonate and organic matter	Atmospheric pCO ₂ affects the relationship between the $\delta^{13}C$ of soil CO ₂ and the $\delta^{13}C$ of soil organic matter at depth in certain soil types, hence measurement of these parameters in paleosols can be used to calculate past pCO ₂ .	1000– ~4000 ppm; 0–400 Ma	Method works better for some soil types than others. CO ₂ loss is difficult to quantify and method and effects of late diagenesis may be difficult to determine.	Isotopic composition of soil CO ₂ is reflected in soil carbonates below a depth of 50 cm. (<i>medium</i>) The concentration of respired CO ₂ in the soil is known or assumed (<i>medium</i>). Isotopic composition of atmospheric CO ₂ is known or can be inferred (<i>low</i>) Soil carbonates were precipitated in the vadose zone in exchange with atmospheric CO ₂ (<i>high</i>). The original depth profile of a paleosol can be determined (<i>low</i>). Burial (late) diagenetic effects are minimal or can be quantified (<i>high</i>).

Stomata in plant leaves	The relative frequency of stomata on fossil leaves (Stomatal Index; (Salisbury, 1928)) can be used to calculate past atmospheric CO ₂ levels.	100– ~1000 ppm; 0–400 Ma	Closely related species have very different responses to pCO ₂ . The assumption that short-term response is the same as the evolutionary response is difficult to test. This and the shape of the calibration curves mean that much greater certainty applies to low pCO ₂ and short timescales.	<p>Measured stomatal index is accurate and precise (<i>high</i>).</p> <p>Measured stomatal index is representative of the plant (<i>high</i>)</p> <p>The target plants adjust their stomatal index of leaves to optimize CO₂ uptake (<i>medium</i>).</p> <p>Atmospheric pCO₂ close to the plant is representative of the atmosphere as a whole (<i>medium</i>).</p> <p>The quantitative relationship between stomatal index and CO₂ observed on short timescales (ecophenotypic or 'plastic response') applies over evolutionary time (<i>low</i>).</p> <p>Environmental factors such as irradiance, atmospheric moisture, water availability, temperature, and nutrient availability do not affect the relationship between stomatal index and CO₂ (<i>medium</i>).</p> <p>Stomatal index response to CO₂ of extinct species can be determined or assumed (<i>low</i>).</p> <p>Taphonomic processes do not affect stomatal index counts (<i>high</i>).</p> <p>Diagenetic processes do not affect stomatal index counts (<i>high</i>).</p>

Table 5.A.3: Summary of SST proxy methods and confidence assessment of their main assumptions.

Method	Scientific Rationale	Estimated Applicability	Limitations	Main Assumptions (<i>relative confidence</i>)
$\delta^{18}\text{O}$ of mixed-layer planktonic foraminifera	Partitioning of $^{18}\text{O}/^{16}\text{O}$ from seawater into calcite shells of all foraminifera is temperature dependent. Verified by theoretical, field and laboratory studies. Utilizes extant and extinct species that resided in the photic zone.	0°C–50°C; 0–150 Ma	The $^{18}\text{O}/^{16}\text{O}$ ratios of recrystallized planktonic foraminifer shells in carbonate-rich sediments are biased toward colder seafloor temperatures, and at most, can only constrain the lower limit of SST. The transition in preservation is progressive with age. Well-preserved forams from clay-rich sequences on continental margins are preferred. Diagenetic calcite is detectable by visual and microscopic techniques.	Analytical errors are negligible (<i>high</i>). Sensitivity to T is high and similar to modern descendants (<i>high</i>). Seawater $\delta^{18}\text{O}$ is known. The uncertainty varies with time depending on presence of continental ice-sheets, though error is negligible in the Pleistocene and during minimal ice periods such as the Eocene ($<\pm 0.25^\circ\text{C}$). Error doubles during periods of Oligocene and early Neogene glaciation because of weak constraints on ice-volume (<i>medium to high</i>). Species lives in the mixed-layer and thus records SST (<i>high</i>). Local salinity/seawater $\delta^{18}\text{O}$ is known (<i>low to medium</i>). Carbonate ion/pH is similar to modern (<i>medium, high</i>). Foraminifera from clay-rich sequences are well preserved and $^{18}\text{O}/^{16}\text{O}$ ratios unaffected by diagenesis (<i>high</i>). Foraminifera from carbonate-rich pelagic sequences are well preserved and ratios unaffected by diagenesis (<i>medium to low</i> ; decreasing confidence with age). Biased towards summer SST in polar oceans (<i>medium</i>).
Mg/Ca in mixed-layer planktonic foraminifera	Partitioning of Mg/Ca from seawater into calcite shells is temperature dependent. Calibration to T is based on empirical field and laboratory culturing studies, as Mg concentrations of inorganically precipitated calcite are an order of magnitude higher than in biogenic calcite. There is no ice-volume influence on seawater Mg/Ca, though sensitivity does change with seawater Mg concentration.	5–35°C; 0–65 Ma	Diagenetic recrystallization of foram shells can bias ratios, though the direction of bias is unknown and comparisons with other proxies suggest it is minor. The Mg/Ca is also slightly sensitive to seawater pH. Long-term changes in seawater Mg/Ca, on the order of a 2–5%/10 Myr, must be constrained via models.	Analytical errors are negligible (<i>high</i>). Mg containing oxide and organic contaminants have been removed by oxidative/reductive cleaning (<i>high</i>). Sensitivity to T in extinct species is similar to modern species (<i>medium</i>). Species lives in the mixed-layer and thus records SST (<i>high</i>). Seawater Mg/Ca is known (<i>high to low</i> ; decreasing confidence with time). Surface water carbonate ion/pH is similar to modern (<i>medium</i>). Foraminifera from clay-rich sequences are well preserved and ratios unaffected by diagenesis (<i>high</i>). Foraminifera from carbonate-rich pelagic sequences are well preserved and ratios unaffected by diagenesis (<i>high to low</i> ; decreasing confidence with age). Biased towards summer SST in polar oceans (<i>medium</i>).
TEX ₈₆ index in Archea	The ratio of cyclopentane rings in archaeal tetraether lipids (TEX), i.e., isoprenoid glycerol dibiphytanyl glycerol tetraethers (GDGTs), is	1°C–40°C; 0–150 Ma	The depth from which the bulk of sedimentary GDGT's are produced is assumed to be the mixed-layer though this cannot be verified, for the modern or past.	Analytical errors are small (<i>high</i>). Sensitivity to T similar to modern (<i>medium</i>). Species that produced tropical sedimentary GDGT's resided mainly in the mixed-layer and thus records SST (<i>high to medium</i>).

	sensitive to the temperature of growth environment. The relationship and calibration with temperature is empirical (based on core tops), as the underlying mechanism(s) for this relationship has yet to be identified. Verification of field calibrations with laboratory cultures is still in progress. The compounds are extracted from bulk sediments.		At least two species with differing ecologies appear to be producing the tetraethers. The GDGT signal is ultimately an integrated community signal allowing the potential for evolutionary changes to influence regional signals over time. Tetraethers are found in measurable abundances on continental shelves and/or organic rich sediments.	Species that produced the sedimentary GDGT's in the sub-polar to polar regions mainly resided in the mixed-layer and thus records SST (<i>low</i>). No alteration of GDGT ratios during degradation of compounds (<i>medium to low</i> : decreasing confidence with age). No contamination by GDGT's derived from terrestrial sources (<i>high to medium</i> if BIT index <0.3). Biased towards summer SST in polar oceans (<i>medium</i>).
UK ₃₇ Index in Algae	Based on the relative concentration of C ₃₇ methyl ketones derived from the cells of haptophyte phytoplankton. Calibrations are empirically derived through field and culture studies.	5°C–28°C; 0–50 Ma	The distribution of haptophyte algae ranges from sub-polar to tropical.	Analytical errors are negligible (<i>high</i>). Sensitivity to SST similar to modern (<i>high to medium</i> ; decreasing confidence with time). Species that produced the sedimentary alkenones lived in the mixed-layer and thus record SST (<i>high</i>). No alteration of alkenone saturation index during degradation of compounds (<i>medium</i> ; decreasing confidence with age). Biased towards summer SST in polar oceans (<i>medium</i>).
Microfossil census modern analogue techniques	Utilises a statistical correlation between extant planktonic microfossil assemblage data (most commonly foraminifera, but also diatoms and radiolarians) and climate parameters. Most commonly used statistical methods are modern analogue technique (MAT) and artificial neural network (ANN).	0°C–40°C; 0–5 Ma	Dependent on quality, coverage, size and representativeness of the core top modern analogue data base. Extant species reduce with increasing age. This and paleogeographic and ocean circulation differences with age-limit applicability to less than 1 Ma.	The composition of modern assemblages can be correlated to SST (<i>high</i>). Sensitivity of paleo-assemblages to SST is similar to modern (<i>high</i> , but decreases with increasing age). Eurythermal assemblages responding to non-temperature (e.g., nutrient availability) influences can be identified (<i>medium</i>). That the extant species used to reconstruct SST mainly reside in the mixed layer (<i>medium to high</i>). Depositional and post-depositional processes have not biased the assemblage (<i>medium to high</i>).

2 publications, main findings, incorporation in IPCC assessments and key uncertainties.
3

Reference	Investigated Source CO ₂ Data Period	Source Temperature Data	Lag Quantification Method	Lag Between Temperature and CO ₂ (positive, temperature lead)	Key Limitations	
(Fischer et al., 1999)	Termination I	Taylor Dome, Byrd ^a (CH ₄ synchronized age scales)	Byrd δ ¹⁸ O, Vostok δD (CH ₄ synchronized age)	Maximum at onset of interglacial periods	Antarctica: 600 ± 400 years	Ice core synchronization for Termination I (~300 years). Gas age-ice age difference simulated by firn models for interglacial conditions could be overestimated by ~400 years. Signal to noise ratio.
(Petit et al., 1999)	Terminations I, II, III	Vostok ^a (gas age scales based on firn modelling)	Vostok ^a δD (GT4 ice age scale)	Onset of transitions	Antarctica: in phase within uncertainties	Resolution of CO ₂ measurements and firnification smoothing (~300 years). Gas age-ice age difference simulated by firn models for glacial conditions could be overestimated by up to 1500 years.
(Pépin et al., 2001)	Terminations I, II, III, IV	Vostok ^a (GT4 gas age scale based on firn modelling)	Vostok δD (GT4 ice age age)	Onset of transitions	Antarctica: in phase within uncertainties	Resolution of CO ₂ measurements and firnification smoothing (~300 years). Signal to noise ratio (1 ice core).
(Mudelsee, 2001)	0–420 ka	Vostok ^a (GT4 gas age scale)	Vostok δD (GT4 ice age age)	Lagged generalised least square regression with parametric bootstrap resampling, entire record	Antarctica : 1300 ± 1000 years	Resolution of CO ₂ measurements and firnification smoothing (~300 years). Signal to noise ratio (1 ice core).

AR4: High-resolution ice core records of temperature proxies and CO₂ during deglaciation indicates that Antarctic temperature starts to rise several hundred years before CO₂ (Monnin et al., 2001; Caillon et al., 2003). During the last deglaciation, and possibly also the three previous ones, the onset of warming at both high southern and northern latitudes preceded by several thousand years the first signals of significant sea level increase resulting from the melting of the northern ice sheets linked with the rapid warming at high northern latitudes (Petit et al., 1999; Shackleton, 2000; Pépin et al., 2001). Current data are not accurate enough to identify whether warming started earlier in the SH or NH, but a major deglacial feature is the difference between North and South in terms of the magnitude and timing of strong reversals in the warming trend, which are not in phase between the hemispheres and are more pronounced in the NH (Blunier and Brook, 2001).

(Monnin et al., 2001)	Termination I	High resolution data from EDC on EDC1 gas age scale (based on firn modelling)	EDC on EDC1 ice age scale	Crossing points of linear fit	Antarctica: 800 ± 600 years	Gas age-ice age difference (±1000 years). Signal to noise ratio (1 ice core).
(Caillon et al., 2003)	Termination III	Vostok on GT4 gas age scale	Vostok $\delta^{40}\text{Ar}$ on GT4 gas age scale	Maximum lagged correlation	Antarctica: 800 ± 200 years	Relationship between $\delta^{40}\text{Ar}$ and temperature assumed to be instantaneous. The 800 years is a minimum CO_2 -temperature lag which does not account for a possible delayed response of firn gravitational fractionation to surface temperature change.
<p><i>AR5: Large-scale reconstructions of SH temperature change (Shakun et al., 2012) for the last glacial termination document a lead of SH averaged temperature over NH temperature. This lead can be explained by the bipolar thermal seesaw concept (Stocker and Johnsen, 2003) (see also Section 5.7) and the related changes in the interhemispheric ocean heat transport, caused by weakening of the AMOC during the last glacial termination (Ganopolski and Roche, 2009). SH warming prior to NH warming can also be explained by the fast sea ice response to changes in austral spring insolation (Stott et al., 2007; Timmermann et al., 2009). According to these mechanisms, southern temperature lead over NH is fully consistent with the NH forcing of deglacial ice volume changes (high confidence) and the importance of the climate-carbon feedbacks in glacial-interglacial transitions. The tight coupling is further highlighted by the near-zero lag between the rise in CO_2 and in Antarctic temperature recently reported from improved estimates of gas-ice age differences (Pedro et al., 2012; Parrenin et al., 2013). Previous studies (Monnin et al., 2001) suggesting a temperature lead of 800 ± 600 years over the deglacial CO_2 rise overestimated gas-ice age differences.</i></p>						
(Shakun et al., 2012)	Termination I	EDC age scale synchronized to GICC05 ^b (Lemieux-Dudon et al., 2010)	NH: stack of 50 records including 2 Greenland ice cores SH: stack of 30 records incl. 4 ice cores (Vostok, EDML, EDC, Dome F) ^a on their original age scale	Lag correlation (20–10 kyr) using Monte-Carlo statistics	SH: 620 ± 660 years NH: –720 ± 660 years Global: –460 ± 340 years	Uncertainties in the original age scales of each record: e.g., reservoir ages of marine sediments, radiocarbon calibration (intCal04), Antarctic gas / ice chronology. Assumption that timescale errors (e.g., from reservoir ages or ice core chronologies) are independent from each other. This could lead to higher-than-reported lag estimation uncertainties. Similar limitations as in earlier studies for Antarctic temperature lead on CO_2 . Non stability of the phase lags: global temperature leads CO_2 at the onset of deglacial warming.
(Pedro et al., 2012)		Siple Dome and Byrd, synchronized to GICC05 ^b age scale	$\delta^{18}\text{O}$ composite (Law Dome, Siple Dome, Byrd, EDML and TALDICE ^a ice cores)	Lag correlation (9–21 kyr) and derivative lag correlation	Antarctica: –60 to 380 years	Uncertainty on gas – ice age difference in high accumulation sites (<300 years) and on synchronization methods to GICC05. Data resolution (145 year for Byrd CO_2 , 266 year for Siple CO_2). The CO_2 data were resampled at 20 year

		synchronized to GICC05 ^b using firn modelling (Pedro et al., 2011)			resolution prior to the lag analysis, which may lead to an underestimation of the statistical error in the lag determination.
					Temperature versus other (e.g., elevation, moisture origin) signals in coastal ice core $\delta^{18}\text{O}$.
					Correlation method sensitive to minima, maxima and inflexion points.
(Parrenin et al., 2013)	EDC, new gas age scale produced from the modified EDC3 ice age scale using lock-in depth derived from $\delta^{15}\text{N}$ of N_2 and adjusted to be consistent with GICC05 ^b gas age scale. Processes affecting the gas lock-in depth such as impurities are implicitly taken into account when using $\delta^{15}\text{N}$ (no use of firn models).	Stack temperature profile derived from water isotopes from EDC ^a , Vostok ^a , Dome Fuji ^a , TALDICE ^a and EDML ^a synchronized to a modified EDC3 ice age scale	Monte-Carlo algorithm at linear break points	Antarctica: Warming onset: -10 ± 160 years Bølling onset: 260 ± 130 years Younger Dryas onset: -60 ± 120 years Holocene onset: 500 ± 90 years	Accuracy, resolution and interpolation of $\delta^{15}\text{N}$ of N_2 ; assumption of no firn convective zone at EDC under glacial conditions. Data resolution and noise (e.g., precipitation intermittency biases in stable isotope records).

Notes:

(a) Names of different Antarctic ice cores (Byrd, Taylor Dome, Vostok, Siple Dome, Law Dome, TALDICE, Dome Fuji, EDML, EDC), with different locations, surface climate and firnification conditions. For the most inland sites (Vostok, EDC, Dome Fuji), at a given ice core depth, gas ages are lower than ice ages by 1500–2000 years (interglacial conditions) and 5000–5500 years (glacial conditions) while this gas age-ice age difference is lower (400–800 years) for coastal, higher accumulation sites (Byrd, Law Dome, Siple Dome).

(b) GICC05: Greenland Ice Core Chronology 2005, based on annual layer counting in Greenland (NGRIP, GRIP and DYE3 ice cores) (Rasmussen et al., 2006), back to 60 ka (Svensson et al., 2008). The synchronism between rapid shifts in Greenland climate and in atmospheric CH_4 variations allows to transfer GICC05 to Greenland and then to Antarctic CH_4 variations (Blunier et al., 2007).

Additional point: CO_2 -Antarctic temperature phase during AIM events

Studies on CO_2 phasing relative to CH_4 during Dansgaard Oeschger event onsets (Ahn and Brook, 2008; Ahn et al., 2012; Bereiter et al., 2012) suggest a lag of maximum CO_2 concentration relative to the Antarctic Isotope Maxima (AIM) 19, 20, 21, 23 and 24 by 260 ± 220 years during MIS5 and $670\text{--}870$ years ± 360 years relative to AIM 12, 14, 17 during MIS3 (Bereiter et al., 2012). Accordingly, the lag is dependent on the climate state. A lag is not discernible for shorter AIM. This study avoids the ice age/gas age difference problem, but relies on the bipolar seesaw concept, i.e., it assumes that maximum Antarctic temperatures are coincident to the onset of DO events and the concurrent CH_4 increase.

1 **Table 5.A.5:** Summary of seasonal estimates of terrestrial surface temperature anomalies (°C) for the Last Interglacial (LIG) plotted in Figure 5.6. *pdf*-method stands for probability-
 2 density function method. Dating methods: AMS=Accelerator mass spectrometry; IRSL=Infrared stimulated luminescence; OSL=Optically stimulated luminescence;
 3 TL=thermoluminescence.

- 1 Notes:
2 (a) Region: L=land only, L+S=land and sea, latitude range indicated
3 (b) Proxy location and coverage: H=high latitude, M=mid latitude, L=low latitude, O=oceans, ☐=none or very few,
4 ☒=limited, * = moderate
5 (c) These studies also present versions without tree-rings or without seven inhomogeneous proxies (including the Lake
6 Korttajärvi sediment records; Tiljander et al., 2003). The latter version is used in Figure 5.7a (Ma08min7eivf) in
7 preference to the reconstruction from the full network. The impact of these seven proxies on the other NH
8 reconstructions is negligible (MA08cpsl) or results in a slightly warmer pre-900 reconstruction compared to the version
9 without them (Ma09regm).

Figures

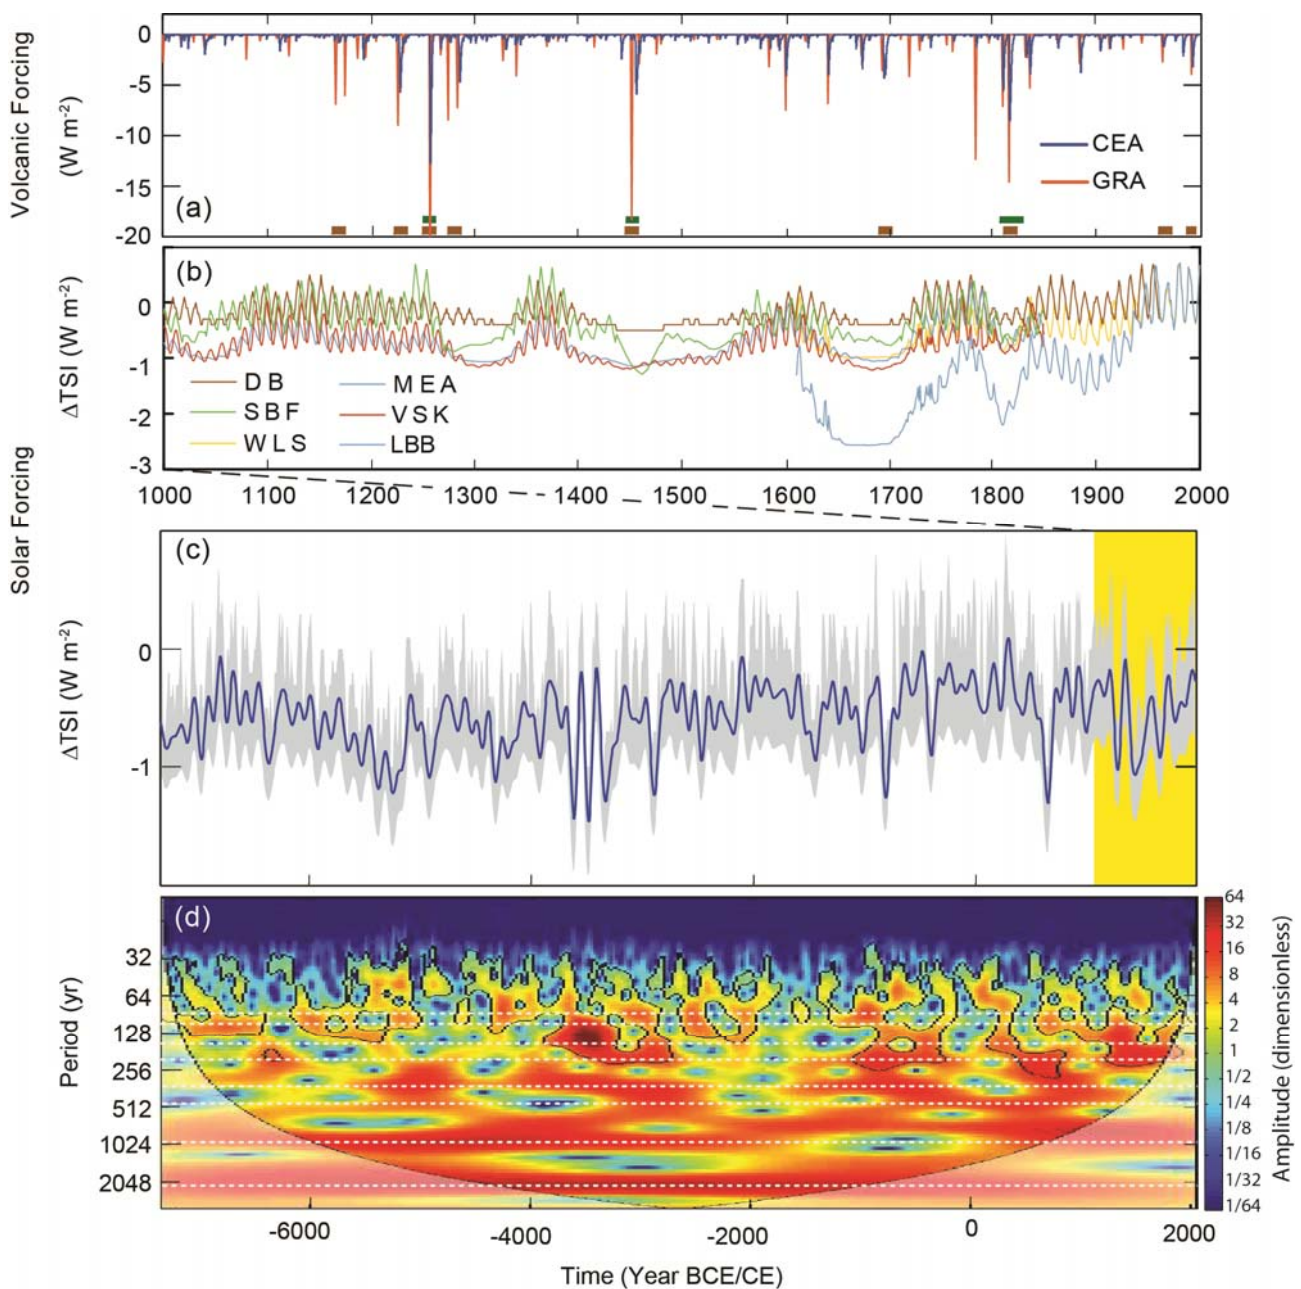

Figure 5.1: (a) Two reconstructions of volcanic forcing for the past 1000 years derived from ice core sulphate and used for PMIP3/CMIP5 simulations (Schmidt et al., 2011). GRA: (Gao et al., 2012); CEA: (Crowley and Unterman, 2013). Volcanic sulphate peaks identified from their isotopic composition as originating from the stratosphere are indicated by squares (green: Greenland; brown: Antarctica) (Baroni et al., 2008; Cole-Dai et al., 2009). (b) Reconstructed TSI anomalies back to the year 1000. Proxies of solar activity (e.g., sunspots, ^{10}Be) are used to estimate the parameters of the models or directly TSI. All records except LBB (Lean et al., 1995b) have been used for PMIP3/CMIP5 simulations (Schmidt et al., 2011). DB: (Delaygue and Bard, 2011); MEA: (Muscheler et al., 2007); SBF: (Steinhilber et al., 2009); WLS: (Wang et al., 2005); VSK: (Vieira et al., 2011). Prior to 1600, the 11-year cycle has been added artificially to the original data with an amplitude proportional to the mean level of TSI. (c) Reconstructed TSI anomalies (100-year low-pass filtered; grey shading: 1 standard deviation uncertainty range) for the past 9300 years (Steinhilber et al., 2009). The reconstruction is based on ^{10}Be and calibrated using the relationship between instrumental data of the open magnetic field, which modulates the production of ^{10}Be , and TSI for the past 4 solar minima. The yellow band indicates the past 1000 years shown in more details in panels a and b. Anomalies are relative to the 1976–2006 mean value (1366.14 W m^{-2}) of Wang et al. (2005). (d) Wavelet analysis (Torrence and Compo, 1998) of TSI anomalies from panel c with dashed white lines highlighting significant periodicities (Stuiver and Braziunas, 1993).

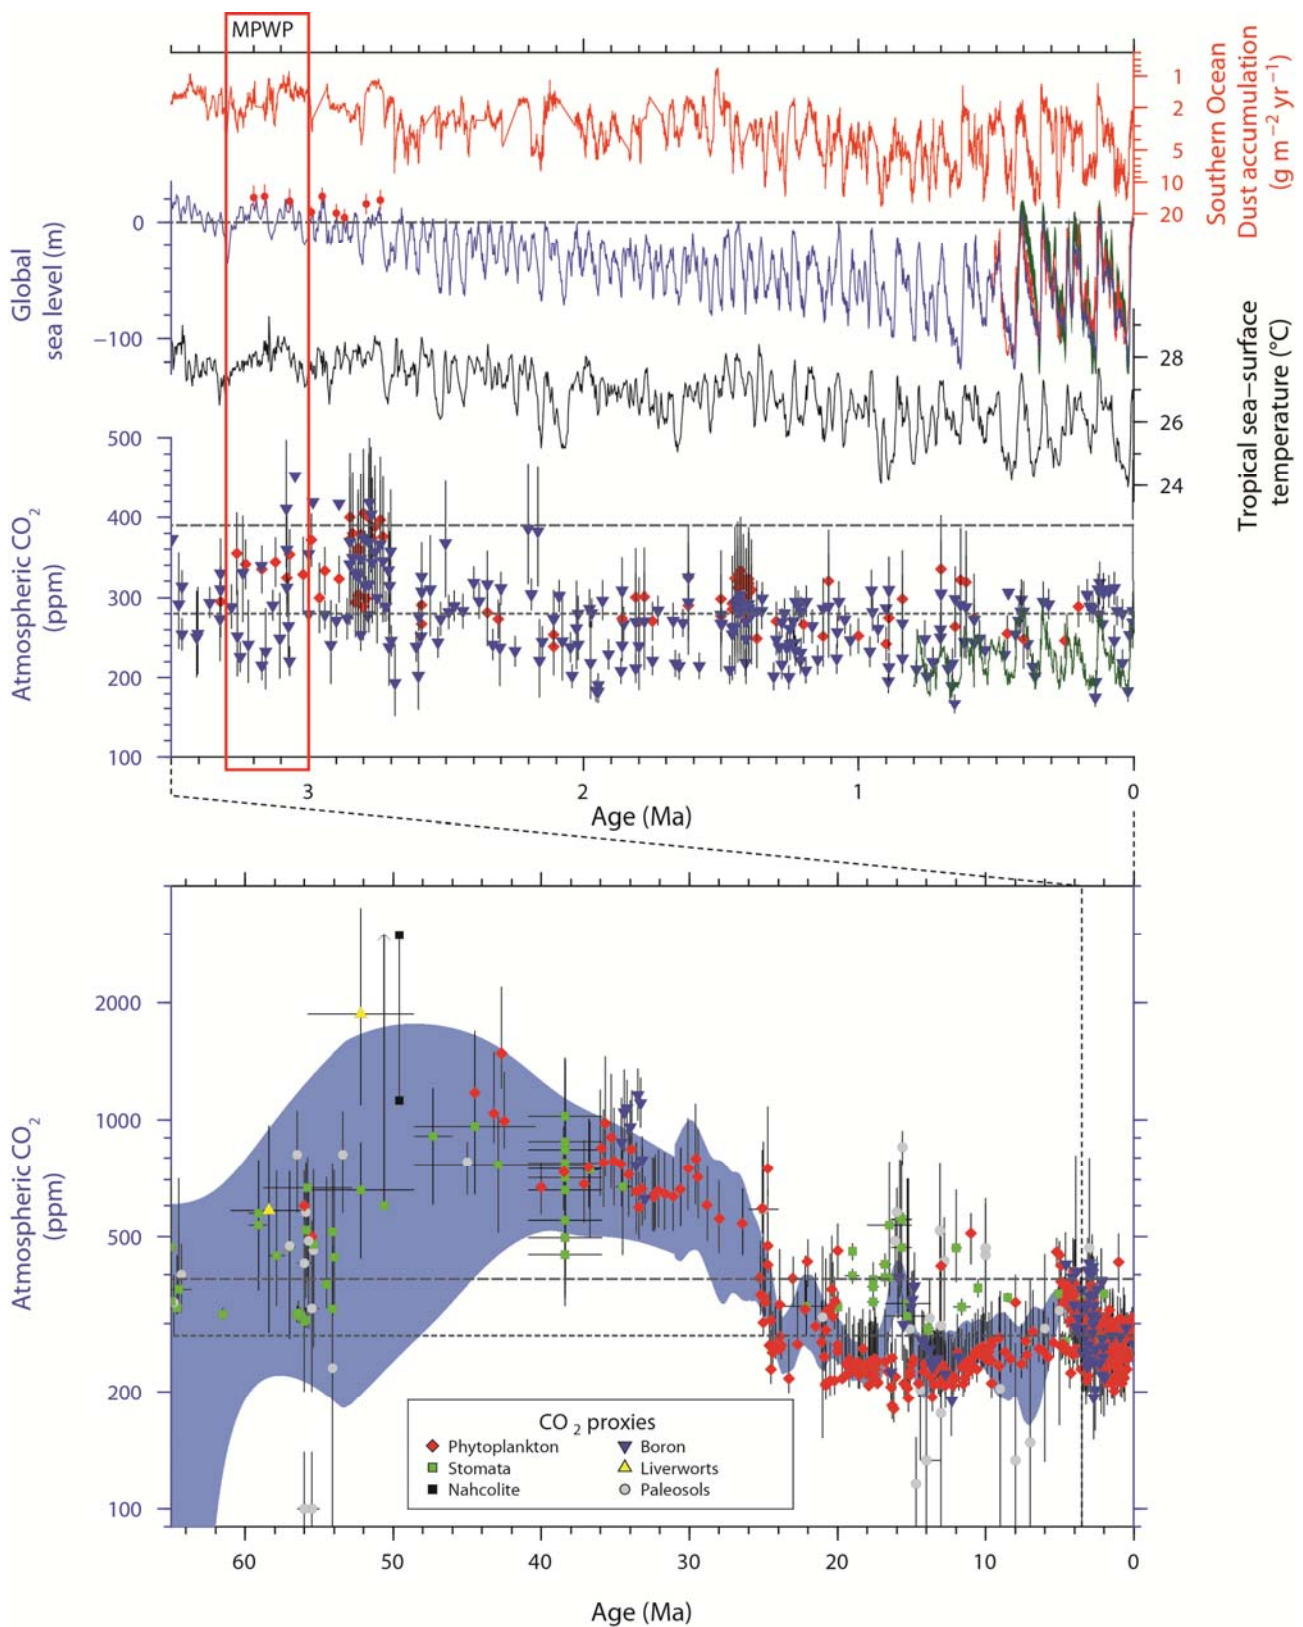

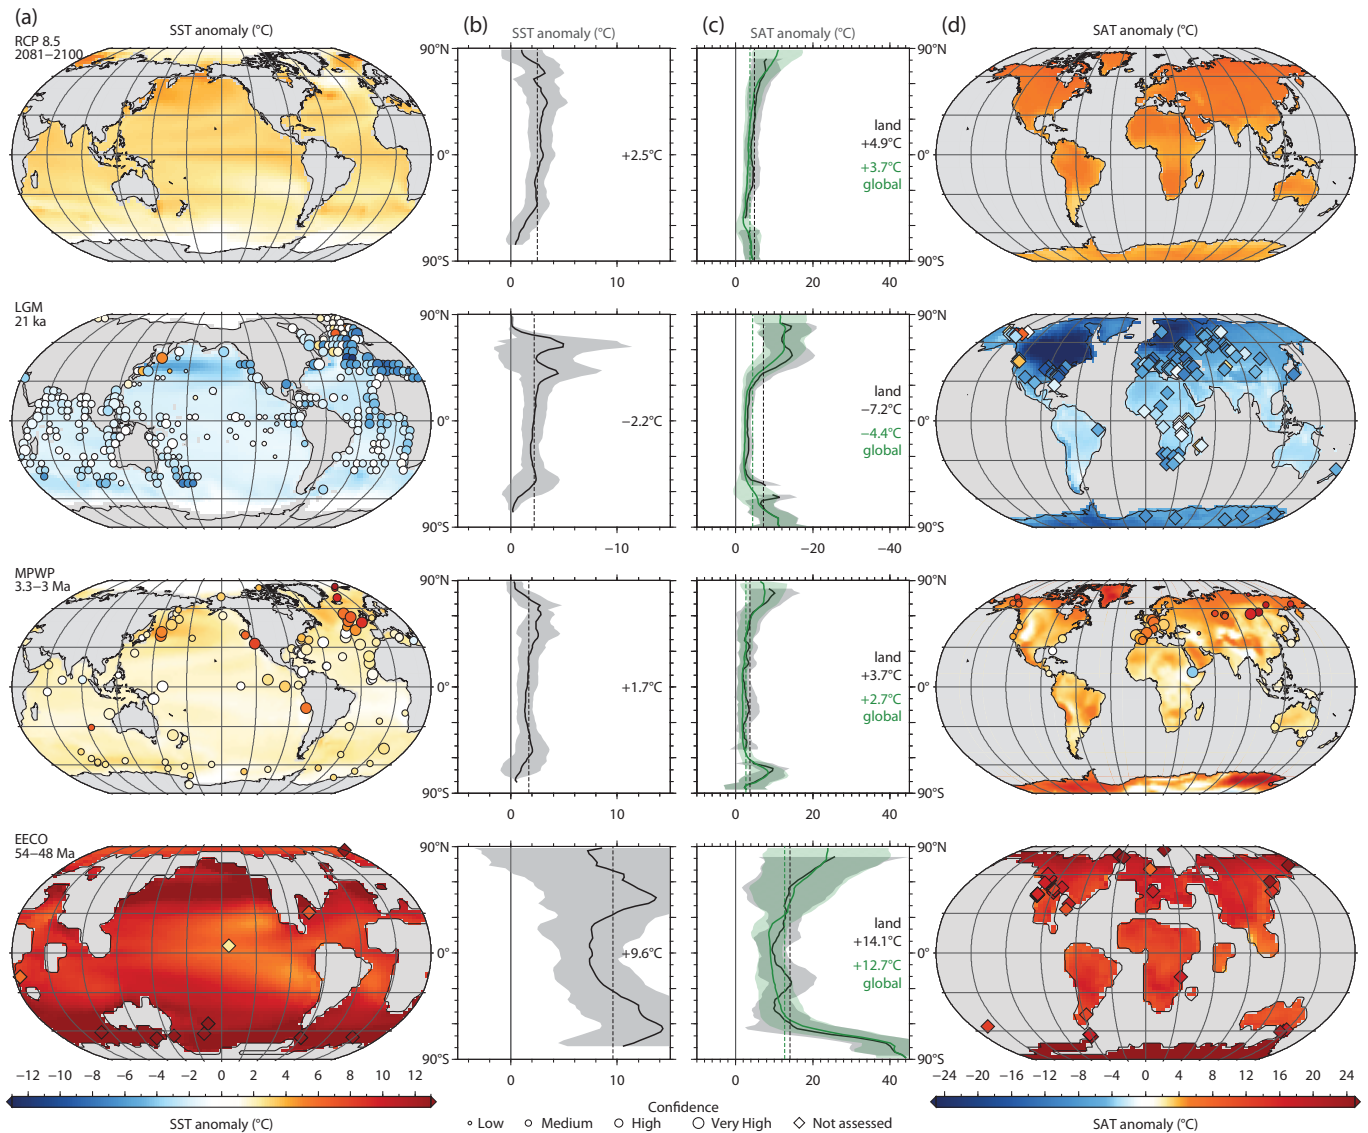

Figure 5.2: (Top) Orbital-scale Earth system responses to radiative forcings and perturbations from 3.5 Ma to present. Reconstructed dust mass accumulation rate is from the Atlantic sector of the Southern Ocean (red) (Martinez-Garcia et al., 2011). Sea level curve (blue) is the stacked $\delta^{18}\text{O}$ proxy for ice volume and ocean temperature (Lisiecki and Raymo, 2005) calibrated to global average eustatic sea level (Naish and Wilson, 2009; Miller et al., 2012a). Also shown are global eustatic sea level reconstructions for the last 500 kyr based on sea level calibration of the $\delta^{18}\text{O}$ curve using dated coral shorelines (grey line; Waelbroeck et al., 2002) and the Red Sea isotopic reconstruction (red line; Rohling et al., 2009). Weighted mean estimates (2 standard deviation uncertainty) for far-field reconstructions of eustatic peaks are

shown for mid-Pliocene interglacials (red dots; Miller et al., 2012a). The dashed horizontal line represents present-day sea level. Tropical sea-surface temperature (black line) based on a stack of 4 alkenone-based SST reconstructions (Herbert et al., 2010). Atmospheric CO₂ measured from Antarctic ice cores (Petit et al., 1999; Siegenthaler et al., 2005) (blue line; Lüthi et al., 2008), and estimates of CO₂ from boron isotopes ($\delta^{11}\text{B}$) in foraminifera in marine sediments (blue triangles; Hönisch et al., 2009; Seki et al., 2010; Bartoli et al., 2011), and phytoplankton alkenone-derived carbon isotope proxies (red diamonds; Pagani et al., 2010; Seki et al., 2010), plotted with 2 standard deviation. Present (2012) and pre-industrial CO₂ concentrations are indicated with long-dashed and short-dashed grey lines, respectively. (Bottom) Concentration of atmospheric CO₂ for the last 65 Ma is reconstructed from marine and terrestrial proxies (Cerling, 1992; Freeman and Hayes, 1992; Koch et al., 1992; Stott, 1992; van der Burgh et al., 1993; Sinha and Stott, 1994; Kürschner, 1996; McElwain, 1998; Ekart et al., 1999; Pagani et al., 1999b; Pagani et al., 1999a; Kürschner et al., 2001; Royer et al., 2001a; Royer et al., 2001b; Beerling et al., 2002; Beerling and Royer, 2002; Nordt et al., 2002; Greenwood et al., 2003; Royer, 2003; Pagani et al., 2005a; Pagani et al., 2005b; Lowenstein and Demicco, 2006; Fletcher et al., 2008; Kürschner et al., 2008; Beerling et al., 2009; Pearson et al., 2009; Retallack, 2009b, 2009a; Tripathi et al., 2009; Pagani et al., 2010; Seki et al., 2010; Smith et al., 2010; Bartoli et al., 2011; Doria et al., 2011; Pagani et al., 2011; Foster et al., 2012). Individual proxy methods are colour-coded (see also Table A5.1). The light blue shading is a 1-standard deviation uncertainty band constructed using block bootstrap re-sampling (Mudelsee et al., 2012) for a kernel regression through all the data points with a bandwidth of 8 Myr prior to 30 Ma, and 1 Myr from 30 Ma to present. Most of the data points for CO₂ proxies are based on duplicate and multiple analyses. The red box labelled MPWP represents the mid-Pliocene Warm Period (3.3–3.0 Ma; Table 5.1).

Box 5.1, Figure 1: Comparison of data and multi-model mean (MMM) simulations, for four periods of time, showing (a) SST anomalies, (b) zonally averaged SST anomalies, (c) zonally averaged global (green) and land (grey) surface-air temperature (SAT) anomalies and (d) land SAT anomalies. The time periods are 2081–2100 (top row), LGM (second row), MPWP (third row) and EECO (bottom row). Model temperature anomalies are calculated relative to the pre-industrial value of each model in the ensemble prior to calculating the MMM anomaly (a, d; colour shading). Zonal MMM gradients (b, c) are plotted with a shaded band indicating 2 standard deviations. Site specific temperature anomalies estimated from proxy data are calculated relative to present site temperatures and are plotted (a, d) using the same colour scale as the model data, and a circle-size scaled to estimates of confidence. Proxy data compilations for the LGM are from MARGO Project Members (2009) and Bartlein et al. (2011), for the MPWP are from Dowsett et al. (2012), Salzmann et al. (2008) and Haywood et al. (2013) and for the EECO are from Hollis et al. (2012) and Lunt et al. (2012). Model ensemble simulations for 2081–2100 are from the CMIP5 ensemble using RCP 8.5, for the LGM are seven PMIP3/CMIP5 models, for the Pliocene are from Haywood et al., (2013), and for the EECO are after Lunt et al. (2012).

Figure 5.3: Orbital parameters and proxy records over the past 800 kyr. (a) Eccentricity, (b) obliquity, (c) precessional parameter (Berger and Loutre, 1991), (d) atmospheric concentration of CO₂ from Antarctic ice cores (Petit et al., 1999; Siegenthaler et al., 2005; Ahn and Brook, 2008; Lüthi et al., 2008), (e) tropical SST stack (Herbert et al., 2010), (f) Antarctic temperature stack based on up to seven different ice cores (Petit et al., 1999; Blunier and Brook, 2001; Watanabe et al., 2003; EPICA Community Members, 2006; Jouzel et al., 2007; Stenni et al., 2011), (g) stack of benthic $\delta^{18}\text{O}$, a proxy for global ice volume and deep-ocean temperature (Lisiecki and Raymo, 2005), (h) reconstructed sea level (dashed line: Rohling et al., 2010; solid line: Elderfield et al., 2012). Lines represent orbital forcing and proxy records, shaded areas represent the range of simulations with climate (GENIE-1, Holden et al., 2010a; Bern3D, Ritz et al., 2011), climate-ice sheet models of intermediate complexity (CLIMBER-2, Ganopolski and Calov, 2011) and an ice-sheet model (IcIES, Abe-Ouchi et al., 2007) forced by variations of the orbital parameters and the atmospheric concentrations of the major greenhouse gases. (i) Rate of changes of global mean temperature during Termination I based on Shakun et al. (2012).

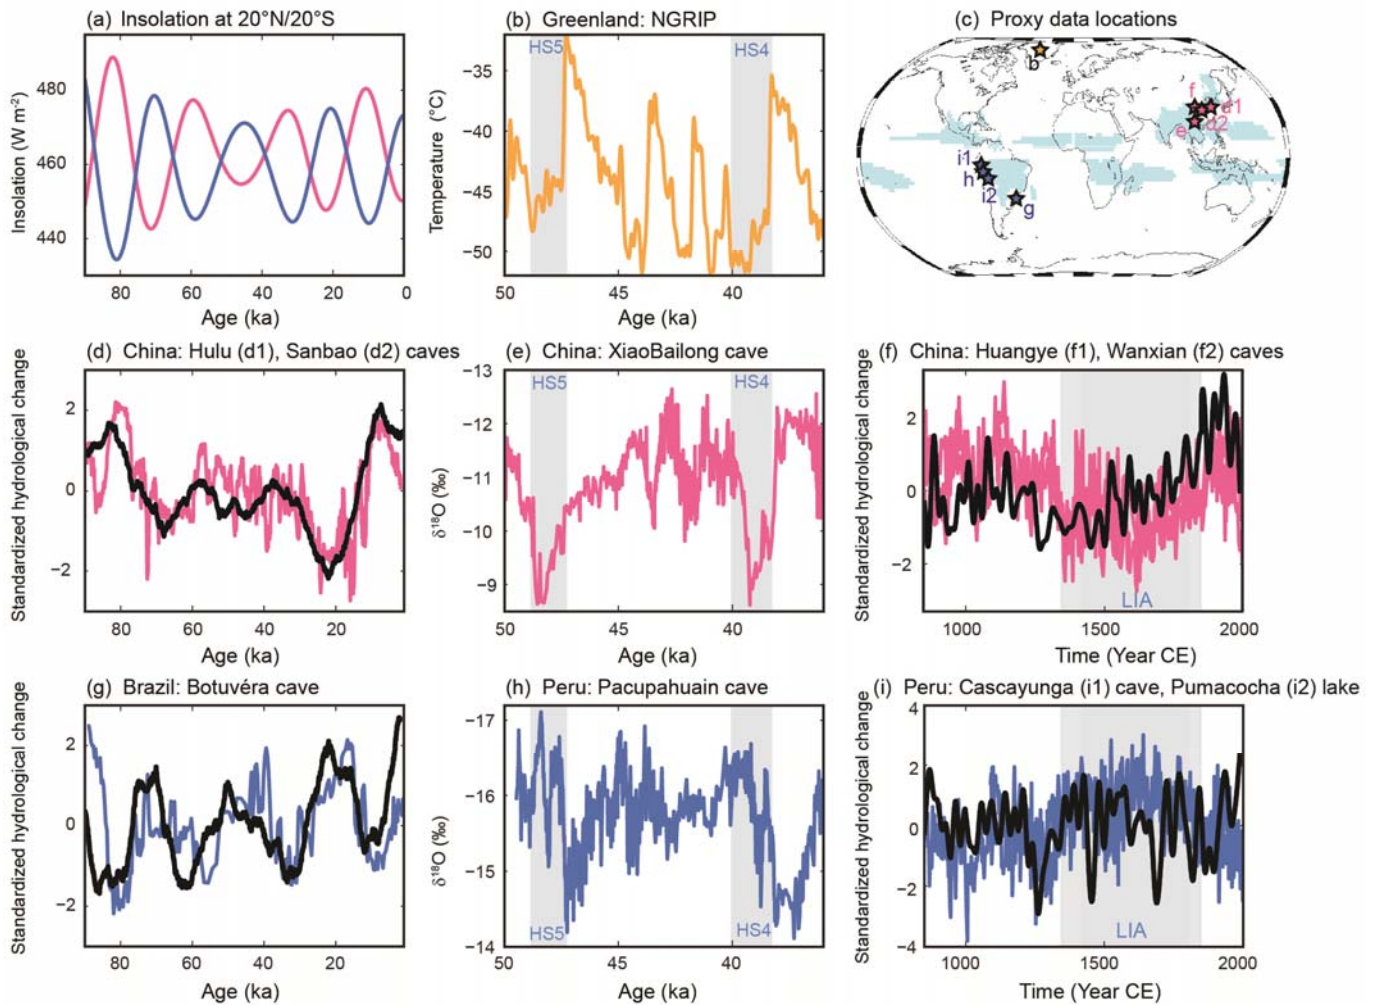

Figure 5.4: Inter-hemispheric response of monsoon systems at orbital, millennial and centennial scales: (a) boreal summer insolation changes at 20°N (red) (W m^{-2}) and austral summer insolation changes at 20°S (blue). (b) Temperature changes in Greenland ($^{\circ}\text{C}$) reconstructed from NGRIP ice core on SS09 timescale (Huber et al., 2006), location indicated by orange star in c. (c) Location of proxy records displayed in panels a,b,d-i in relation to the global monsoon regions (cyan shading) (Wang and Ding, 2008). (d) Reconstructed (red) standardized negative $\delta^{18}\text{O}$ anomaly in East Asian Summer Monsoon region derived from Hulu (Wang et al., 2001) and Sanbao (Wang et al., 2008) cave speleothem records, China and simulated standardized multi-model average (black) of annual mean rainfall anomalies averaged over region 108°E–123°E and 25°N–40°N using the transient runs conducted with LOVECLIM (Timm et al., 2008), FAMOUS (Smith and Gregory, 2012), and the HadCM3 snapshot simulations (Singarayer and Valdes, 2010). (e) $\delta^{18}\text{O}$ from Xiaobailong cave, China (Cai et al., 2010). (f) Standardized negative $\delta^{18}\text{O}$ anomalies (red) in Huangye (Tan et al., 2011) and Wanxian (Zhang et al., 2008) caves, China and simulated standardized annual mean and 30-year low pass filtered rainfall anomalies (black) in region 100°E–110°E, 20°N–35°N, ensemble averaged over externally forced AOGCM experiments conducted with CCSM4, ECHO-G, MPI-ESM, CSIRO-Mk3L-1-2, MIROC, HADCM3 (Table 5.A.1). (g) Standardized negative $\delta^{18}\text{O}$ anomaly (blue) from Botuverá speleothem, Brazil (Cruz et al., 2005) and simulated standardized multi-model average (black) of annual mean rainfall anomalies averaged over region 45°W–60°W and 35°S–15°S using same experiments as in panel d. (h) Standardized $\delta^{18}\text{O}$ anomaly (blue) from Pacupahuain cave, Peru (Kanner et al., 2012). (i) Standardized negative $\delta^{18}\text{O}$ anomalies (blue) from Cascayunga Cave, Peru (Reuter et al., 2009) and Pumacocha Lake, Peru (Bird et al., 2011) and simulated standardized annual mean and 30-year low-pass filtered rainfall anomalies (black) in region 76°W–70°W, 16°S–8°S, ensemble averaged over the same model simulations as in f. HS4/5 denote Heinrich stadials 4 and 5, and LIA Little Ice Age (Table 5.1).

Box 5.2, Figure 1: Schematic illustration of multiple interactions between ice sheets, solid earth, and the climate system which can drive internal variability and affect the coupled ice sheet–climate response to external forcings on timescales of months to millions of years. The inlay figure represents a typical height profile of atmospheric temperature and moisture in the troposphere.

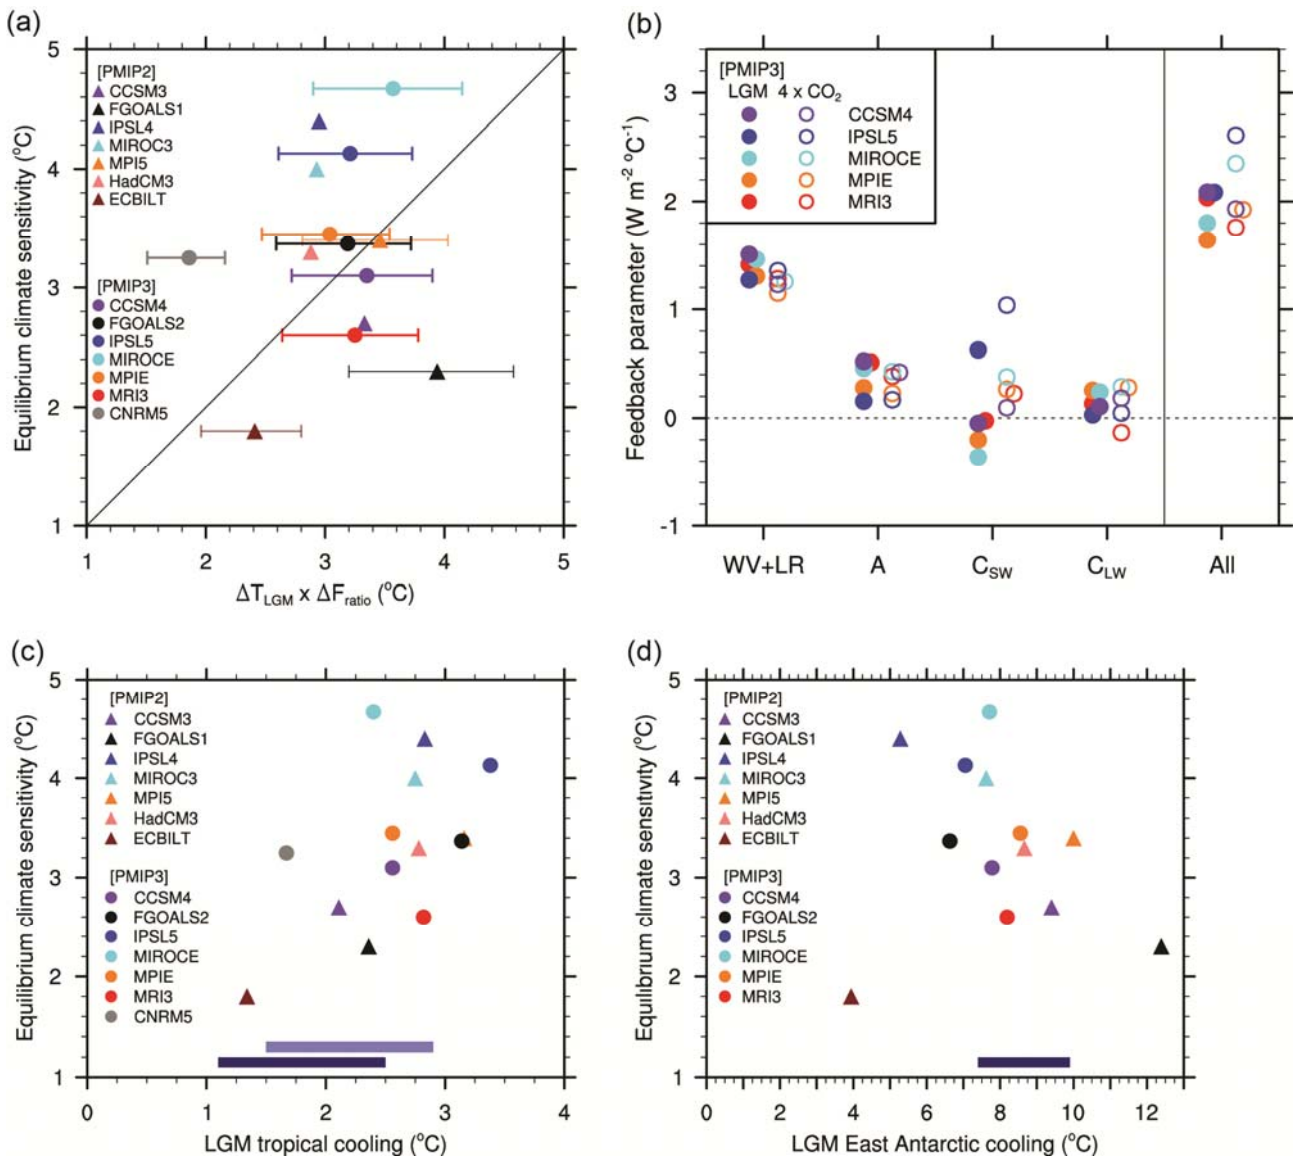

Figure 5.5: (a) Relation between equilibrium climate sensitivity (ECS) estimated from LGM simulations and that estimated from equilibrium $2 \times CO_2$ or abrupt $4 \times CO_2$ experiments. All experiments are referenced to pre-industrial simulations. FGOALS1, IPSL4, MPI5, and ECBILT of PMIP2 models stand for FGOALS-1.0g, IPSL-CM4-V1-MR, ECHAM53-MPIOM127-LPJ, and ECBILTCLIO, respectively. FGOALS2, IPSL5, MIROCE, MPIE, MRI3, and CNRM5 of PMIP3 models stand for FGOALS-g2, IPSL-CM5A-LR, MIROC-ESM, MPI-ESM-P, MRI-CGCM3, and CNRM-CM5, respectively. ECS based on LGM simulations (abscissa) was derived by multiplying the LGM global mean temperature anomaly (ΔT_{LGM}) and the ratio of radiative forcing between $2 \times CO_2$ and LGM (ΔF_{ratio}). ΔF_{ratio} for three PMIP2 models (CCSM3, HadCM3, and IPSL4) were taken from Crucifix (2006), and it was taken from Yoshimori et al. (2009) for MIROC3. Its range, -0.80 to -0.56 , with a mean of -0.69 was used for other PMIP2 and all PMIP3 models. ECS of PMIP2 models (ordinate) was taken from Hargreaves et al. (2012). ECS of PMIP3 models was taken from Andrews et al. (2012) and Brady et al. (2013), or computed using the method of Andrews et al. (2012) for FGOALS2. Also plotted is a one-to-one line. (b) Strength of individual feedbacks for the PMIP3/CMIP5 abrupt $4 \times CO_2$ (131–150 years) and LGM (stable states) experiments following the method in Yoshimori et al. (2011). “WV+LR”, “A”, “C_{sw}”, “C_{lw}” denote water vapour plus lapse-rate, surface albedo, shortwave cloud, and longwave cloud feedbacks, respectively. “All” denotes the sum of all feedbacks except for the Planck response. Feedback parameter here is defined as the change in net radiation at the top of the atmosphere due to the change in individual fields, such as water vapour, with respect to the pre-industrial simulations. It was normalized by the global mean surface air temperature change. Positive (negative) value indicates that the feedback amplifies (damp) the initial temperature response. Only models with all necessary data available for the analysis are displayed. (c) Relation between LGM tropical (20°S–30°N) surface air temperature anomaly from pre-industrial simulations and ECS across models. A dark blue bar represents a 90% confidence interval for the estimate of reconstructed temperature anomaly of Annan and Hargreaves (2013). A light blue bar represents the same with additional $0.4^{\circ}C$ anomaly increase according to the result

of the sensitivity experiment conducted in Annan and Hargreaves (2013), in which additional 1°C lowering of tropical SST proxy data was assumed. (d) Same as in c but for the average of East Antarctica ice core sites of Dome F, Vostok, EDC and EDML. A dark blue bar represents a range of reconstructed temperature anomaly based on stable isotopes at these core sites (Stenni et al., 2010; Uemura et al., 2012). A value below zero is not displayed (the result of CNRM5). Note that the Antarctic ice sheet used for PMIP3 simulations, based on several different methods (Tarasov and Peltier, 2007; Argus and Peltier, 2010; Lambeck et al., 2010) differs in elevation from that used in PMIP2 (panel d).

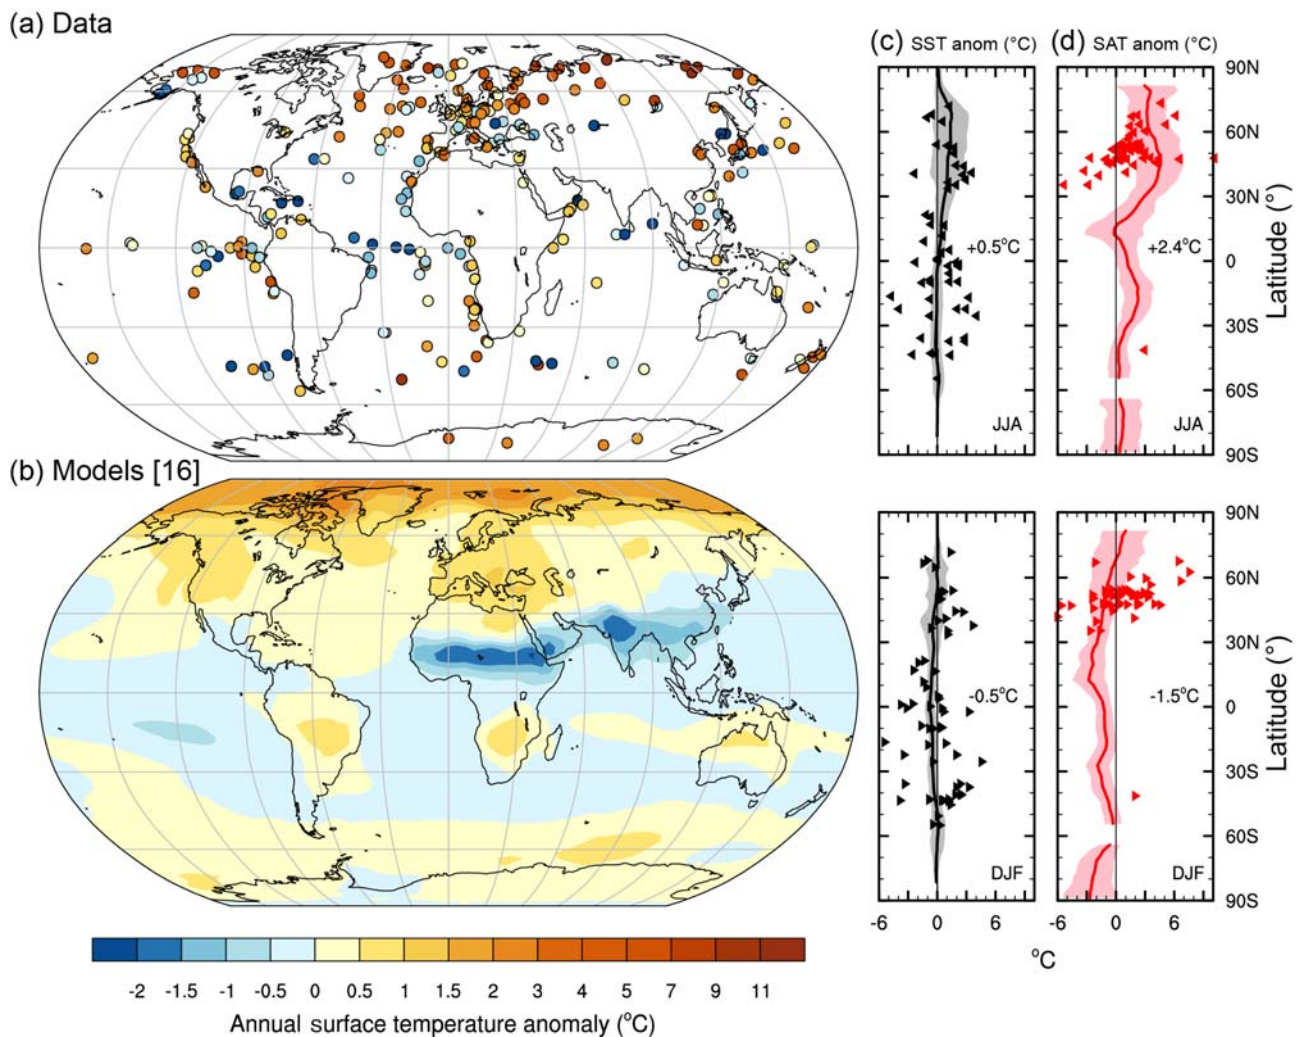

Figure 5.6: Changes in surface temperature for the LIG as reconstructed from data and simulated by an ensemble of climate model experiments in response to orbital and WMGHG forcings. (a) Proxy data syntheses of annual surface temperature anomalies as published by Turney and Jones (2010) and McKay et al. (2011). McKay et al., (2011) calculated an annual anomaly for each record as the average SST of the 5-kyr period centred on the warmest temperature between 135 ka and 118 ka and then subtracting the average SST of the late Holocene (last 5 kyr). Turney and Jones (2010) calculated the annual temperature anomalies relative to 1961–1990 by averaging the LIG temperature estimates across the isotopic plateau in the marine and ice records and the period of maximum warmth in the terrestrial records (assuming globally synchronous terrestrial warmth). (b) Multi-model average of annual surface air temperature anomalies simulated for the LIG computed with respect to pre-industrial. The results for the LIG are obtained from 16 simulations for 128–125 ka conducted by 13 modelling groups (Lunt et al., 2013). (c) Seasonal SST anomalies. Multi-model zonal averages are shown as solid line with shaded bands indicating 2 standard deviations. Plotted values are the respective seasonal multi-mean global average. Symbols are individual proxy records of seasonal SST anomalies from McKay et al., 2011. (d) Seasonal terrestrial surface temperature anomalies. As in (c) but with symbols representing terrestrial proxy records as compiled from published literature (Table 5.A.5). Observed seasonal terrestrial anomalies larger than 10°C or less than –6°C are not shown.

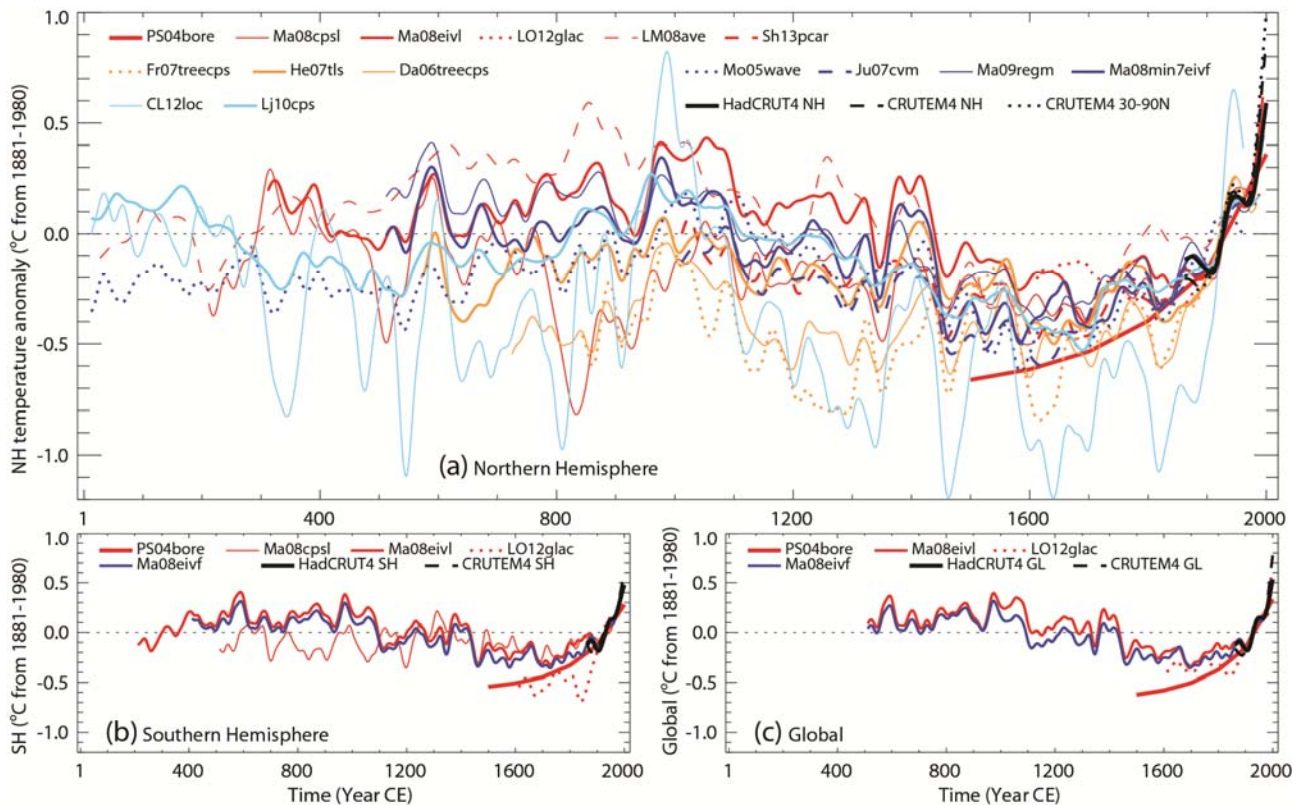

Figure 5.7: Reconstructed (a) Northern Hemisphere and (b) Southern Hemisphere, and (c) global annual temperatures during the last 2000 years. Individual reconstructions (see Appendix 5.A.1 for further information about each one) are shown as indicated in the legends, grouped by colour according to their spatial representation (red: land-only all latitudes; orange: land-only extra-tropical latitudes; light blue: land and sea extra-tropical latitudes; dark blue: land and sea all latitudes) and instrumental temperatures shown in black (HadCRUT4 land and sea, and CRUTEM4 land-only; Morice et al., 2012). All series represent anomalies ($^{\circ}\text{C}$) from the 1881–1980 mean (horizontal dashed line) and have been smoothed with a filter that reduces variations on timescales less than ~ 50 years.

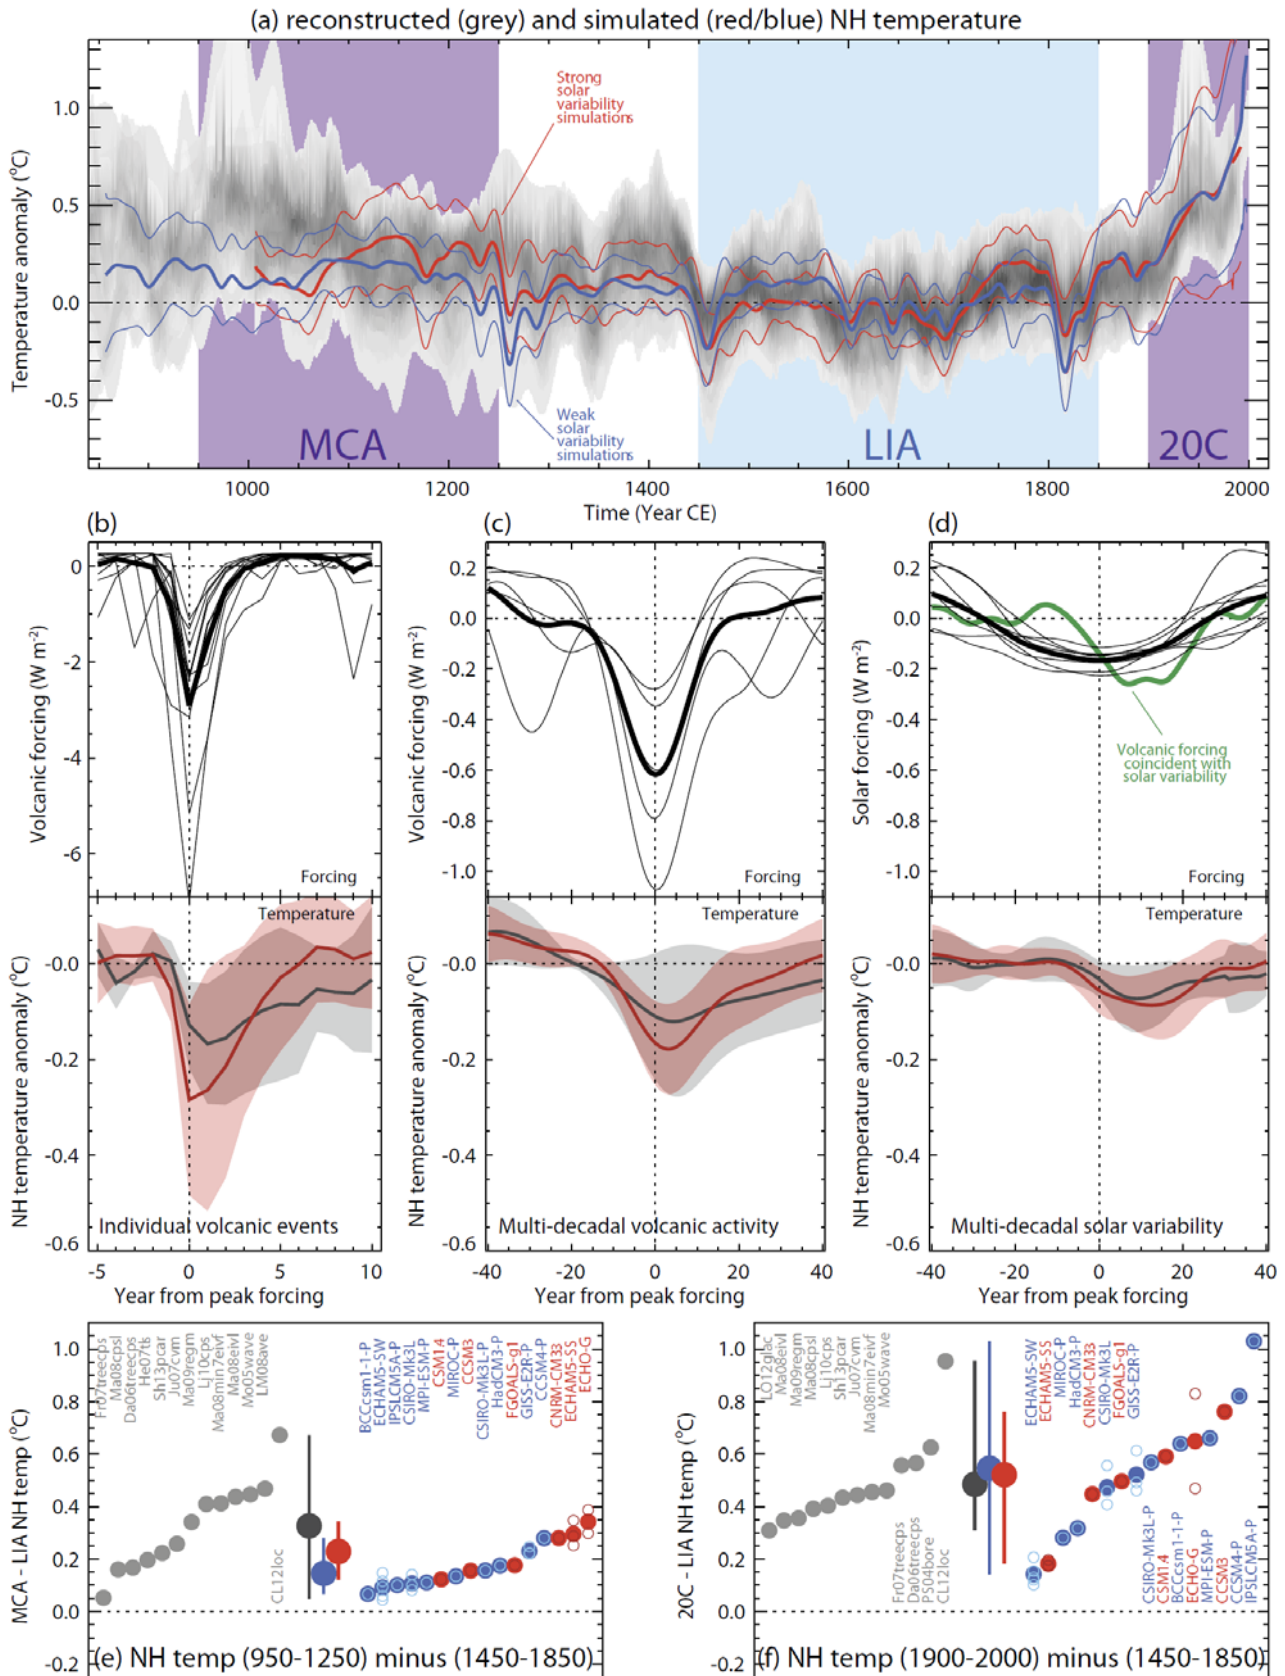

Figure 5.8: Comparisons of simulated and reconstructed NH temperature changes. (a) Changes over the last millennium. (b) Response to individual volcanic events. (c) Response to multidecadal periods of volcanic activity. (d) Response to multidecadal variations in solar activity. (e) Mean change from MCA to LIA. (f) Mean change from 20th century to LIA. Note that some reconstructions represent a smaller spatial domain than the full NH or a specific season, while annual temperatures for the full NH mean are shown for the simulations. (a) Simulations shown by coloured lines

(thick lines: multi-model-mean; thin lines: multi-model 90% range; red/blue lines: models forced by stronger/weaker solar variability, though other forcings and model sensitivities also differ between the red and blue groups); overlap of reconstructed temperatures shown by grey shading; all data are expressed as anomalies from their 1500–1850 mean and smoothed with a 30-year filter. Superposed composites (time segments from selected periods positioned so that the years with peak negative forcing are aligned) of the forcing and temperature response to: (b) 12 of the strongest individual volcanic forcing events after 1400 (the data shown are not smoothed); (c) multidecadal changes in volcanic activity; (d) multidecadal changes in solar irradiance. Upper panels show volcanic or solar forcing for the individual selected periods together with the composite mean (thick line); in (d), the composite mean of volcanic forcing (green) during the solar composite is also shown. Lower panels show the NH temperature composite means and 90% range of spread between simulations (red line, pink shading) or reconstructions (grey line and shading), with overlap indicated by darker shading. Mean NH temperature difference between (e) MCA (950–1250) and LIA (1450–1850) and (f) 20th century (1900–2000) and LIA, from reconstructions (grey), multi-reconstruction mean and range (dark grey), multi-model mean and range and individual simulations (red/blue for models forced by stronger/weaker solar variability). Where an ensemble of simulations is available from one model, the ensemble mean is shown in solid and the individual ensemble members by open circles. Results are sorted into ascending order and labelled. Reconstructions, models and further details are given in Appendix 5.A.1 and Tables 5.A.1 and 5.A.6.

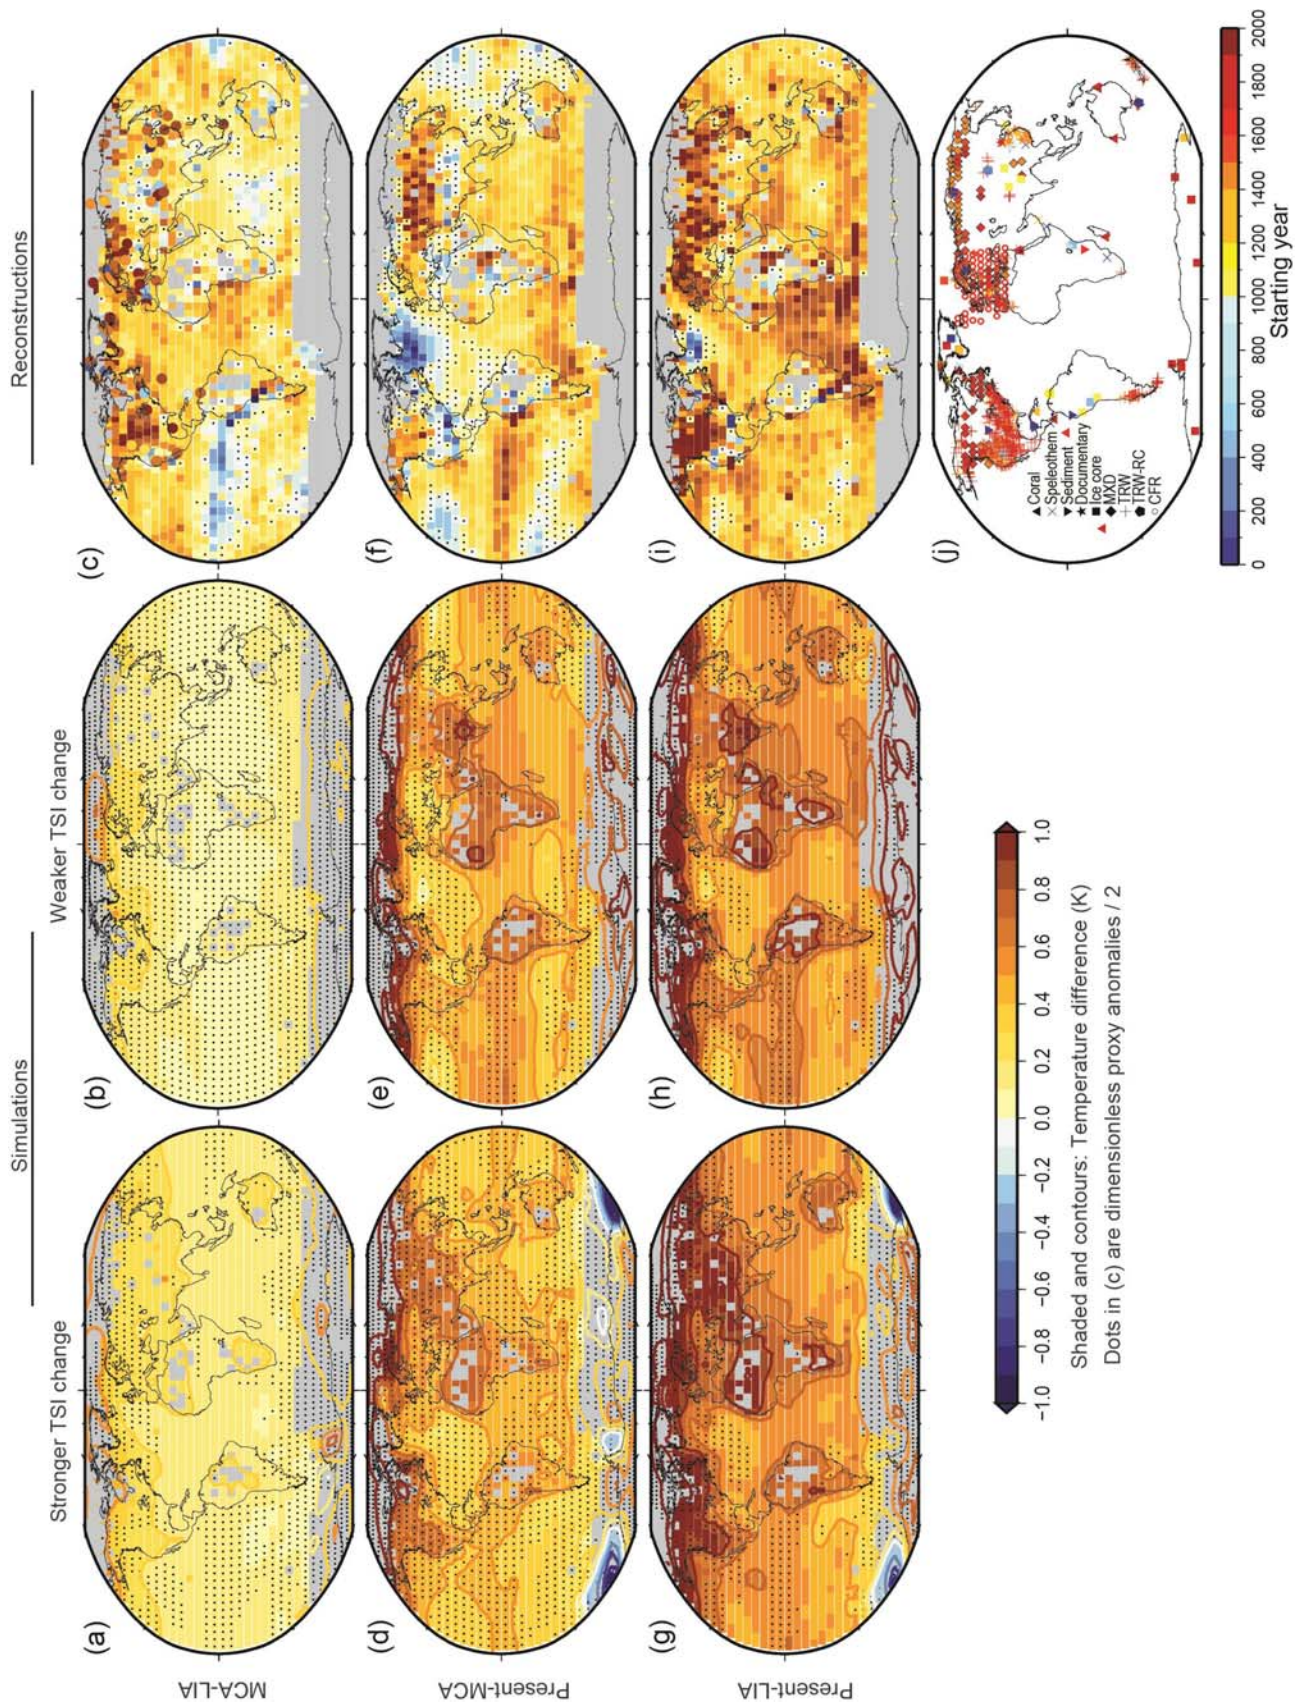

Figure 5.9: Simulated and reconstructed temperature changes for key periods in the last millennium. Annual temperature differences for: (a) to (c) MCA (950–1250) minus LIA (1450–1850); (d) to (f) present (1950–2000) minus MCA; (g) to (i) present minus LIA. Model temperature differences (left and middle columns) are average temperature changes in the ensemble of available model simulations of the last millennium, grouped into those using stronger (TSI change from the LMM to present >0.23%; left column; SS in Table 5.A.1) or weaker solar forcing changes (TSI change

from the LMM to present <0.1%; middle column; SW in Table 5.A.1). Right column panels (c, f, i) show differences (shading) for the Mann et al. (2009) field reconstruction. In (c), dots represent additionally proxy differences from Ljungqvist et al. (2012), scaled by 0.5 for display purposes. The distribution, type and temporal span of the input data used in the field reconstruction of Mann et al. (2009) are shown in (j); proxy types are included in the legend, acronyms stand for: tree-ring maximum latewood density (MXD); tree-ring width (TRW); regional TRW composite (TRW-RC); and multi-proxy climate field reconstruction (CFR). Dotted grid-cells indicate non-significant differences (<0.05 level) in reconstructed fields (right) or that <80% of the simulations showed significant changes of the same sign (left and middle). For simulations starting after 950, the period 1000–1250 was used to estimate MCA values. Grid-cells outside the domain of the Mann et al. (2009) reconstruction are shaded grey in the model panels to enable easier comparison, though contours (interval 0.2 K) illustrate model output over the complete global domain. Only simulations spanning the whole millennium and including at least solar, volcanic and greenhouse gas forcing have been used (Table 5.A.1): BCC-csm1-1 (1), CCSM3 (1), CCSM4 (1), CNRM-CM3.3, CSIRO-mk3L-1-2 (4), CSM1.4 (1), ECHAM5-MPIOM (8), ECHO-G (1), MPI-ESM-P (1), FGOALS-g1 (1), GISS-E2-R (3), HadCM3 (1), IPSL-CM5A-LR (1). Averages for each model are calculated first, to avoid models with multiple simulations having greater influence on the ensemble means shown here.

Figure 5.10: Relative changes in amplitude of the annual cycle of SST in Niño 3 region (average over 5°S–5°N and 150°W–90°W) (left) and in amplitude of interannual SST anomalies in the Niño 3.4 region (average over 5°S–5°N and 170°W–120°W) (right) simulated by an ensemble of climate model experiments in response to external forcing. Left: Multi-model average of relative changes (%) in amplitude of the mean seasonal cycle of Niño 3 SST for mid Holocene (MH) and LGM time-slice experiments and for freshwater perturbation experiments (Hosing) that lead to a weakening of the AMOC by more than 50%. Bars encompass the 25 and 75 percentiles, with the red horizontal lines indicating the median in the respective multi-model ensemble, red crosses are values in the upper and lower quartile of the distribution; Right: same as left, but for the SST anomalies in the Niño 3.4 region, representing ENSO variability. The MH ensemble includes 4 experiments performed by models participating in PMIP2 (FGOALS1.0g, IPSL-CM4, MIROC3.2 medres, CCSM3.0) and 7 experiments (mid-Holocene) performed by models participating in PMIP3/CMIP5 (CCSM4.0, CSIRO-Mk3-6-0, HadGEM2-CC, HadGEM2-ES, MIROC-ESM, MPI-ESM-P, MRI-CGCM3). The LGM ensemble includes 5 experiments performed by models participating in PMIP2 (FGOALS1.0g, IPSL-CM4, MIROC3.2 medres, CCSM3.0, HadCM3) and 5 experiments (LGM) performed by models participating in PMIP3/CMIP5 (CCSM4, GISS-E2-R, IPSL-CM5A-LR, MIROC-ESM, and MPI-ESM-P). The changes in response to MH and LGM forcing are computed with respect to the pre-industrial control simulations coordinated by PMIP2 and PMIP3/CMIP5. The results for Hosing are obtained from freshwater perturbation experiments conducted with CCSM2.0, CCSM3.0, HadCM3, ECHAM5-MPIOM, GFDL-CM2.1 (Timmermann et al., 2007), CSM1.4 (Bozbiyik et al., 2011) for pre-industrial or present-day conditions and with CCSM3 for glacial conditions (Merkel et al., 2010). The changes in response to fresh water forcing are computed with respect the portion of simulations when the AMOC is high.

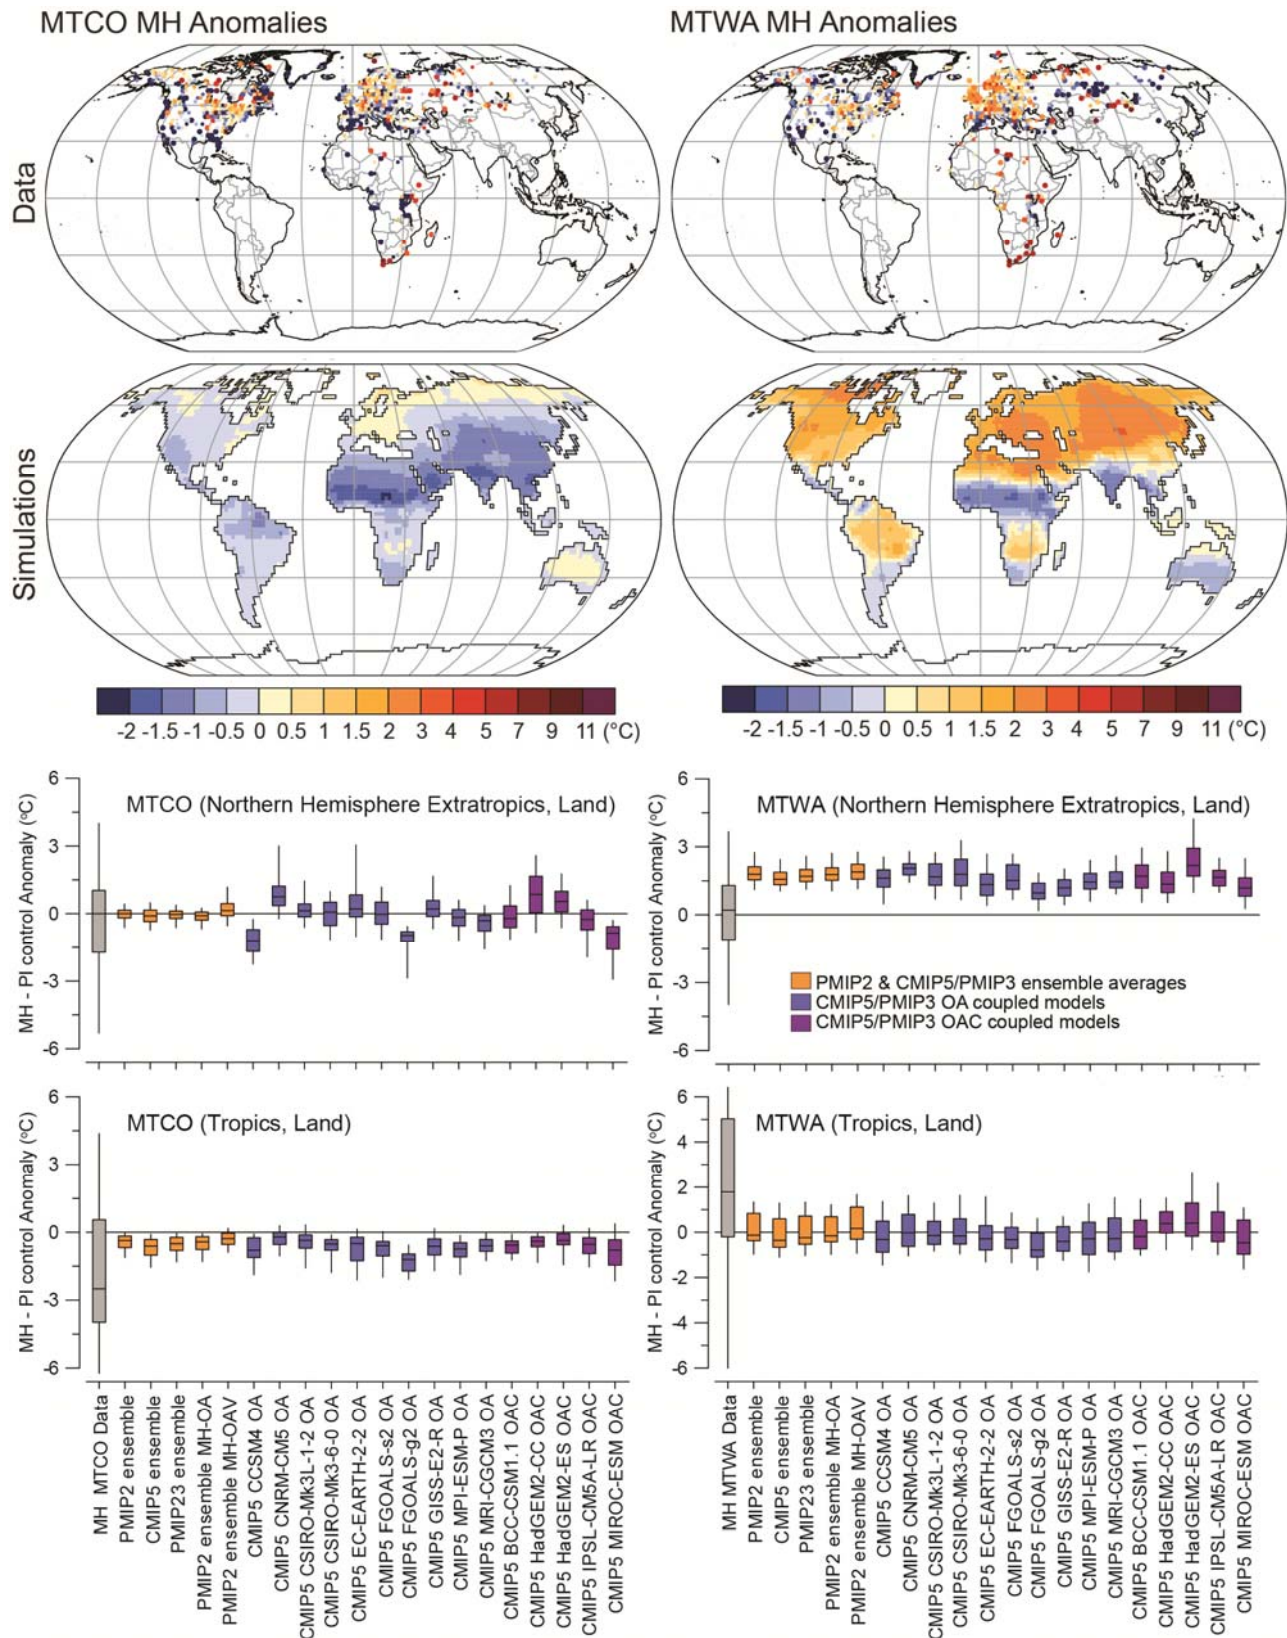

Figure 5.11: Model-data comparison of surface temperature anomalies for the mid-Holocene (6 ka). MTCO is the mean temperature of the coldest month; MTWA is the mean temperature of the warmest month. Top panels are pollen-based reconstructions of Bartlein et al., (2011) with anomalies defined as compared to modern, which varies among the records. The bulk of the records fall within the range of 5.5–6.5 ka, with only 3.5% falling outside this range. Middle panels are corresponding surface temperature anomalies simulated by the PMIP2 and PMIP3/CMIP5 models for 6 ka as compared to pre-industrial. Bottom panels contain boxplots for reconstructions (grey), for model ensembles and for the

individual CMIP5 models interpolated to the locations of the reconstructions. Included are OA (Ocean-Atmosphere), OAV (Ocean-Atmosphere-Vegetation), and OAC (Ocean-Atmosphere-Carbon cycle) models. The boxes are drawn using the 25th, 50th and 75th percentiles (bottom, middle and top of the box, respectively), and whiskers extend to the 5th and 95th percentiles of data or model results within each area. The northern extratropics are defined as 30°N–90°N and the tropics as 30°S–30°N. For additional model-data comparisons for the mid-Holocene, see Section 9.4.1.4 and Figures 9.11 and 9.12.

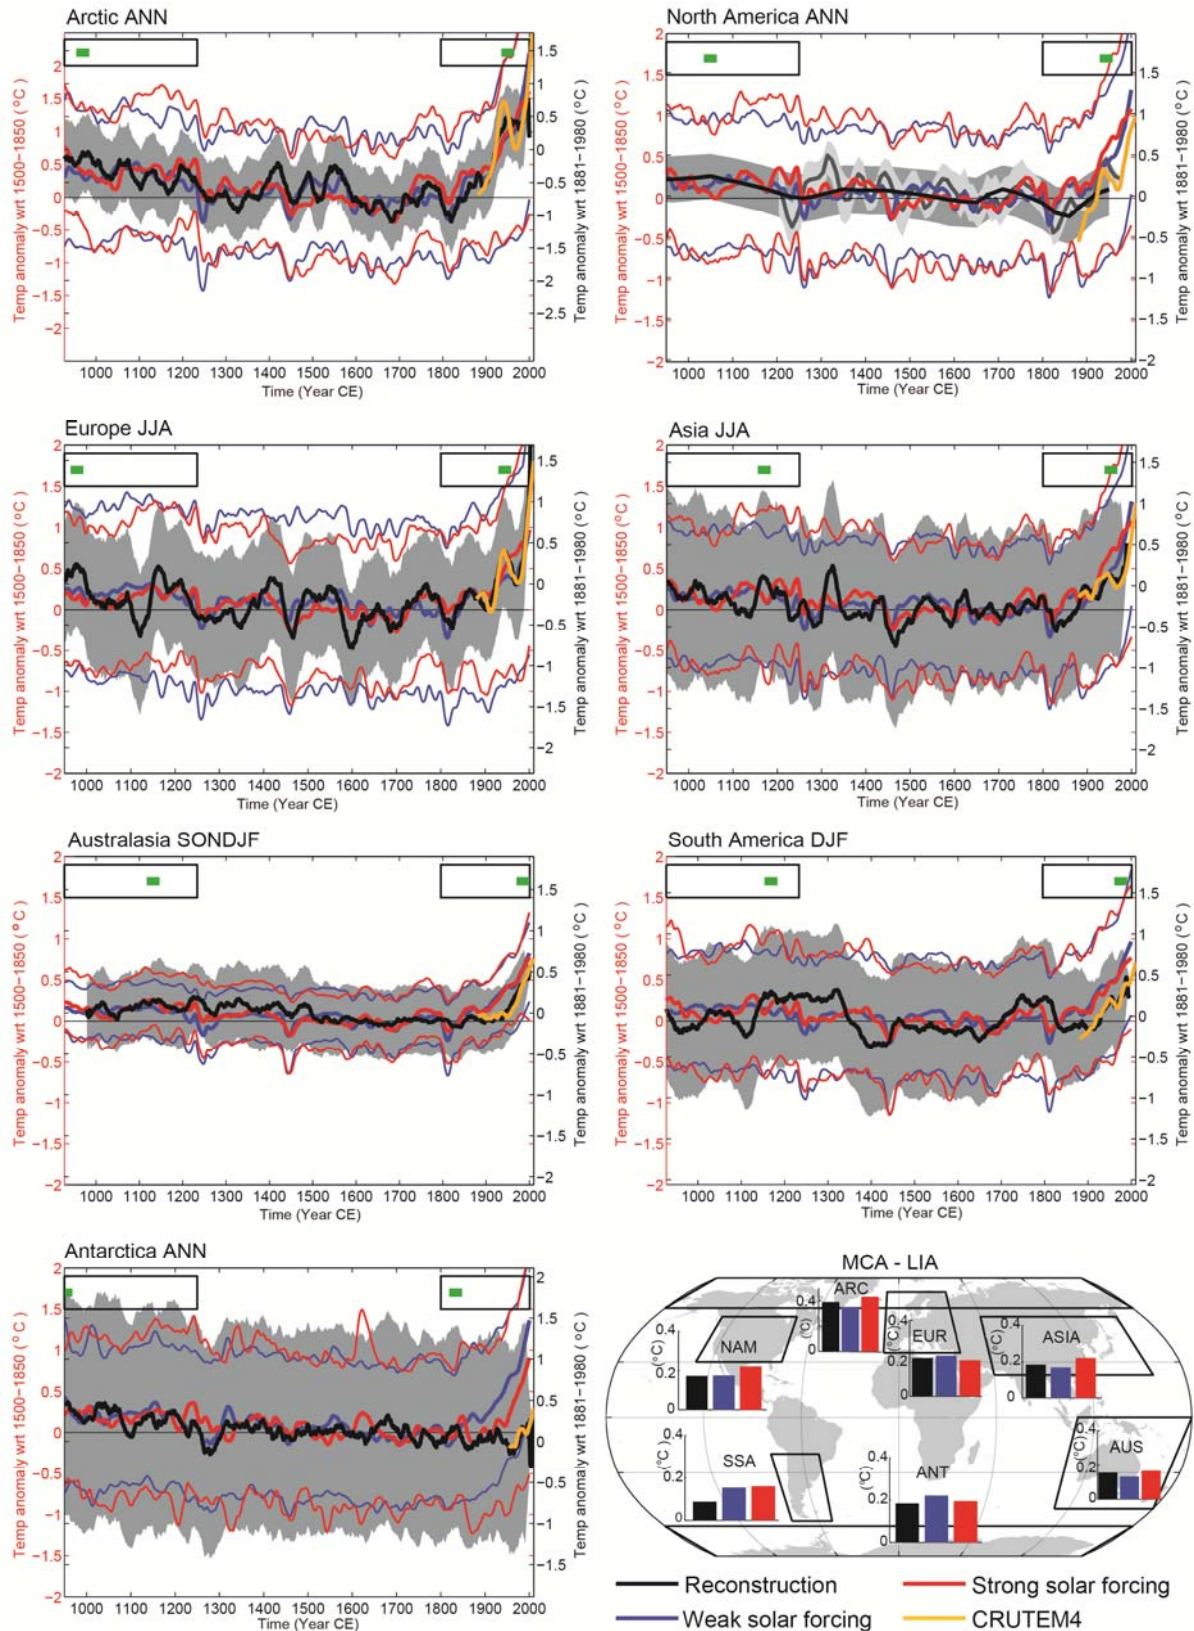

Figure 5.12: Regional temperature reconstructions, comparison with model simulations over the past millennium (950–2010). Temperature anomalies (thick black line), and uncertainty estimated provided by each individual reconstruction (grey envelope). Uncertainties: Arctic: 90% confidence bands. Antarctica, Australasia, North American pollen and South America: ± 2 standard deviation. Asia: ± 2 root mean square error. Europe: 95% confidence bands. North American trees: upper/lower 5% bootstrap bounds. Simulations are separated into 2 groups: High solar forcing (red

thick line), and weak solar forcing (blue thick line). For each model subgroup, uncertainty is shown as 1.645 times sigma level (light red and blue lines). For comparison with instrumental record, the CRUTEM4 dataset is shown (yellow line). Green bars in rectangles on top of each panel indicate the 30 warmest years in the 950–1250 period (left rectangle) and 1800–2010 period (right rectangle). All lines are smoothed by applying a 30 year moving average. Map at bottom right shows the individual regions for each reconstruction, and in bars the MCA (950-1250) – LIA (1450-1850) differences over those regions. Reconstructions: from PAGES 2k Consortium (2013). Models used: simulations with strong solar forcing (mostly pre-PMIP3 simulations): CCSM3 (1), CNRM-CM3.3 (1), CSM1.4 (1), CSIRO-MK3L-1-2 (3), ECHAM5/MPIOM (3), ECHO-G (1) IPSLCM4 (1), FGOALS-g1 (1). Simulations with weak solar forcing (mostly PMIP3/CMIP5 simulations): BCC-csm1-1 (1), CCSM4 (1), CSIRO-MK3L-1-2 (1), GISS-E2-R (3, ensemble members 121, 124, 127), HadCM3 (1), MPI-ESM, ECHAM5/MPIOM (5), IPSL-CM5A-LR (1). In parenthesis are the number of simulations used for each model. All simulations are treated individually, in the timeseries as well as in the MCA–LIA bars. More information about forcings used in simulations and corresponding references are given in Table 5.A.1.

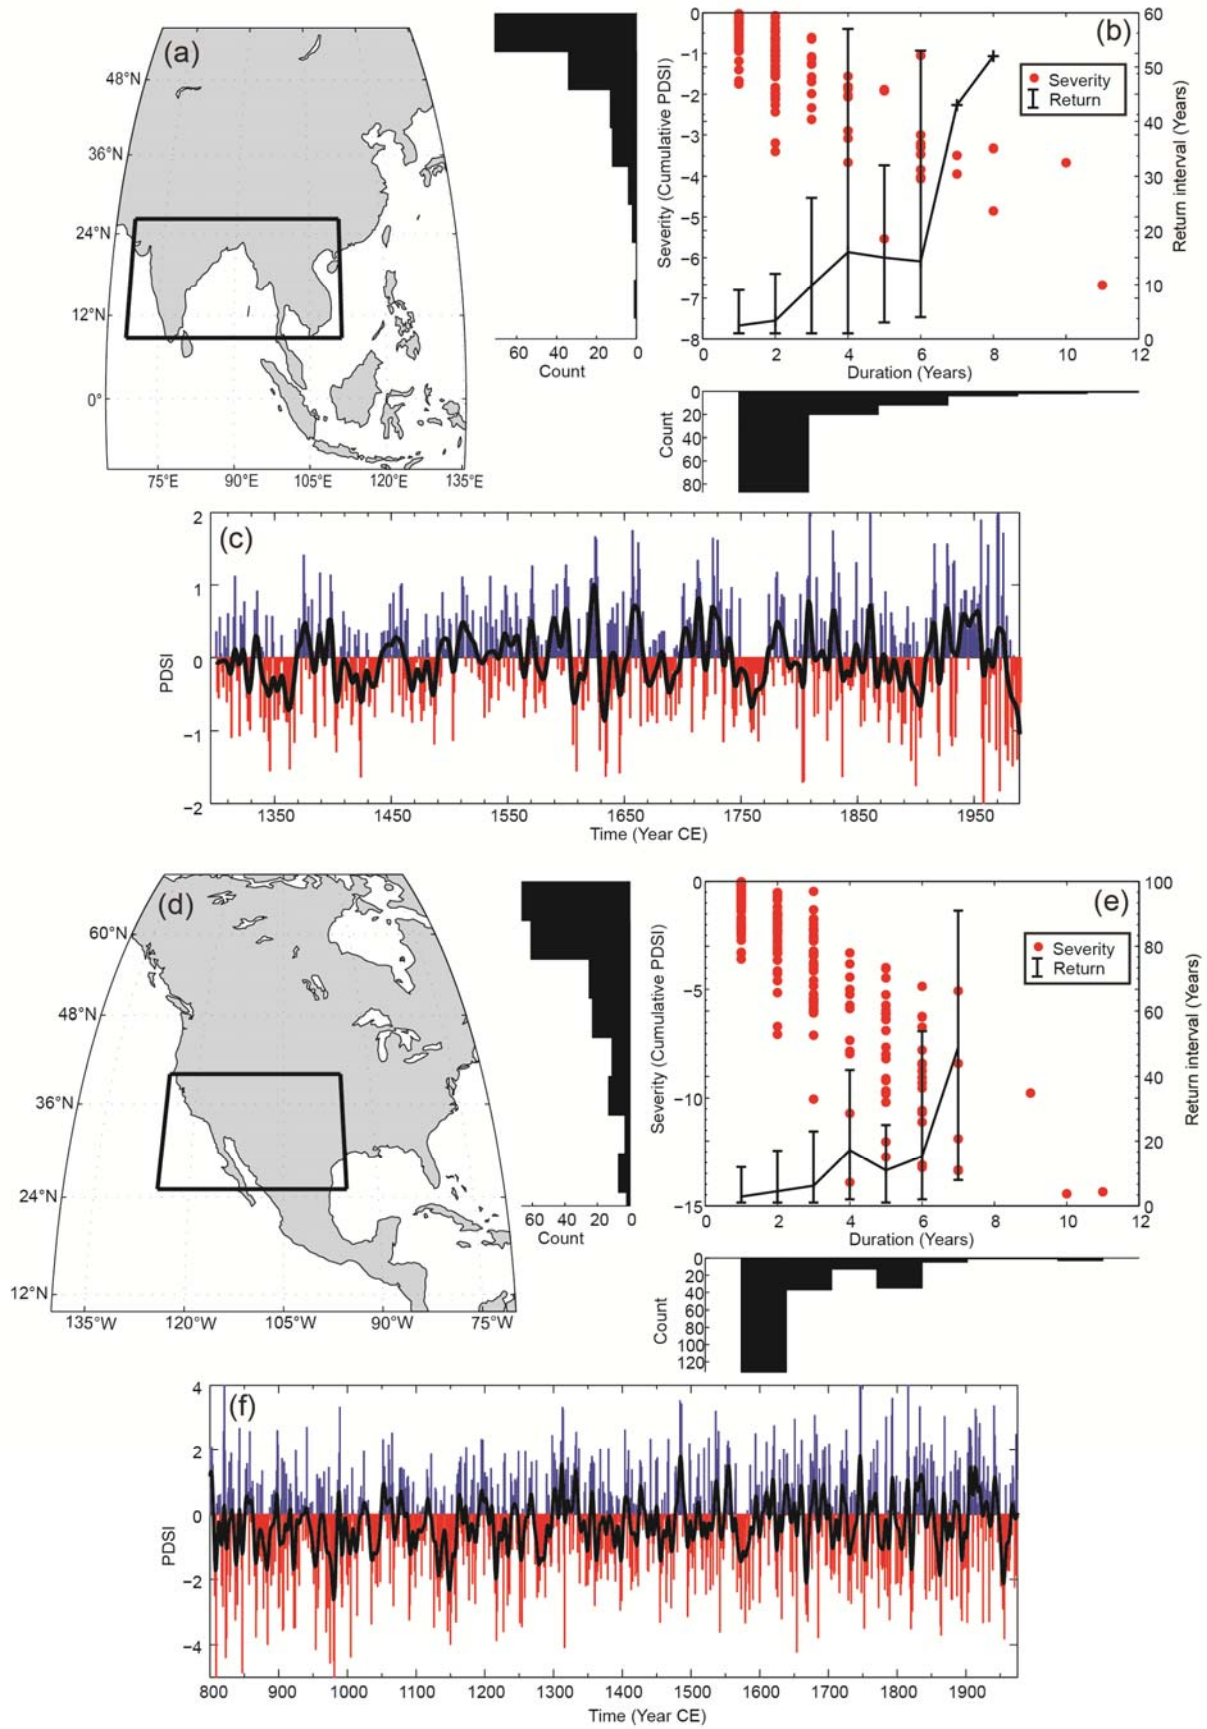

Figure 5.13: Severity, duration, and frequency of droughts in the Monsoon Asia (Cook et al., 2010b) and North American (Cook et al., 2004) Drought Atlases. The box in (a) and (d) indicates the region over which the tree-ring reconstructed Palmer Drought Severity Index (PDSI) values have been averaged to form the regional mean time series

shown in (c) and (f), respectively. Solid black lines in (c) and (f) are a 9-year Gaussian smooth on the annual data shown by the red and blue bars. The covariance of drought (PDSI <0) duration and cumulative severity for each region is shown in panels (b) and (e) by the red circles (corresponding to the left y-axes), along with the respective marginal frequency histograms for each quantity. Not shown in b) is an outlier with an apparent duration of 24 years, corresponding to the 'Strange Parallels' drought identified in Cook et al. (2010b). Return intervals for droughts of given durations are shown in the same panels and are estimated as the mean interval between their occurrence, with the minimum and maximum reconstructed intervals indicated (corresponding to the right y-axes, shown as connected lines and their corresponding range). No range is given if there is only a single observation of a drought of that duration. The period of analysis is restricted by the availability of tree-ring data to the period 1300–1989 for Monsoon Asia, following Cook et al. (2010a), and from 800 to 1978 for southwestern North America, following Cook et al. (2004).

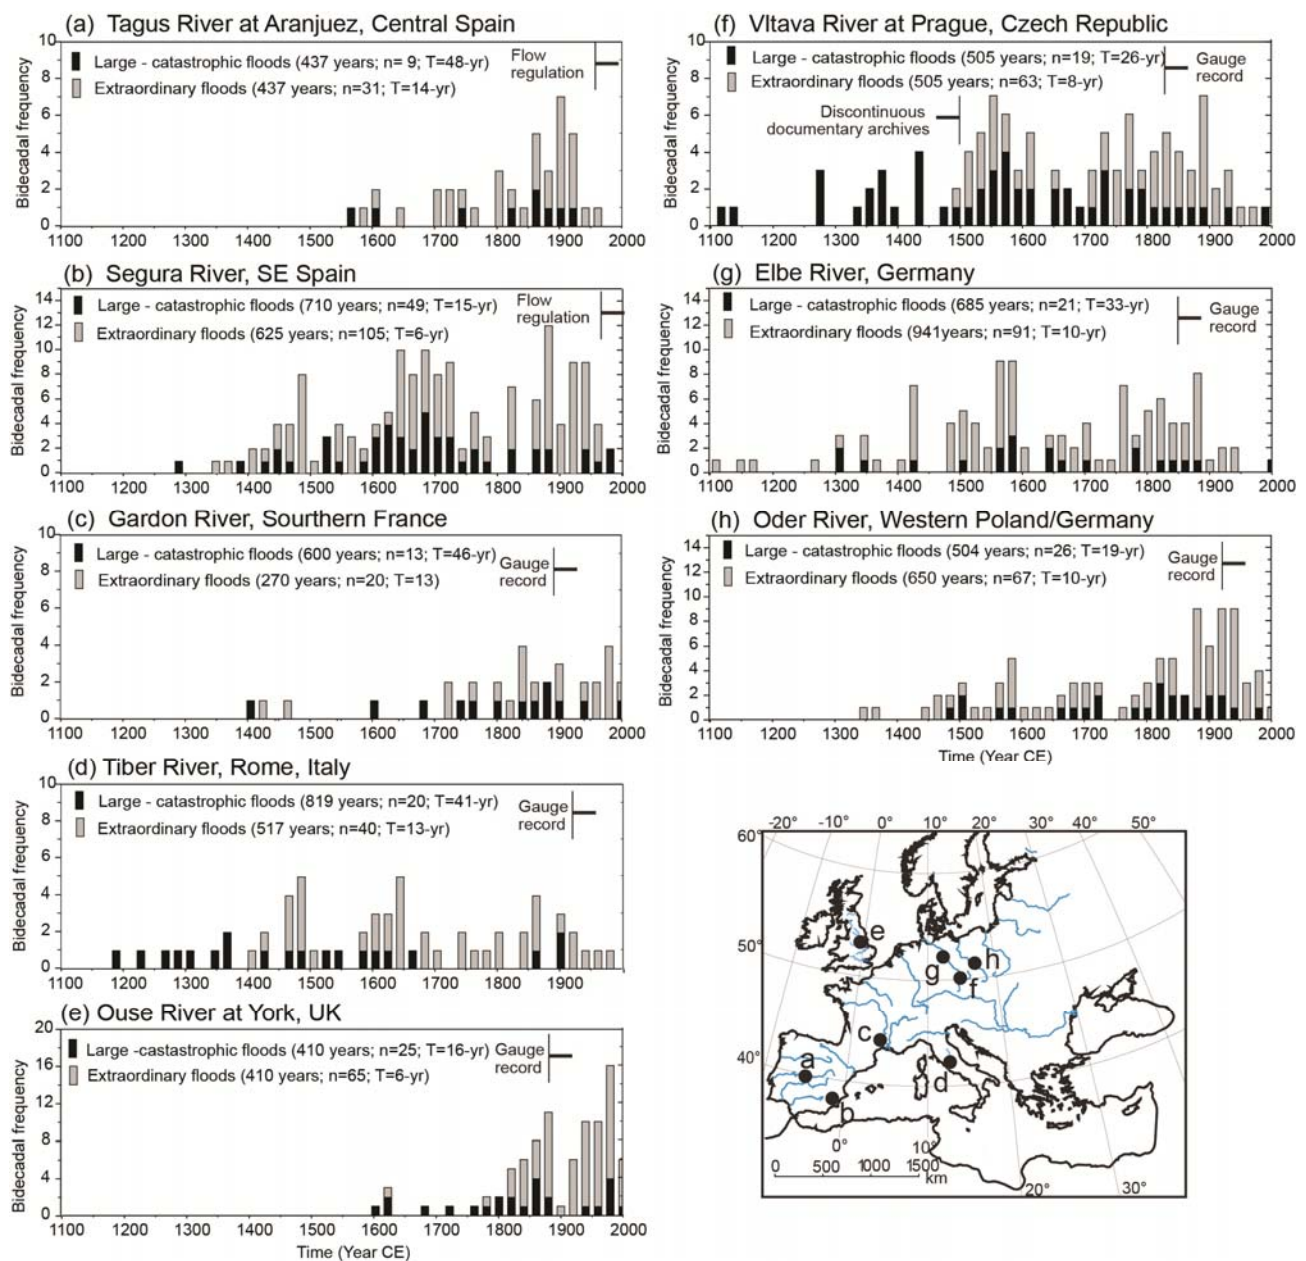

Figure 5.14: Flood frequency from paleofloods, historical and instrumental records in selected European rivers. Depicted is the number of floods exceeding a particular discharge threshold or flood height over periods of 20 years (bidecadal). Flood categories include rare or catastrophic floods (CAT) associated with high flood discharge or severe damages, and extraordinary floods (EXT) causing inundation of the floodplain with moderate-to-minor damages. Legend at each panel indicates for each category the period of record in years, number of floods (n) over the period, and the average occurrence interval (T in years). (a) Tagus River combined paleoflood, historical and instrumental flood records from Aranjuez and Toledo with thresholds of $100\text{--}400\text{ m}^3\text{ s}^{-1}$ (EXT) and $>400\text{ m}^3\text{ s}^{-1}$ (CAT) (data from Benito et al., 2003a; 2003b). (b) Segura River Basin (SE Spain) documentary and instrumental records at Murcia (Barriendos and Rodrigo, 2006; Machado et al., 2011). (c) Gardon River combined discharges from paleofloods at La Baume (Sheffer et al., 2008), documented floods (since the 15th century) and historical and daily water stage readings at Anduze (1741–2005; Neppel et al., 2010). Discharge thresholds referred to Anduze are $1000\text{--}3000\text{ m}^3\text{ s}^{-1}$ (EXT), $>3000\text{ m}^3\text{ s}^{-1}$ (CAT). At least five floods larger than the 2002 flood (the largest in the gauged record) occurred in the period 1400–1800 (Sheffer et al., 2008). (d) Tiber River floods in Rome from observed historical stages (since 1100; Camuffo and Enzi, 1996; Calenda et al., 2005) and continuous stage readings (1870 to present) at the Ripetta landing (Calenda et al., 2005). Discharge thresholds set at $2300\text{--}2900\text{ m}^3\text{ s}^{-1}$ (EXT) and $>2900\text{ m}^3\text{ s}^{-1}$ (CAT; $>17\text{ m}$ stage at Ripetta). Recent flooding is difficult to evaluate in context due to river regulation structures. (e) River Ouse at York combined documentary and instrumental flood record (Macdonald and Black, 2010). Discharge thresholds for large floods were set at $500\text{ m}^3\text{ s}^{-1}$ (CAT) and $350\text{--}500\text{ m}^3\text{ s}^{-1}$ (EXT). (f) Vltava River combined documentary and instrumental flood record at Prague (Brázdil et al., 2005) discharge thresholds: CAT, flood index 2 and 3 or discharge $>2900\text{ m}^3\text{ s}^{-1}$; EXT flood index 1 or

discharge 2000–2900 m³ s⁻¹. (g) Elbe River combined documentary and instrumental flood record (Mudelsee et al., 2003). Classes refer to Mudelsee et al. (2003) strong (EXT) and exceptionally strong (CAT) flooding. (h) Oder River combined documentary and instrumental flood record (Mudelsee et al., 2003). The map shows the location of rivers used in the flood frequency plots. Note that flood frequencies obtained from historical sources may be down biased in the early part of the reported periods owing to document loss.

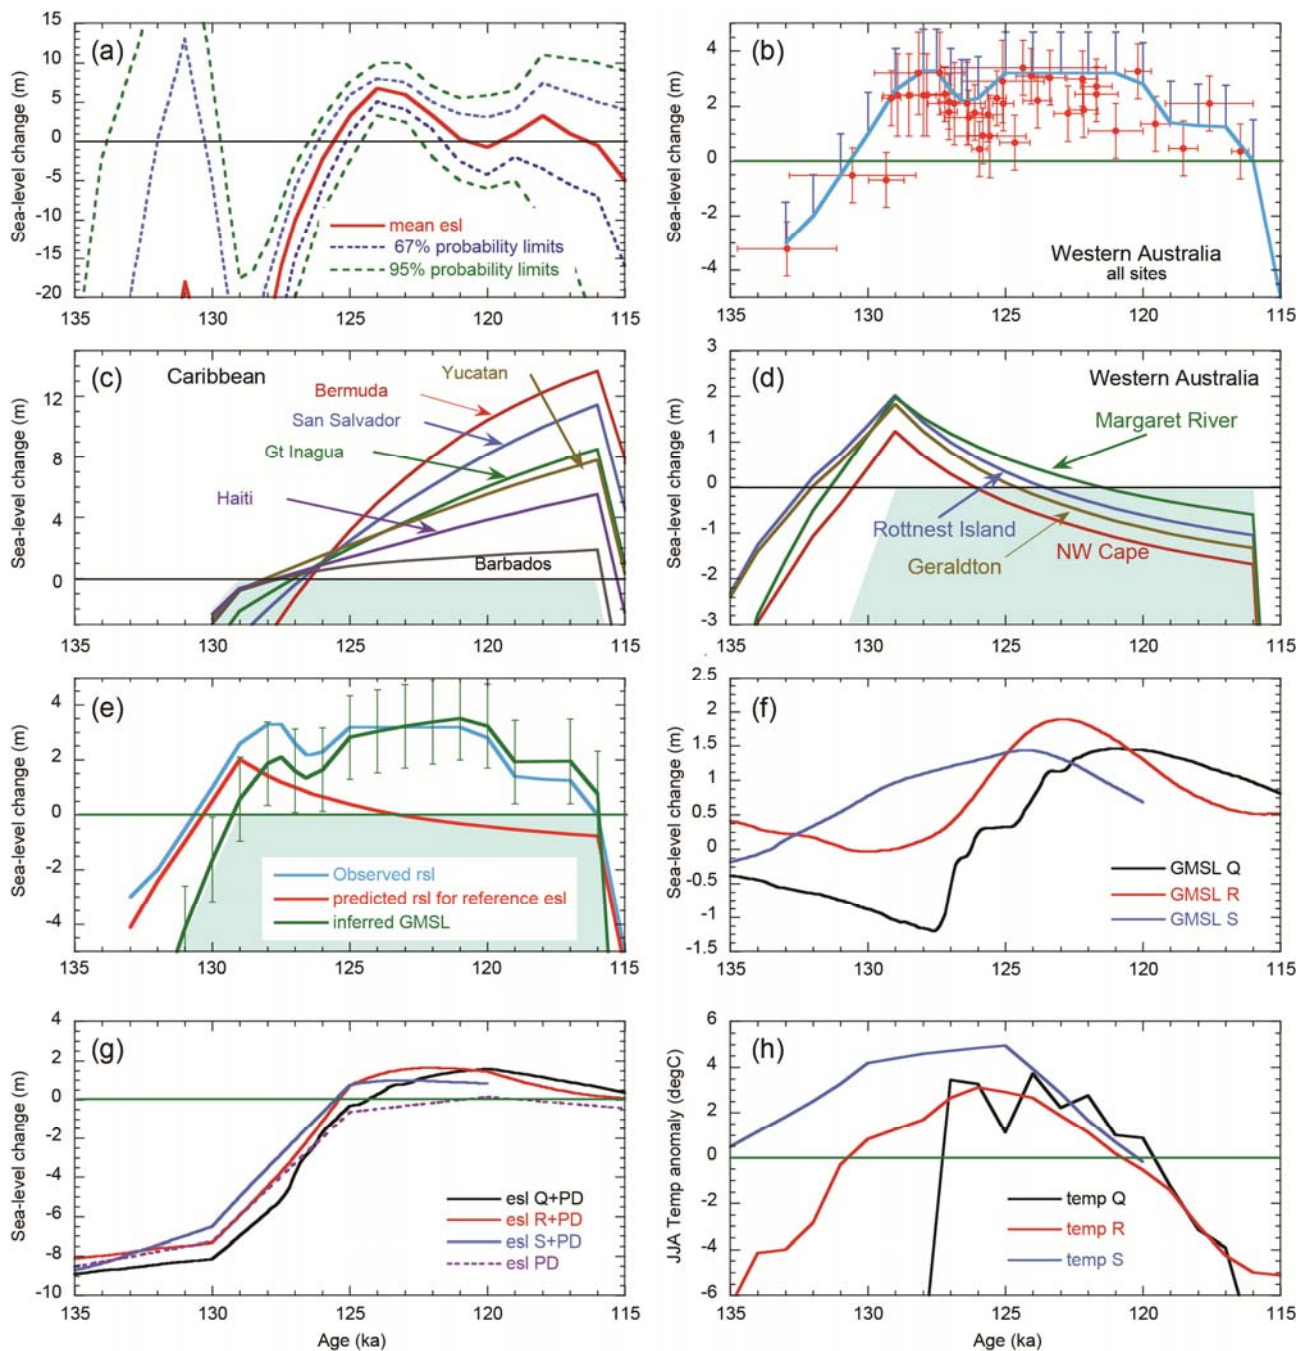

Figure 5.15: Sea level during the Last Interglacial period. (a) Proxy-derived estimate of global mean sea level anomaly from Kopp et al. (2013). Mean GMSL (red line), 67% confidence limits (blue dashed lines) and 95% confidence limits (green dashed lines). The chronology is based on open-system U/Th dates. (b) Local LIG relative sea level reconstructions from Western Australia based on in-situ coral elevations (red) that pass diagenetic screening (Dutton and Lambeck, 2012). Age error bars correspond to 2 standard deviation uncertainties. All elevations have been normalised to the upper growth limit of corals corresponding to mean low water spring or mean low sea level. The blue line indicates the simplest interpretation of local sea level consistent with reef stratigraphy and should be considered as lower limits by an amount indicated by the blue upper limit error bars. The chronology is based on closed system U/Th dates. (c) Predicted sea levels for selected sites in the Caribbean and North Atlantic in the absence of tectonics with the assumption that ice volumes during the interval from 129–116 ka are equal to those of today (Lambeck et al., 2012) illustrating the spatial variability expected across the region due to glacio-isostatic effects of primarily the MIS-6 and MIS-2 deglaciations (see also Raymo and Mitrovica, 2012). The reference ice-volume model for the LIG interval (blue shaded), earth rheology and ice sheet parameters are based on rebound analyses from different regions spanning the interval from Marine Isotope Stage 6 to the present (c.f. Lambeck et al., 2006). LIG sea level observations from these sites contain information on these ice histories and on GMSL. (d) Same as (c) but for different sites along the Western Australia coast contributing to the data set in (b). The dependence on details of the ice sheet and on Earth-model

parameters is less important at these sites than for those in (c). Thus data from these locations, assuming tectonic stability, is more appropriate for estimating GMSL. (e) The Western Australian reconstructed evidence (blue) from (b), compared with the model-predicted result (red) for a reference site midway between the northern and southern most localities. The difference between the reconstructed and predicted functions provides an estimate of GMSL (green). Uncertainties in this estimate (67% confidence limits) include the observational uncertainties from (b) and model uncertainties (see e.g., Lambeck et al., 2004a, for a treatment of model errors). (f) Simulated contribution of GIS to GMSL change (black, Q, Quiquet et al. (2013); red, R, Robinson et al. (2011); blue, S, Stone et al. (2013), The Q, R, S correspond to the labels in Figure 5.16). (g) Simulated total GMSL contribution from the GIS (Q, R, S as in panel (f)) and the Antarctic ice sheet contribution (PD) according to Pollard and DeConto (2009). (h) Central Greenland surface-air temperature anomalies for summer (June–August, JJA) used for ice sheet simulations displayed in panel (f) and in Figure 5.16. Anomalies in all panels are calculated relative to present.

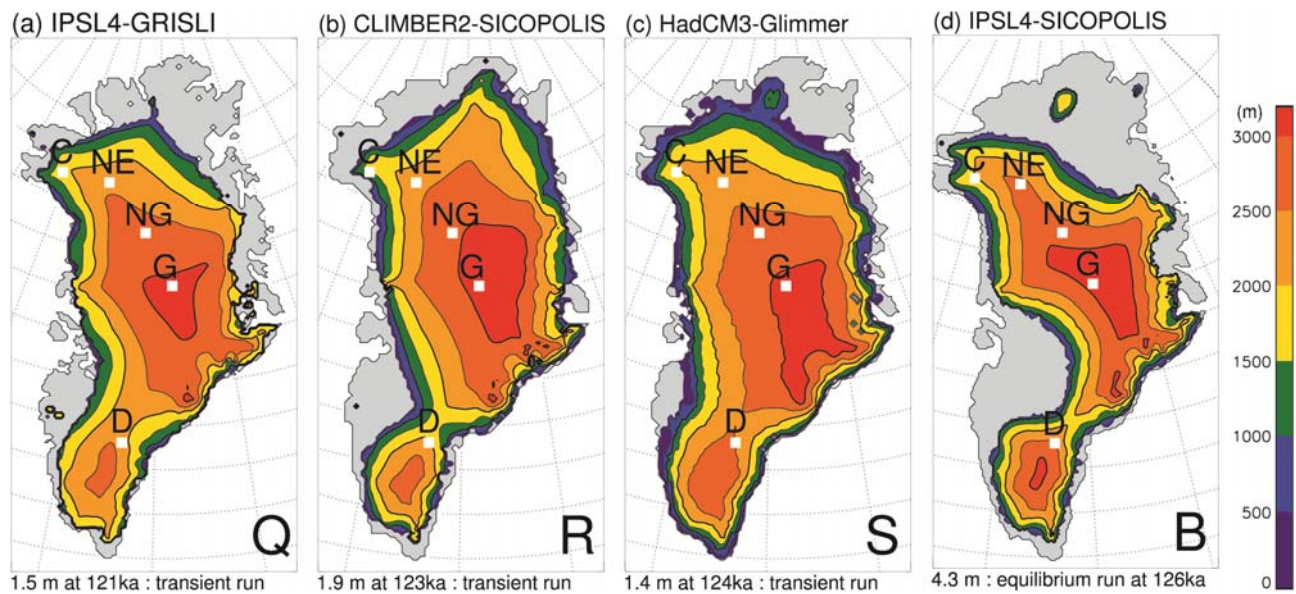

Figure 5.16: Simulated GIS elevation at the LIG in transient (Q, R, S) and constant-forcing experiments (B). (Q) GRISLI ice sheet model with transient climate forcing derived from IPSL simulations and paleoclimate reconstructions (Quiquet et al., 2013). (R) Simulation, most consistent with independent evidence from ice cores, from ensemble runs SICOPOLIS ice sheet model driven by transient LIG climate simulations downscaled from CLIMBER2 with the regional model REMBO (Robinson et al., 2011). (S) As R but from ensemble simulations with the Glimmer ice sheet model forced with transient climate forcing from 135 to 120 ka with HadCM3 (Stone et al., 2013). (B) SICOPOLIS ice sheet model forced with a constant Eemian climate simulation of IPSL (at 126 ka), running for 6000 years starting from fully glaciated present-day GIS (Born and Nisancioglu, 2012). White squares in each panel show the locations of ice core sites: GRIP/GISP from the summit (G), NGRIP (NG), NEEM (NE), Camp Century (C), and Dye3 (D). For ice sheet simulations using transient climate forcing, the minimum in ice volume is illustrated. All panels use original model resolution and grids. Below each panel, maximum contribution to global mean sea level rise and time of minimum ice volume are denoted together with information on experimental design (either "transient" run of the Interglacial period starting from the former glacial or "equilibrium" run of a time slice at the peak interglacial). The differences in model outputs regarding timing and ice elevations result from different methodologies (e.g., transient climate change or equilibrium climate, with the latter assumption leading to the highest estimate of the four models), melt schemes (van de Berg et al., 2011), and the reference climate input (Quiquet et al., 2013).

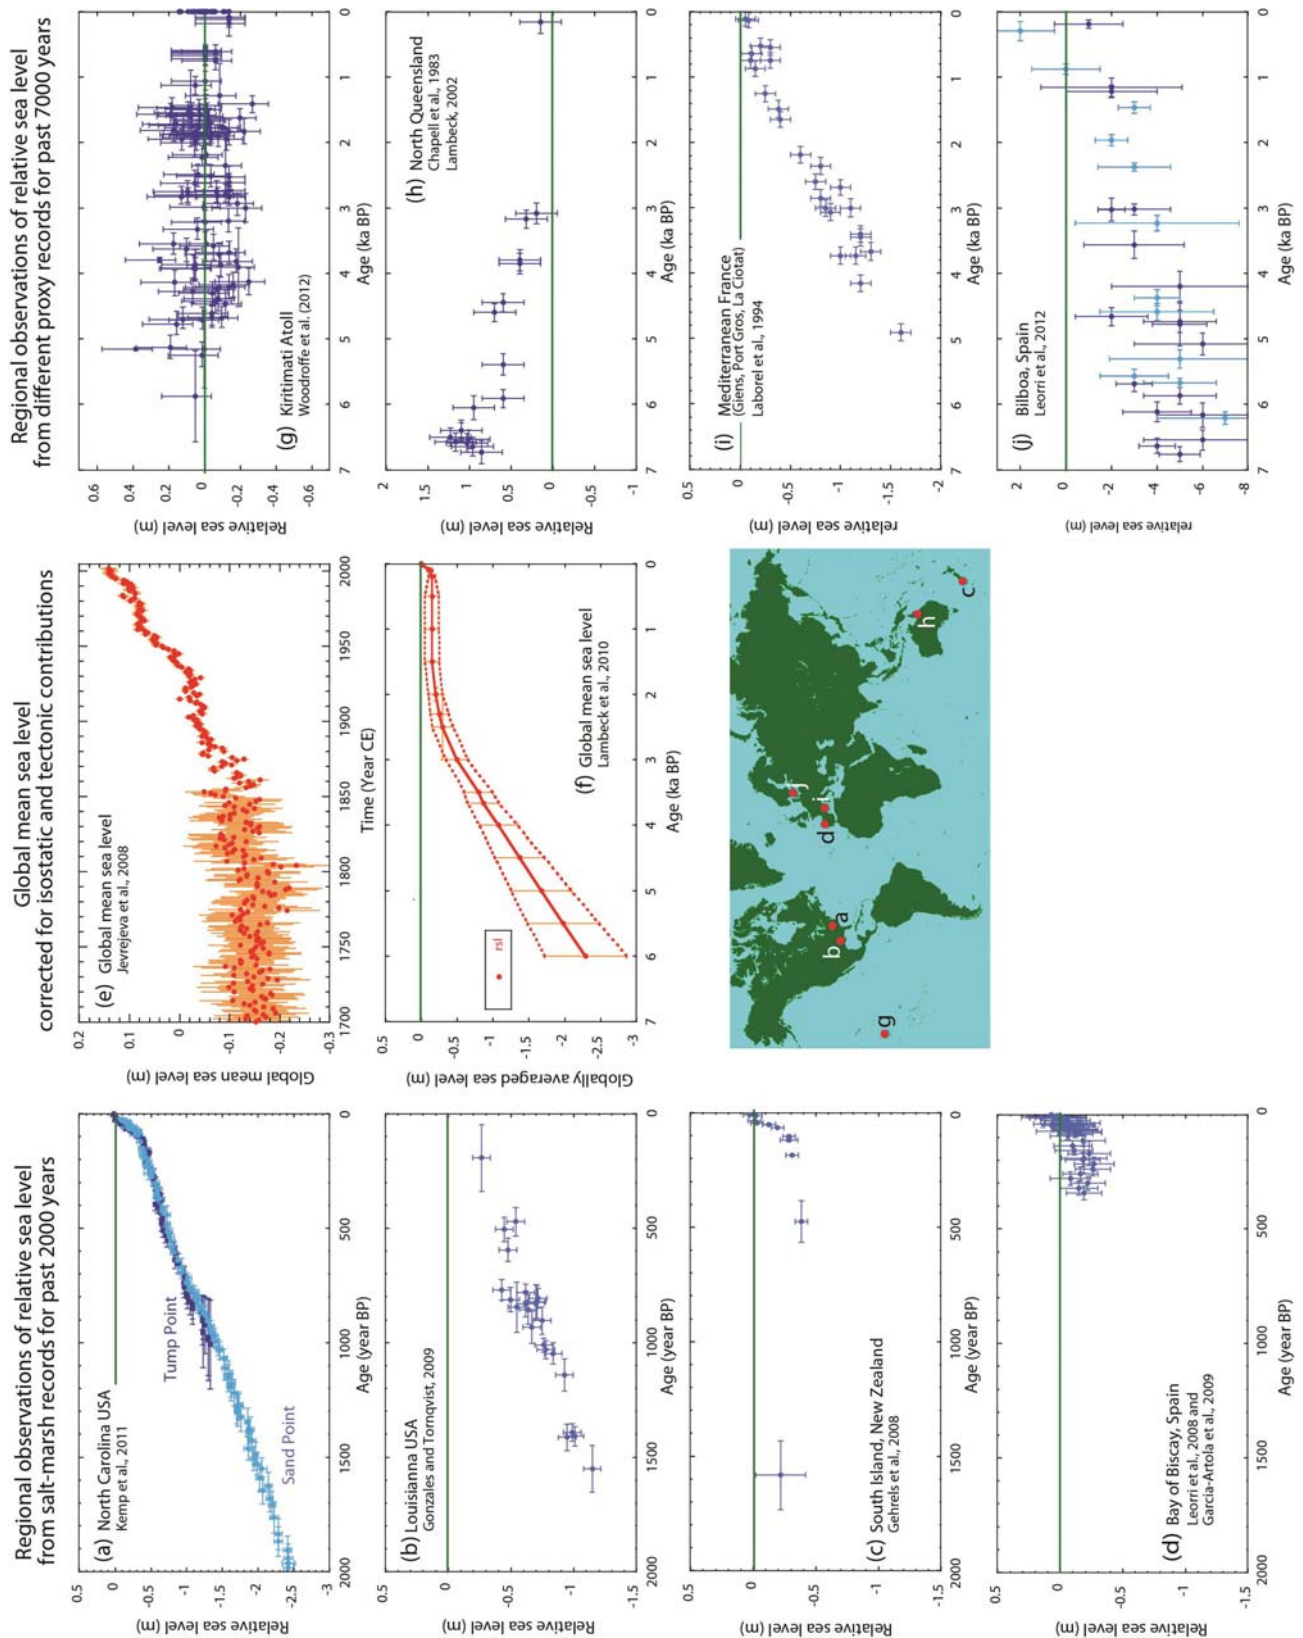

Figure 5.17: Observational evidence for sea level change in the recent and late Holocene. Left panels (a-d): High-resolution, relative sea level results from salt-marsh data at representative sites, without corrections for glacial isostatic movement of land and sea surfaces. Locations are given on the map. The North Carolina (a) result is based on two nearby locations, Tump Point (dark blue) and Sand Point (light blue). They are representative of other North American Atlantic coast locations (e.g., b; Kemp et al., 2011). The rate of change occurring late in the 19th century are seen in all high resolution salt-marsh records—e.g., in New Zealand (c) (Gehrels et al., 2008; Gehrels and Woodworth, 2013) and in Spain (d) (Leorri et al., 2008; García-Artola et al., 2009)—that extend into modern time and is consistent with

Roman archaeological evidence (Lambeck et al., 2004b). The oscillation in sea level seen in the North Carolina record at about 1000 years ago occurs in some (González and Törnqvist, 2009) but not all records (cf. Gehrels et al., 2011; Kemp et al., 2011). Right hand side panels (g-j): Observational evidence for sea level change from lower resolution but longer period records. All records are uncorrected for isostatic effects resulting in spatially variable near-linear trend in sea level over the 7000 year period. The Kiritimati record (Christmas Island) (g) consists of coral microatoll elevations whose fossil elevations are with respect to the growth position of living microatolls (Woodroffe et al., 2012). The North Queensland record (h) is also based on microatoll evidence from several sites on Orpheus Island (Chappell, 1983; Lambeck et al., 2002a). The data from Mediterranean France (i) is based on biological indicators (Laborel et al., 1994) restricted to three nearby locations between which differential isostatic effects are less than the observational errors (Lambeck and Bard, 2000). The Spanish record (j) from estuarine sedimentary deposits is for two nearby localities; Bilboa (dark blue) and Urdaibai (light blue) (Leorri et al., 2012). The two global records (central panels) are estimates of change in global mean sea level from (i) the instrumental record (Jevrejeva et al., 2008) that overlaps the salt-marsh records, and (j) from a range of geological and archaeological indicators from different localities around the world (Lambeck et al., 2010), with the contributing records corrected individually for the isostatic effects at each location.

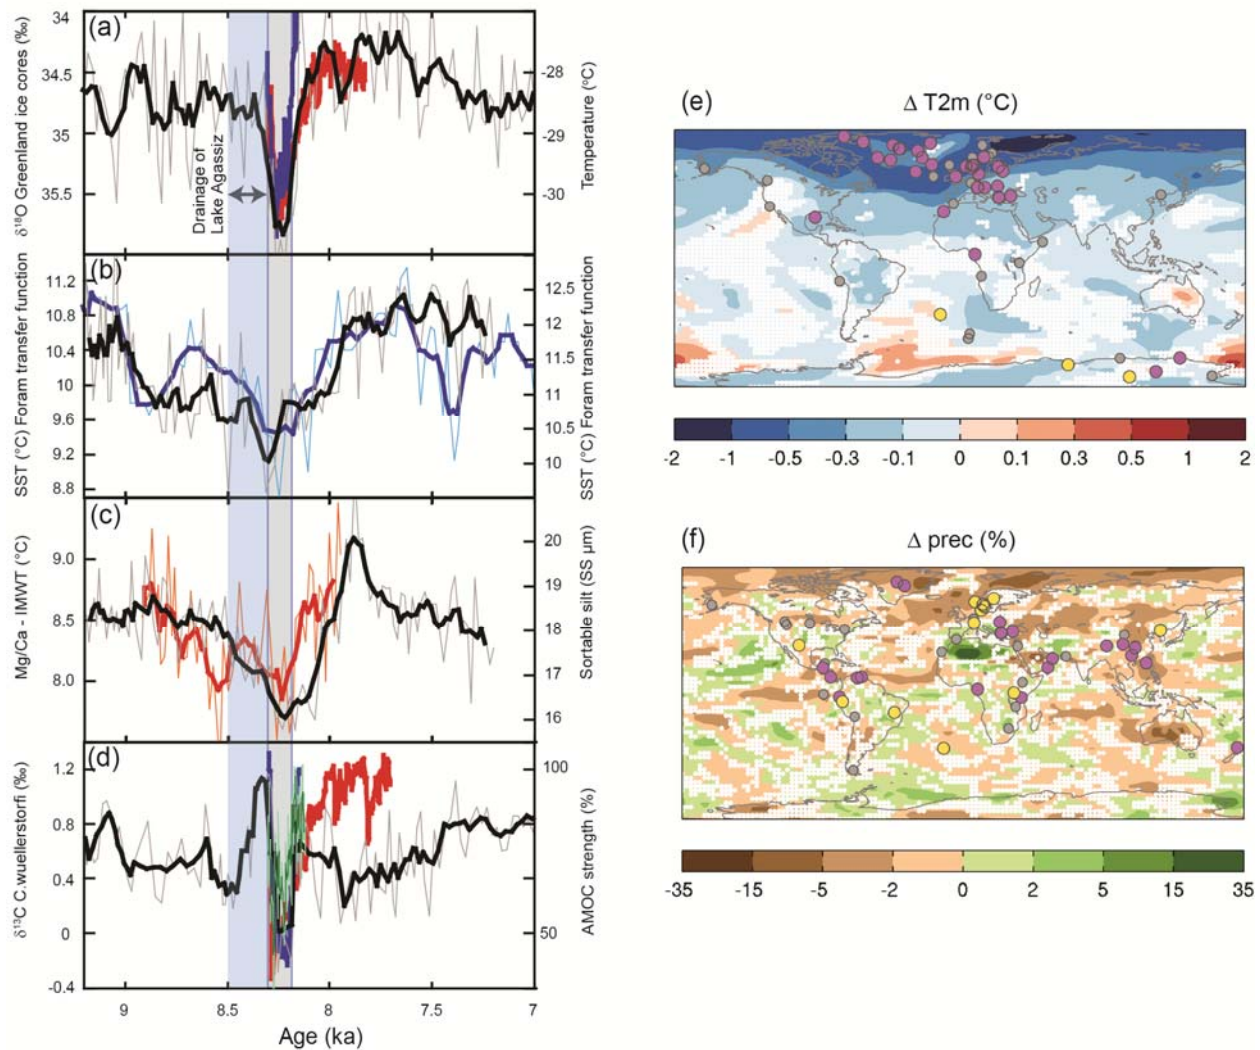

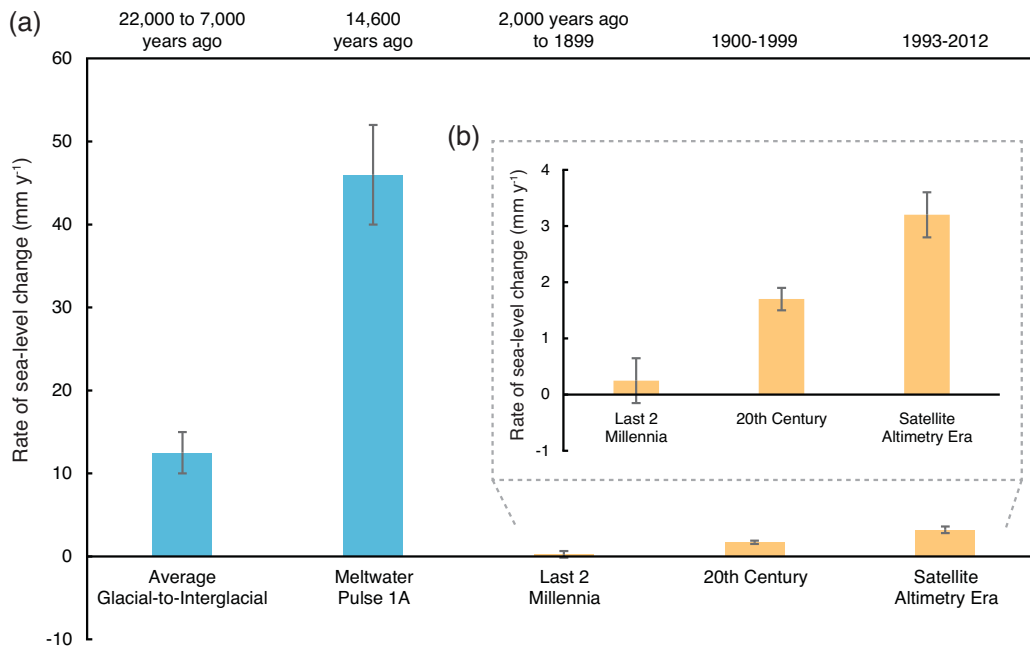

Figure 5.18: Compilation of selected paleoenvironmental and climate model data for the abrupt Holocene cold event at 8.2 ka, documenting temperature and ocean-circulation changes around the event and the spatial extent of climate anomalies following the event. Published age constraints for the period of release of freshwater from glacier lakes Agassiz and Ojibway are bracketed inside the vertical blue bar. Vertical grey bar denotes the time of the main cold event as found in Greenland ice-core records (Thomas et al., 2007). Thick lines in panel a-d denote 5-pt. running mean of underlying data in thin lines. (a) Black curve: NGRIP $\delta^{18}\text{O}$ (temperature proxy) from Greenland Summit (North Greenland Ice Core Project members, 2004). Red curve: Simulated Greenland temperature in an 8.2-ka event simulation with the ECBilt-CLIO-VECODE model (Wiersma et al., 2011). Blue curve: Simulated Greenland temperature in an 8.2 event simulation with the CCSM3 model (Morrill et al., 2011). (b) North Atlantic/Nordic Seas SST-reconstructions, age models are aligned on the peak of the cold-event (less than 100-year adjustment). Blue curve: Nordic Seas (Risebrobakken et al., 2011). Black curve: Gardar Drift south of Iceland (Ellison et al., 2006). (c) Deep- and intermediate-water records. Black curve: Sortable silt record (overflow strength proxy) from Gardar Drift south of Iceland (Ellison et al., 2006), Atlantic intermediate water temperature reconstruction (Bamberg et al., 2010). (d) Black curve: $\delta^{13}\text{C}$ (deep water ventilation proxy) at 3.4 km water depth south of Greenland (Kleiven et al., 2008). Age model is aligned on the minimum overflow strength in (c) (less than 100-year adjustment). Modelled change in the strength of the AMOC—Green curve: an 8.2 ka event simulation with the GISS model (LeGrande et al., 2006). Red curve: an 8.2 ka event simulation with the ECBilt-CLIO-VECODE (v. 3) model (Wiersma et al., 2011). Blue curve: an 8.2 ka event simulation with the CCSM3 model (Morrill et al., 2011). (e) Spatial distribution of the 4-member ensemble mean annual mean surface temperature anomaly ($^{\circ}\text{C}$) compared with the control experiment from model simulations of the effects of a freshwater release at 8.2 ka (based on Morrill et al., 2013a). White dots indicate regions where less than 3 models agree on the sign of change. Coloured circles show paleoclimate data from records resolving the 8.2 ka event: purple = cold anomaly, yellow = warm anomaly, grey = no significant anomaly. Data source and significance thresholds are as summarized by Morrill et al. (2013b). (f) Same as (e) but for annual mean precipitation anomalies in %. Coloured circles show paleoclimate data from records resolving the 8.2 ka-event: purple = dry anomaly, green = wet anomaly, grey = no significant anomaly.

FAQ 5.1, Figure 1: Global surface temperature anomalies from 1870 to 2010, and the natural (solar, volcanic, and internal) and anthropogenic factors that influence them. (a) Global surface temperature record (1870–2010) relative to the average global surface temperature for 1961–1990 (black line). A model of global surface temperature change (panel a: red line) produced using the sum of the impacts on temperature of natural (panels b, c, d) and anthropogenic factors (panel e). (b) Estimated temperature response to solar forcing. (c) Estimated temperature response to volcanic eruptions. (d) Estimated temperature variability due to internal variability, here related to the El Niño Southern Oscillation. (e) Estimated temperature response to anthropogenic forcing, consisting of a warming component from greenhouse gases, and a cooling component from most aerosols.

FAQ 5.2, Figure 1: (a) Estimates of the average rate of global mean sea level change (in mm yr⁻¹) for five selected time intervals: last glacial-to-interglacial transition; Meltwater Pulse 1a; last 2 millennia; 20th century; satellite altimetry era (1993–2012). Blue columns denote time intervals of transition from a glacial to an interglacial period, whereas orange columns denote the current interglacial period. Black bars indicate the range of likely values of the average rate of global mean sea level change. Note the overall higher rates of global mean sea level change characteristic of times of transition between glacial and interglacial periods. (b) Expanded view of the rate of global mean sea level change during three time intervals of the present interglacial.

Executive Summary

This chapter addresses the biogeochemical cycles of carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O). The three greenhouse gases have increased in the atmosphere since pre-industrial times, and this increase is the main driving cause of climate change (Chapter 10). CO₂, CH₄ and N₂O altogether amount to 80% of the total radiative forcing from well-mixed greenhouse gases (Chapter 8). The increase of CO₂, CH₄ and N₂O is caused by anthropogenic emissions from the use of fossil fuel as a source of energy and from land use and land use change, in particular agriculture. The observed change in the atmospheric concentration of CO₂, CH₄ and N₂O results from the dynamic balance between anthropogenic emissions, and the perturbation of natural processes that leads to a partial removal of these gases from the atmosphere. Natural processes are linked to physical conditions, chemical reactions, and biological transformations and they respond themselves to perturbed atmospheric composition and climate change. Therefore, the physical climate system and the biogeochemical cycles of CO₂, CH₄ and N₂O are coupled. This chapter addresses the present human-caused perturbation of the biogeochemical cycles of CO₂, CH₄ and N₂O, their variations in the past coupled to climate variations, and their projected evolution during this century under future scenarios.

The Human-Caused Perturbation in the Industrial Era

CO₂ increased by 40% from 278 ppm circa 1750 to 390.5 ppm in 2011. During the same time interval, CH₄ increased by 150% from 722 ppb to 1803 ppb, and N₂O by 20% from 271 ppb to 324.2 ppb in 2011. It is unequivocal that the current concentrations of atmospheric CO₂, CH₄ and N₂O exceed any level measured for at least the past 800,000 years, the period covered by ice cores. Furthermore, the average rate of increase of these three gases observed over the past century exceeds any observed rate of change over the previous 20,000 years. [2.2, 5.2, 6.1, 6.2]

Anthropogenic CO₂ emissions to the atmosphere were 545 ± 85 PgC (1 PgC = 10¹⁵ gC) between 1750 and 2011. Of this amount, fossil fuel combustion and cement production contributed 365 ± 30 PgC and land use change (including deforestation, afforestation and reforestation) contributed 180 ± 80 PgC. [6.3.1, Table 6.1]

With a very high level of confidence¹, the increase in CO₂ emissions from fossil fuel burning and those arising from land use change are the dominant cause of the observed increase in atmospheric CO₂ concentration. About half of the emissions remained in the atmosphere (240 ± 10 PgC) since 1750. The rest was removed from the atmosphere by sinks, and stored in the natural carbon cycle reservoirs. The ocean reservoir stored 155 ± 30 PgC. Vegetation biomass and soils not affected by land use change, stored 150 ± 90 PgC. [6.1, 6.3, 6.3.2.3, Table 6.1, Figure 6.8]

Carbon emissions from fossil fuel combustion and cement production increased faster during the 2000–2011 period than during the 1990–1999 period. These emissions were 9.5 ± 0.8 PgC yr⁻¹ in 2011, 54% above their 1990 level. Anthropogenic net CO₂ emissions from land use change were 0.9 ± 0.8 PgC yr⁻¹ throughout the past decade, and represent about 10% of the total anthropogenic CO₂ emissions. It is *more likely than not*² that net CO₂ emissions from land use change decreased during 2000–2011 compared to 1990–1999. [6.3, Table 6.1, Table 6.2, Figure 6.8]

Atmospheric CO₂ concentration increased at an average rate of 2.0 ± 0.1 ppm yr⁻¹ during 2002–2011. This decadal rate of increase is higher than during any previous decade since direct atmospheric

¹ In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

² In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

concentration measurements began in 1958. Globally, the size of the combined natural land and ocean sinks of CO₂ approximately followed the atmospheric rate of increase, removing 55% of the total anthropogenic emissions every year on average during 1958–2011. [6.3, Table 6.1]

After almost one decade of stable CH₄ concentrations since the early 1990s, atmospheric measurements have shown renewed CH₄ concentrations growth since 2007. The drivers of this renewed growth are still debated. The methane budget for the decade of 2000–2009 (bottom-up estimates) is 177–284 Tg(CH₄) yr⁻¹ for natural wetlands emissions, 187–224 Tg(CH₄) yr⁻¹ for agriculture and waste (rice, animals and waste), 85–105 Tg(CH₄) yr⁻¹ for fossil fuel related emissions, 61–200 Tg(CH₄) yr⁻¹ for other natural emissions including, among other fluxes, geological, termites, and fresh water emissions, and 32–39 Tg(CH₄) yr⁻¹ for biomass and biofuel burning (the range indicates the expanse of literature values). Anthropogenic emissions account for 50–65% of total emissions. By including natural geological CH₄ emissions that were not accounted for in previous budgets, the fossil component of the total CH₄ emissions (i.e., anthropogenic emissions related to leaks in the fossil fuel industry and natural geological leaks) is now estimated to amount to about 30% of the total CH₄ emissions (*medium confidence*). Climate driven fluctuations of CH₄ emissions from natural wetlands are the main drivers of the global inter-annual variability of CH₄ emissions (*high confidence*), with a smaller contribution from the variability in emissions from biomass burning emissions during high fire years. [6.3.3, Figure 6.2, Table 6.8]

The concentration of N₂O increased at a rate of 0.73 ± 0.03 ppb yr⁻¹ over the last three decades.

Emissions of N₂O to the atmosphere are mostly caused by nitrification and de-nitrification reactions of reactive nitrogen in soils and in the ocean. Anthropogenic N₂O emissions increased steadily over the last two decades and were 6.9 (2.7–11.1) TgN (N₂O) yr⁻¹ in 2006. Anthropogenic N₂O emissions are 1.7–4.8 TgN (N₂O) yr⁻¹ from the application of fertilizers in agriculture, 0.2–1.8 TgN (N₂O) yr⁻¹ from fossil fuel use and industrial processes, 0.2–1.0 TgN (N₂O) yr⁻¹ from biomass burning (including biofuels), and 0.4–1.3 TgN (N₂O) yr⁻¹ from land emissions due to atmospheric nitrogen deposition (the range indicates expand of literature values). Natural N₂O emissions derived from soils, oceans, and a small atmospheric source, are together 5.4–19.6 TgN (N₂O) yr⁻¹. [6.3, 6.3.4, Figure 6.4c, Figure 6.19, Table 6.9]

The human-caused creation of reactive nitrogen in 2010 was at least two times larger than the rate of natural terrestrial creation. The human-caused creation of reactive nitrogen is dominated by the production of ammonia for fertilizer and industry, with important contributions from legume cultivation and combustion of fossil fuels. Once formed, reactive nitrogen can be transferred to waters and the atmosphere. In addition to N₂O, two important nitrogen compounds emitted to the atmosphere are NH₃ and NO_x which both influence tropospheric O₃ and aerosols through atmospheric chemistry. All of these effects contribute to radiative forcing. It is also *likely* that reactive nitrogen deposition over land currently increases natural CO₂ sinks, in particular in forests, but the magnitude of this effect varies between regions. [6.1.3, 6.3, 6.3.2.6.5, 6.3.4, 6.4.6, Figures 6.4a and 6.4b, Table 6.9, Chapter 7]

Before the Human-Caused Perturbation

During the last 7000 years prior to 1750, atmospheric CO₂ from ice cores shows only very slow changes (increase) from 260 ppm to 280 ppm, in contrast to the human caused increase of CO₂ since pre-industrial times. The contribution of CO₂ emissions from early anthropogenic land use is unlikely sufficient to explain the CO₂ increase prior to 1750. Atmospheric CH₄ from ice cores increased by about 100 ppb between 4000 years ago and around 1750. *About as likely as not*, this increase can be attributed to early human activities involving livestock, human-caused fires and rice cultivation. [6.2, Figures 6.6 and 6.7]

Further back in time, during the past 800,000 years prior to 1750, atmospheric CO₂ varied from 180 ppm during glacial (cold) up to 300 ppm during interglacial (warm) periods. This is well established from multiple ice core measurements. Variations in atmospheric CO₂ from glacial to interglacial periods were caused by decreased ocean carbon storage (500–1200 PgC), partly compensated by increased land carbon storage (300–1000 PgC). [6.2.1, Figure 6.5]

Future Projections

With very high confidence, ocean carbon uptake of anthropogenic CO₂ emissions will continue under all four Representative Concentration Pathways through to 2100, with higher uptake corresponding to higher concentration pathways. The future evolution of the land carbon uptake is much more uncertain, with a majority of models projecting a continued net carbon uptake under all RCPs, but with some models simulating a net loss of carbon by the land due to the combined effect of climate change and land use change. In view of the large spread of model results and incomplete process representation, there is *low confidence* on the magnitude of modelled future land carbon changes. [6.4.3, Figure 6.24]

There is high confidence that climate change will partially offset increases in global land and ocean carbon sinks caused by rising atmospheric CO₂. Yet, there are regional differences among CMIP5 Earth System Models, in the response of ocean and land CO₂ fluxes to climate. There is a high agreement between models that tropical ecosystems will store less carbon in a warmer climate. There is medium agreement between models that at high latitudes warming will increase land carbon storage, although none of the models account for decomposition of carbon in permafrost, which may offset increased land carbon storage. There is high agreement between CMIP5 Earth System models that ocean warming and circulation changes will reduce the rate of carbon uptake in the Southern Ocean and North Atlantic, but that carbon uptake will nevertheless persist in those regions. [6.4.2, Figures 6.21 and 6.22]

It is very likely, based on new experimental results [6.4.6.3] and modelling, that nutrient shortage will limit the effect of rising atmospheric CO₂ on future land carbon sinks, for the four RCP scenarios. There is *high confidence* that low nitrogen availability will limit carbon storage on land, even when considering anthropogenic nitrogen deposition. The role of phosphorus limitation is more uncertain. Models that combine nitrogen limitations with rising CO₂ and changes in temperature and precipitation thus produce a systematically larger increase in projected future atmospheric CO₂, for a given fossil fuel emissions trajectory. [6.4.6, 6.4.6.3, 6.4.8.2, Figure 6.35]

Taking climate and carbon cycle feedbacks into account, we can quantify the fossil fuel emissions compatible with the RCPs. Between 2012 and 2100, the RCP2.6, RCP4.5, RCP6.0, and RCP8.5 scenarios imply cumulative compatible fossil fuel emissions of 272 ± 101 PgC, 780 ± 149 PgC, 1062 ± 144 PgC and 1687 ± 201 PgC respectively (±1 standard deviation derived from CMIP5 model results). For RCP2.6, an average 50% (range 14–96%) emission reduction is required by 2050 relative to 1990 levels. It is about as *likely as not* that sustained globally negative emissions will be required to achieve the reductions in atmospheric CO₂ in this scenario. [6.4.3, Figure 6.25]

There is high confidence that reductions in permafrost extent due to warming will cause thawing of some currently frozen carbon. However, there is low confidence on the magnitude of carbon losses through CO₂ and CH₄ emissions to the atmosphere, with a range from 50 to 250 PgC between 2000 and 2100 for RCP8.5. The CMIP5 Earth System Models did not include frozen carbon feedbacks. [6.4.3, Chapter 12]

There is medium confidence that emissions of CH₄ from wetlands are likely to increase under elevated CO₂ and a warmer climate. But there is *low confidence* in quantitative projections of these changes. The likelihood of the future release of CH₄ from marine gas hydrates in response to seafloor warming is poorly understood. In the event of a significant release of CH₄ from hydrates in the sea floor by the end of the 21st century, it is *likely* that subsequent emissions to the atmosphere would be in the form of CO₂, due to CH₄ oxidation in the water column. [6.4.7, Figure 6.37]

It is likely that N₂O emissions from soils will increase due to the increased demand for feed/food and the reliance of agriculture on nitrogen fertilizers. Climate warming will likely amplify agricultural and natural terrestrial N₂O sources, but there is *low confidence* in quantitative projections of these changes. [6.4.6, Figure 6.32]

It is virtually certain that the increased storage of carbon by the ocean will increase acidification in the future, continuing the observed trends of the past decades. Ocean acidification in the surface ocean will follow atmospheric CO₂ while it will also increase in the deep ocean as CO₂ continues to penetrate the abyss. The CMIP5 models consistently project worldwide increased ocean acidification to 2100 under all RCPs. The corresponding decrease in surface ocean pH by the end of the 21st century is 0.065 (0.06–0.07) for RCP2.6, 0.145 (0.14–0.15) for RCP4.5, 0.203 (0.20–0.21) for RCP6.0, and 0.31 (0.30–0.32) for RCP8.5

(CMIP5 model spread). Surface waters become seasonally corrosive to aragonite in parts of the Arctic and in some coastal upwelling systems within a decade, and in parts of the Southern Ocean within 1 to 3 decades in most scenarios. Aragonite undersaturation becomes widespread in these regions at atmospheric CO₂ levels of 500–600 ppm. [6.4.4, Figures 6.28 and 6.29]

It is very likely that the dissolved oxygen content of the ocean will decrease by a few percent during the 21st century. CMIP5 models suggest that this decrease in dissolved oxygen will predominantly occur in the subsurface mid-latitude oceans, caused by enhanced stratification, reduced ventilation and warming. However, there is no consensus on the future development of the volume of hypoxic and suboxic waters in the open-ocean because of large uncertainties in potential biogeochemical effects and in the evolution of tropical ocean dynamics. [6.4.5, Figure 6.30]

Irreversible Long-Term Impacts of Human-Caused Emissions

With very high confidence, the physical, biogeochemical carbon cycle in the ocean and on land will continue to respond to climate change and rising atmospheric CO₂ concentrations created during the 21st century. Ocean acidification will *very likely* continue in the future as long as the oceans take up atmospheric CO₂. Committed land ecosystem carbon cycle changes will manifest themselves further beyond the end of the 21st century. In addition, it is *virtually certain* that large areas of permafrost will experience thawing over multiple centuries. There is, however, *low confidence* in the magnitude of frozen carbon losses to the atmosphere, and the relative contributions of CO₂ and CH₄ emissions. [6.4.4, 6.4.9, Chapter 12]

The magnitude and sign of the response of the natural carbon reservoirs to changes in climate and rising CO₂ vary substantially over different timescales. The response to rising CO₂ is to increase cumulative land and ocean uptake, regardless of the timescale. The response to climate change is variable, depending of the region considered because of different responses of the underlying physical and biological mechanisms at different timescales. [6.4, Table 6.10, Figures 6.14 and 6.17]

The removal of human-emitted CO₂ from the atmosphere by natural processes will take a few hundred thousand years (*high confidence*). It is *very likely* that more than 20% of emitted CO₂ will remain in the atmosphere longer than 1000 years after anthropogenic emissions have stopped. This extremely long time required by sinks to remove anthropogenic CO₂ makes climate change irreversible on human time scale. [Box 6.1]

Geoengineering Methods and the Carbon Cycle

Unconventional ways to remove CO₂ from the atmosphere on a large scale are termed Carbon Dioxide Removal (CDR) methods. CDR could in theory be used to reduce CO₂ atmospheric concentrations but these methods have biogeochemical and technological limitations to their potential. Uncertainties make it difficult to quantify how much CO₂ emissions could be offset by CDR on a human timescale, although it is *likely* that CDR would have to be deployed at large-scale for at least one century to be able to significantly reduce atmospheric CO₂. In addition, it is *virtually certain* that the removal of CO₂ by CDR will be partially offset by outgassing of CO₂ from the ocean and land ecosystems. [6.5, Figures 6.39 and 6.40, Table 6.15, Box 6.1, FAQ 7.3]

The level of confidence on the side effects of CDR methods on carbon and other biogeochemical cycles is low. Some of the climatic and environmental effects of CDR methods are associated with altered surface albedo (for afforestation), de-oxygenation and enhanced N₂O emissions (for artificial ocean fertilization). Solar Radiation Management (SRM) methods (Chapter 7) will not directly interfere with the effects of elevated CO₂ on the carbon cycle, such as ocean acidification, but will impact carbon and other biogeochemical cycles through their climate effects. [6.5.3, 6.5.4, Tables 6.14 and 6.15, 7.7]

6.1 Introduction

The radiative properties of the atmosphere are strongly influenced by the abundance of well-mixed greenhouse gases (see Glossary), mainly carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O), which have substantially increased since the beginning of the Industrial Era (defined as beginning in the year 1750), due primarily to anthropogenic emissions (see Chapter 2). Well-mixed greenhouse gases represent the gaseous phase of global biogeochemical cycles, which control the complex flows and transformations of the elements between the different components of the Earth System (atmosphere, ocean, land, lithosphere) by biotic and abiotic processes. Since most of these processes are themselves also dependent on the prevailing environment, changes in climate and human impacts on ecosystems (e.g., land use and land use change) also modify the atmospheric concentrations of CO₂, CH₄ and N₂O. During the glacial-interglacial cycles (see Glossary), in absence of significant direct human impacts, long variations in climate also affected CO₂, CH₄ and N₂O and vice versa (see Chapter 5, Section 5.2.2). In the coming century, the situation is quite different, because of the dominance of anthropogenic emissions that affect global biogeochemical cycles, and in turn, climate change (see Chapter 12). Biogeochemical cycles thus constitute feedbacks in the Earth System.

This chapter summarizes the scientific understanding of atmospheric budgets, variability and trends of the three major biogeochemical trace gases, CO₂, CH₄ and N₂O, their underlying source and sink processes and their perturbations caused by direct human impacts, past and present climate changes as well as future projections of climate change. After the introduction (Section 6.1), Section 6.2 assesses the present understanding of the mechanisms responsible for the variations of CO₂, CH₄ and N₂O in the past emphasizing glacial-interglacial changes, and the smaller variations during the Holocene (see Glossary) since the last glaciation and over the last millennium. Section 6.3 focuses on the Industrial Era addressing the major source and sink processes, and their variability in space and time. This information is then used to evaluate critically the models of the biogeochemical cycles, including their sensitivity to changes in atmospheric composition and climate. Section 6.4 assesses future projections of carbon and other biogeochemical cycles computed, in particular, with CMIP5 Earth System Models. This includes a quantitative assessment of the direction and magnitude of the various feedback mechanisms as represented in current models, as well as additional processes that might become important in the future but which are not yet fully understood. Finally, Section 6.5 addresses the potential effects and uncertainties of deliberate carbon dioxide removal methods (see Glossary) and solar radiation management (see Glossary) on the carbon cycle.

6.1.1 Global Carbon Cycle Overview

6.1.1.1 CO₂ and the Global Carbon Cycle

Atmospheric CO₂ represents the main atmospheric phase of the global carbon cycle. The global carbon cycle can be viewed as a series of reservoirs of carbon in the Earth System, which are connected by exchange fluxes of carbon. Conceptually, one can distinguish two domains in the global carbon cycle. (1) A fast domain with large exchange fluxes and relatively ‘rapid’ reservoir turnovers, which consists of carbon in the atmosphere, the ocean, surface ocean sediments and on land in vegetation, soils, and freshwaters. Reservoir turnover times, defined as reservoir mass of carbon divided by the exchange flux, range from a few years for the atmosphere, to decades-millennia for the major carbon reservoirs of the land vegetation and soil and the various domains in the ocean. (2) A second, slow domain consists of the huge carbon stores in rocks and sediments, which exchange carbon with the fast domain through volcanic emissions of CO₂, chemical weathering (see Glossary), erosion and sediment formation on the sea floor (Sundquist, 1986). Turnover times of the (mainly geological) reservoirs of the slow domain are 10,000 years or longer. Natural exchange fluxes between the slow and the fast domain of the carbon cycle are relatively small (<0.3 PgC yr⁻¹, 1 PgC = 10¹⁵ gC) and can be assumed as approximately constant in time (volcanism, sedimentation) over the last few centuries, although erosion and river fluxes may have been modified by human induced changes in land use (Raymond and Cole, 2003).

During the Holocene (beginning 11,700 years ago) prior to the Industrial Era the fast domain was close to steady state as evidenced by the relatively small variations of atmospheric CO₂ recorded in ice cores (see Section 6.2), despite small emissions from human caused changes in land use over the last millennia (Pongratz et al., 2009). By contrast, since the beginning of the Industrial Era, fossil fuel extraction from

geological reservoirs, and their combustion has resulted in the transfer of significant amount of fossil carbon from the slow domain into the fast domain, thus causing an unprecedented, major human induced perturbation in the carbon cycle. A schematic of the global carbon cycle with focus on the fast domain is shown in Figure 6.1. The numbers represent the estimated current pool sizes in PgC and the magnitude of the different exchange fluxes in PgC yr⁻¹ averaged over the time period 2000–2009 (see Section 6.3).

[INSERT FIGURE 6.1 HERE]

Figure 6.1: Simplified schematic of the global carbon cycle. Numbers represent reservoir mass, also called ‘carbon stocks’ in PgC (1 PgC = 10¹⁵ gC) and annual carbon exchange fluxes (in PgC yr⁻¹). Black numbers and arrows indicate reservoir mass and exchange fluxes estimated for the time prior to the Industrial Era, circa 1750 (see Section 6.1.1.1 for references). Fossil fuel reserves are from GEA (2006) and are consistent with numbers used by IPCC WGIII for future scenarios. The sediment storage is a sum of 150 PgC of the organic carbon in the mixed layer (Emerson and Hedges, 1988) and 1,600 PgC of the deep-sea CaCO₃ sediments available to neutralize fossil fuel CO₂ (Archer et al., 1998). Red arrows and numbers indicate annual “anthropogenic” fluxes averaged over the 2000–2009 time period. These fluxes are a perturbation of the carbon cycle during Industrial Era post 1750. These fluxes (red arrows) are: *Fossil fuel and cement emissions of CO₂* (6.3.1), *Net land use change* (6.3.2), and the *Average atmospheric increase of CO₂* in the atmosphere also called ‘CO₂ growth rate’ (6.3). The uptake of anthropogenic CO₂ by the ocean and by terrestrial ecosystems, often called ‘carbon sinks’ are the red arrows part of *Net land flux* and *Net ocean flux*. Red numbers in the reservoirs denote cumulative changes of anthropogenic carbon over the Industrial Period 1750–2011 (column 2 in Table 6.1). By convention, a positive cumulative change means that a reservoir has gained carbon since 1750. The cumulative change of anthropogenic carbon in the terrestrial reservoir is the sum of carbon cumulatively lost through land use change and carbon accumulated since 1750 in other ecosystems (Table 6.1). Note that the mass balance of the two ocean carbon stocks *Surface ocean* and *Intermediate and deep ocean* includes a yearly accumulation of anthropogenic carbon (not shown). Uncertainties are reported as 90% confidence intervals. Emission estimates and land and ocean sinks (in red) are from Table 6.1 in Section 6.3. The change of gross terrestrial fluxes (red arrows of *Gross Photosynthesis* and *Total Respiration and Fires*) has been estimated from CMIP5 model results (Section 6.4). The change in air-sea exchange fluxes (red arrows of ocean atmosphere gas exchange) have been estimated from the difference in atmospheric partial pressure of CO₂ since 1750 (Sarmiento and Gruber, 2006). Individual gross fluxes and their changes since the beginning of the Industrial Era have typical uncertainties of more than 20%, while their differences (*Net land flux* and *Net ocean flux* in the figure) are determined from independent measurements with a much higher accuracy (see Section 6.3). Therefore, to achieve an overall balance, the values of the more uncertain gross fluxes have been adjusted so that their difference matches the *Net land flux* and *Net ocean flux* estimates. Fluxes from volcanic eruptions, rock weathering (silicates and carbonates weathering reactions resulting into a small uptake of atmospheric CO₂), export of carbon from soils to rivers, burial of carbon in freshwater lakes and reservoirs and transport of carbon by rivers to the ocean are all assumed to be pre-industrial fluxes, that is unchanged during 1750–2011. Some recent studies (Section 6.3) indicate that this assumption is likely not verified, but global estimates of the Industrial Era perturbation of all these fluxes was not available from peer-reviewed literature. The atmospheric inventories have been calculated using a conversion factor of 2.12 PgC/ppm (Prather et al., 2012).

In the atmosphere, CO₂ is the dominant carbon bearing trace gas with a current (2011) concentration of approximately 390.5 ppm (Dlugokencky and Tans, 2012), which corresponds to a mass of 828 PgC (Prather et al., 2012; Joos et al., 2013). Additional trace gases include methane (CH₄, current content mass ~3.7 Pg C) and carbon monoxide (CO, current content mass ~0.2 PgC), and still smaller amounts of hydrocarbons, black carbon aerosols, and organic compounds.

The terrestrial biosphere reservoir contains carbon in organic compounds in vegetation living biomass (450–650 PgC; Prentice et al., 2001) and in dead organic matter in litter and soils (1500–2400 PgC; Batjes, 1996). There is an additional amount of old soil carbon in wetland soils (300–700 PgC; Bridgham et al., 2006) and in permafrost soils (see Glossary) (~1700 PgC; Tarnocai et al., 2009). CO₂ is removed from the atmosphere by plant photosynthesis (GPP) and carbon fixed into plants is then cycled through plant tissues, litter and soil carbon and can be released back into the atmosphere by autotrophic (plant) and heterotrophic (soil microbial and animal) respiration and additional disturbance processes (e.g., sporadic fires) on a very wide range of time scales (seconds to millennia). Since CO₂ uptake by photosynthesis occurs only during the growing season, while CO₂ release by respiration occurs near year-round, the greater land mass in the northern hemisphere impart a characteristic ‘saw-tooth’ seasonal cycle in atmospheric CO₂ (Keeling, 1960) (see Figure 6.3). A significant amount of terrestrial carbon (1.7 PgC yr⁻¹; Figure 6.1) is transported from soils to rivers headstreams. A fraction of this carbon is outgassed as CO₂ by rivers and lakes to the atmosphere, a fraction is buried in freshwaters organic sediments, and the remaining amount (~0.8 PgC yr⁻¹; Figure 6.1) is delivered by rivers to the coastal ocean as dissolved inorganic carbon, dissolved and particulate organic carbon (Tranvik et al., 2009).

Atmospheric CO₂ is exchanged with the surface ocean through gas exchange. This exchange flux is driven by the partial CO₂ pressure difference between the air and the sea. In the ocean, carbon is predominantly available as Dissolved Inorganic Carbon (DIC, ~38,000 PgC; Figure 6.1), that is carbonic acid (dissolved CO₂ in water), bicarbonate and carbonate ions, which are tightly coupled via ocean chemistry. In addition, the ocean contains a pool of Dissolved Organic Carbon (DOC, ~700 PgC), of which a substantial fraction has a turnover time of 1000 years or longer (Hansell et al., 2009). The marine biota, predominantly phytoplankton and other microorganisms represent a small organic carbon pool (~3 PgC), which is turned over very rapidly in days to a few weeks.

Carbon is transported within the ocean by three mechanisms (Figure 6.1): (1) The ‘solubility pump’ (see Glossary), (2) The ‘biological pump’ (see Glossary), and (3) The ‘marine carbonate pump’ that is generated by the formation of calcareous shells of certain oceanic microorganisms in the surface ocean, which, after sinking to depth are re-mineralized back into DIC and calcium ions. The marine carbonate pump operates counter to the marine biological soft-tissue pump with respect to its effect on CO₂: in the formation of calcareous shells, two bicarbonate ions are split into one carbonate and one dissolved CO₂ molecules, which increases the partial CO₂ pressure in surface waters (driving a release of CO₂ to the atmosphere). Only a small fraction (~0.2 PgC yr⁻¹) of the carbon exported by biological processes (both soft-tissue and carbonate pumps) from the surface reaches the sea floor where it can be stored in sediments for millennia and longer.

[START BOX 6.1 HERE]

Box 6.1: Multiple Residence Times for an Excess of CO₂ Emitted in the Atmosphere

On average, CO₂ molecules are exchanged between the atmosphere and the Earth surface every few years. This fast CO₂ cycling through the atmosphere is coupled to a slower cycling of carbon through land vegetation, litter and soils, and the upper ocean (decades to centuries), deeper soils and the deep sea (centuries to millennia), and geological reservoirs, such as deep-sea carbonate sediments and the upper mantle (up to millions of years) as explained in Section 6.1.1.1. Atmospheric CO₂ represents only a tiny fraction of the carbon in the Earth System, the rest of which is tied up in these other reservoirs. Emission of carbon from fossil fuel reserves, and additionally from land use change (see Section 6.3) is now rapidly increasing atmospheric CO₂ content, but the ultimate removal of the excess carbon into the slower reservoirs will take at least tens of thousands of years. An extremely long atmospheric CO₂ recovery timescale from a large emission pulse of CO₂ has been inferred from geological evidence when during the Paleocene-Eocene thermal maximum event ca. 55 million years ago a large amount of CO₂ was released to the atmosphere (McInerney and Wing, 2011).

Box 6.1, Table 1: The main natural processes that remove CO₂ consecutive to a large emission pulse to the atmosphere, their atmospheric CO₂ adjustment timescales, and main (bio)chemical reactions involved are:

<i>Processes</i>	<i>Timescale (years)</i>	<i>Reactions</i>
Land uptake: Photosynthesis – respiration	1–10 ²	6CO ₂ + 6H ₂ O + photons → C ₆ H ₁₂ O ₆ + 6O ₂ C ₆ H ₁₂ O ₆ + 6O ₂ → 6CO ₂ + 6H ₂ O + heat
Ocean invasion: seawater buffer	10–10 ³	CO ₂ + CO ₃ ²⁻ + H ₂ O ⇌ 2HCO ₃ ⁻
Reaction with calcium carbonate	10 ³ –10 ⁴	CO ₂ + CaCO ₃ + H ₂ O → Ca ²⁺ + 2HCO ₃ ⁻
Silicate weathering	10 ⁴ –10 ⁶	CO ₂ + CaSiO ₃ → CaCO ₃ + SiO ₂

These processes are active on all time scales, but the relative importance of their role in the CO₂ removal is changing with time and depends on the level of emissions. Accordingly, the times of atmospheric CO₂ adjustment to anthropogenic carbon emissions can be divided into three phases associated with increasingly longer timescales.

Phase 1. Within several decades of CO₂ emissions, about a third to half of an initial pulse of anthropogenic CO₂ goes into the land and ocean, while the rest stays in the atmosphere (Box 6.1, Figure 1a). Within a few centuries, most of the anthropogenic CO₂ will be in the form of additional dissolved inorganic carbon in the

ocean, thereby decreasing ocean pH (Box 6.1, Figure 1b). Within a thousand years, the remaining atmospheric fraction of the CO₂ emissions (see Section 6.3.2.4) is expected to be between 15 and 40%, depending on the amount of carbon released (Archer et al., 2009b). The carbonate buffer capacity of the ocean decreases with higher CO₂, so the larger the cumulative emissions, the higher the remaining atmospheric fraction (Eby et al., 2009; Joos et al., 2013).

Phase 2. In the second stage, within a few thousands of years, the pH of the ocean that has decreased in Phase 1 will be restored by reaction of ocean dissolved CO₂ and CaCO₃ of seafloor sediments, partly replenishing the buffer capacity of the ocean and further drawing down atmospheric CO₂ as a new balance is re-established between CaCO₃ sedimentation in the ocean and terrestrial weathering (Box 6.1, Figure 1c right). This second phase will pull the remaining atmospheric CO₂ fraction down to 10–25% of the original CO₂ pulse after about 10 thousands years (Lenton and Britton, 2006; Montenegro et al., 2007; Ridgwell and Hargreaves, 2007; Tyrrell et al., 2007; Archer and Brovkin, 2008).

Phase 3. In the third stage, within several hundred thousand years, the rest of the CO₂ emitted during the initial pulse will be removed from the atmosphere by silicate weathering, a very slow process of CO₂ reaction with CaSiO₃ and other minerals of igneous rocks (e.g., Sundquist, 1990; Walker and Kasting, 1992).

Involvement of extremely long-time scale processes into the removal of a pulse of CO₂ emissions into the atmosphere complicates comparison with the cycling of the other greenhouse gases. This is why the concept of a single, characteristic atmospheric lifetime is not applicable to CO₂ (Chapter 8).

[INSERT BOX 6.1, FIGURE 1 HERE]

Box 6.1, Figure 1: A percentage of emitted CO₂ remaining in the atmosphere in response to an idealized instantaneous CO₂ pulse emitted to the atmosphere in year 0 as calculated by a range of coupled climate-carbon cycle models. (Left and middle panels, **a** and **b**) Multi-model mean (blue line) and the uncertainty interval (± 2 standard deviations, shading) simulated during 1,000 years following the instantaneous pulse of 100 PgC (Joos et al., 2013). (Right panel, **c**) A mean of models with oceanic and terrestrial carbon components and a maximum range of these models (shading) for instantaneous CO₂ pulse in year 0 of 100 PgC (blue), 1,000 PgC (orange) and 5,000 PgC (red line) on a time interval up to ten thousand years (Archer et al., 2009b). Text at the top of the panels indicates the dominant processes that remove the excess of CO₂ emitted in the atmosphere on the successive timescales. Note that higher pulse of CO₂ emissions leads to higher remaining CO₂ fraction (Section 6.3.2.4) due to reduced carbonate buffer capacity of the ocean and positive climate-carbon cycle feedback (Section 6.3.2.6.6).

[END BOX 6.1 HERE]

6.1.1.2 CH₄ Cycle

Methane absorbs infrared radiation relatively stronger per molecule of CH₄ compared to CO₂ (Chapter 8), and it interacts with photochemistry. On the other hand, the methane turnover time (see Glossary) is less than 10 years in the troposphere (Prather et al., 2012; see Chapter 7). The sources of CH₄ at the surface of the Earth (see Section 6.3.3.2) can be thermogenic including (1) natural emissions of fossil CH₄ from geological sources (marine and terrestrial seepages, geothermal vents and mud volcanoes), and (2) emissions caused by leakages from fossil fuel extraction and use (natural gas, coal and oil industry; Figure 6.2). There are also pyrogenic sources due to incomplete burning of fossil fuels and plant biomass (both natural and anthropogenic fires). Last, biogenic sources include natural biogenic emissions predominantly from wetlands, from termites, and very small emissions from the ocean (see Section 6.3.3). Anthropogenic biogenic emissions occur from rice paddy agriculture, ruminants, landfills, man-made lakes and wetlands and waste treatment. In general, biogenic CH₄ is produced from organic matter under low oxygen conditions by fermentation processes of methanogenic microbes (Conrad, 1996). Atmospheric CH₄ is primarily removed by photochemistry, through atmospheric chemistry reactions with the OH radicals. Other smaller removal processes of atmospheric CH₄ take place in the stratosphere through reaction with chlorine and oxygen radicals, by oxidation in well aerated soils, and possibly by reaction with chlorine in the marine boundary layer (Allan et al., 2007; see Section 6.3.3.3).

[INSERT FIGURE 6.2 HERE]

Figure 6.2: Schematic of the global cycle of CH₄. Numbers represent annual fluxes in Tg(CH₄) yr⁻¹ estimated for the time period 2000–2009 and CH₄ reservoirs in Tg(CH₄): the atmosphere, and three geological reservoirs (hydrates on

land and in the ocean floor, and gas reserves) (see Section 6.3.3). Black arrows denote ‘natural’ fluxes, i.e., fluxes that are not directly caused by human activities since 1750, red arrows anthropogenic fluxes, and the light brown arrow denotes a combined natural+anthropogenic flux. Note that human activities (e.g., land use) may have modified indirectly the global magnitude of the natural fluxes (6.3.3). Ranges represent minimum and maximum values from cited references as given in Table 6.8 in Section 6.3.3. Gas reserves are from GEA (2006) and are consistent with numbers used by IPCC WG III for future scenarios. Hydrate reservoir sizes are from Archer et al., 2007. The atmospheric inventories have been calculated using a conversion factor of 2.75 TgCH₄/ppb (Prather et al., 2012). The assumed preindustrial annual mean globally averaged CH₄ concentration was 722 ± 25 ppb taking the average of the Antarctic Law Dome ice core observations (MacFarling-Meure et al., 2006) and the measurements from the GRIP ice core in Greenland (Blunier et al., 1995; see also Chapter 2, Table 2.1). The atmospheric inventory in the year 2011 is based on an annual globally averaged CH₄ concentration of 1803 ± 4 ppb in the year 2011 (see Chapter 2, Table 2.1). It is the sum of the atmospheric increase between 1750 and 2011 (in red) and of the pre-industrial inventory (in black). The *average atmospheric increase* each year, also called growth rate, is based on a measured concentration increase of 2.2 ppb yr⁻¹ during the time period 2000–2009 (Dlugokencky et al., 2011).

A very large geological stock (globally 1500–7000 PgC, that is 2,000,000–9,300,000 TgCH₄ in Figure 6.2; Archer, (2007); with *low confidence in estimates*) of CH₄ exists in the form of frozen hydrate deposits (‘clathrates’) in shallow ocean sediments and on the slopes of continental shelves, and permafrost soils. These CH₄ hydrates are stable under conditions of low temperature and high pressure. Warming or changes in pressure could render some of these hydrates unstable with a potential release of CH₄ to the overlying soil/ocean, and/or atmosphere. Possible future CH₄ emissions from CH₄ released by gas hydrates are discussed in Section 6.4.7.3.

6.1.2 Industrial Era

6.1.2.1 CO₂ and the Global Carbon Cycle

Since the beginning of the Industrial Era, humans have been producing energy by burning of fossil fuels (coal, oil and gas), a process which is releasing large amounts of carbon dioxide into the atmosphere (Rotty, 1983; Boden et al., 2011; see Section 6.3.2.1). The amount of fossil fuel CO₂ emitted to the atmosphere can be estimated with an accuracy of about 5–10% for recent decades from statistics of fossil fuel use (Andres et al., 2012). Total cumulative emissions between 1750 and 2011 amount to 365 ± 30 PgC (see Section 6.3.2.1 and Table 6.1), including a contribution of 8 PgC from the production of cement.

The second major source of anthropogenic CO₂ emissions to the atmosphere is caused by changes in land use (mainly deforestation), which causes globally a net reduction in land carbon storage, although recovery from past land use change can cause a net gain in in land carbon storage in some regions. Estimation of this CO₂ source to the atmosphere requires knowledge of changes in land area as well as estimates of the carbon stored per area before and after the land use change. In addition, longer-term effects, such as the decomposition of soil organic matter after land use change, have to be taken into account (see Section 6.3.2.2). Since 1750, anthropogenic land use changes have resulted into about 50 million km² being used for cropland and pasture, corresponding to about 38% of the total ice-free land area (Foley et al., 2007; Foley et al., 2011), in contrast to an estimated cropland and pasture area of 7.5–9 million km² circa 1750 (Ramankutty and Foley, 1999; Goldewijk, 2001). The cumulative net CO₂ emissions from land use changes between 1750 and 2011 are estimated at approximately 180 ± 80 PgC (see Section 6.3 and Table 6.1).

Multiple lines of evidence indicate that the observed atmospheric increase in the global CO₂ concentration since 1750 (Figure 6.3) is caused by the anthropogenic CO₂ emissions (see Section 6.3.2.3). The rising atmospheric CO₂ content induces a disequilibrium in the exchange fluxes between the atmosphere and the land and oceans respectively. The rising CO₂ concentration implies a rising atmospheric CO₂ partial pressure which induces a globally averaged net-air-to-sea flux and thus an ocean sink for CO₂ (see Section 6.3.2.5). On land, the rising atmospheric CO₂ concentration fosters photosynthesis via the CO₂ fertilization effect (see Section 6.3.2.6). However, the efficacy of these oceanic and terrestrial sinks does also depend on how the excess carbon is transformed and redistributed within these sink reservoirs. The magnitude of the current sinks is shown in Figure 6.1 (averaged over the years 2000–2009, red arrows), together with the cumulative reservoir content changes over the industrial era (1750–2011, red numbers) (see Table 6.1, Section 6.3).

6.1.2.2 CH₄ Cycle

After 1750, atmospheric CH₄ levels rose almost exponentially with time, reaching 1650 ppb by the mid-1980s and 1803 ppb by 2011. Between the mid-1980s and the mid-2000s the atmospheric growth of CH₄ declined to nearly zero (see Section 6.3.3.1, see also Chapter 2). More recently since 2006, atmospheric CH₄ is observed to increase again (Rigby et al., 2008), however, it is unclear if this is a short term fluctuation or a new regime for the CH₄ cycle (Dlugokencky et al., 2009).

There is *very high* level of *confidence* that the atmospheric CH₄ increase during the Industrial Era is caused by anthropogenic activities. The massive increase in the number of ruminants (Barnosky, 2008), the emissions from fossil fuel extraction and use, the expansion of rice paddy agriculture and the emissions from landfills and waste, are the dominant anthropogenic CH₄ sources. Total anthropogenic sources contribute at present between 50 and 65% of the total CH₄ sources (see Section 6.3.3). The dominance of CH₄ emissions mostly located in the Northern Hemisphere (wetlands and anthropogenic emissions) is evidenced by the observed positive north-south gradient in CH₄ concentrations (Figure 6.3). Satellite based CH₄ concentration measurements averaged over the entire atmospheric column also indicate higher concentrations of CH₄ above and downwind of densely populated and intensive agriculture areas where anthropogenic emissions occur (Frankenberg et al., 2011).

(a) CO₂ from Mauna Loa (MLO) northern hemisphere and South Pole southern hemisphere (SPO) atmospheric stations (Keeling et al., 2005), (b) O₂ from Alert northern hemisphere (ALT) and Cape Grim southern hemisphere (CGO) stations (<http://scrippso2.ucsd.edu/> right axes, expressed relative to a reference standard value), (c) ¹³C/¹²C: Mauna Loa, South Pole (Keeling et al., 2005), (d) CH₄ from Mauna Loa and South Pole stations (Dlugokencky et al., 2012), (e) N₂O from Mace-Head northern hemisphere (MHD) and Cape Grim stations (Prinn et al., 2000).

6.1.3 Connections Between Carbon and the Nitrogen and Oxygen Cycles

6.1.3.1 Global Nitrogen Cycle including N₂O

The biogeochemical cycles of nitrogen and carbon are tightly coupled with each other due to the metabolic needs of organisms for these two elements. Changes in the availability of one element will influence not only biological productivity but also availability and requirements for the other element (Gruber and Galloway, 2008) and in the longer term, the structure and functioning of ecosystems as well.

Before the Industrial Era, the creation of reactive nitrogen Nr (all nitrogen species other than N₂) from non-reactive atmospheric N₂ occurred primarily through two ‘natural’ processes: lightning and biological nitrogen fixation (BNF). BNF is a set of reactions that convert N₂ to ammonia in a microbially mediated process. This input of Nr to the land and ocean biosphere was in balance with the loss of Nr through denitrification, a process which returns N₂ back to the atmosphere (Ayres et al., 1994). This equilibrium is broken since the beginning of the Industrial Era. Nr is produced by human activities and delivered to ecosystems. During the last decades, the production of Nr by humans has been much greater than the natural production (Figure 6.4a; Section 6.3.4.3). There are three main anthropogenic sources of Nr: (1) the Haber-Bosch industrial process, used to make NH₃ from N₂, for N-fertilizers and as a feedstock for some industries; (2) the cultivation of legumes and other crops, which increases BNF; (3) the combustion of fossil fuels, which converts atmospheric N₂ and fossil fuel nitrogen into nitrogen oxides (NO_x) emitted to the atmosphere and re-deposited at the surface (Figure 6.4a). In addition, there is a small flux from the mobilization of sequestered Nr from N-rich sedimentary rocks (Morford et al., 2011) (not shown in Figure 6.4a).

The amount of anthropogenic Nr converted back to non-reactive N₂ by denitrification is much smaller than the amount of Nr produced each year, i.e., about 30–60% of the total Nr production, with a large uncertainty (Galloway et al., 2004; Canfield et al., 2010; Bouwman et al., 2013). What is more certain is the amount of N₂O emitted to the atmosphere. Anthropogenic sources of N₂O are about the same size as natural terrestrial sources (see Section 6.3.4 and Table 6.8 for the global N₂O budget). In addition, emissions of Nr to the atmosphere, as NH₃ and NO_x, are caused by agriculture and fossil fuel combustion. A portion of the emitted NH₃ and NO_x are deposited over the continents, while the rest gets transported by winds and deposited over

the oceans. This atmospheric deposition flux of Nr over the oceans is comparable to the flux going from soils to rivers and delivered to the coastal ocean (Galloway et al., 2004; Suntharalingam et al., 2012). The increase of Nr creation during the Industrial Era, the connections among its impacts, including on climate, and the connections with the carbon cycle are presented in Box 6.2.

For the global ocean, the best BNF estimate is 160 TgN yr^{-1} , which is roughly the midpoint of the minimum estimate of 140 TgN yr^{-1} of Deutsch et al. (2007) and the maximum estimate of 177 TgN yr^{-1} (Groszkopf et al., 2012). The probability that this estimate will need an upward revision in the near future is high, since several additional processes are not yet considered (Voss et al., 2013).

A global denitrification rate is much more difficult to constrain than the BNF considering the changing paradigms of N-cycling in the oxygen minimum zones or the unconstrained losses in permeable sediments on the continental shelves (Gao et al., 2012). The coastal ocean may have losses in the range of 100–250 (Voss et al., 2011). For the open and distal ocean Codispoti (2007) estimated an upper limit of denitrification of 400 TgN yr^{-1} . Voss et al. (2013) used a conservative estimate of 100 TgN yr^{-1} for the coastal ocean, and $200\text{--}300 \text{ TgN yr}^{-1}$ for the open ocean. Since the upper limit in the global ocean is 400 TgN yr^{-1} , $300 \pm 100 \text{ TgN yr}^{-1}$ is the best estimate for global ocean losses of reactive nitrogen (Table 6.9).

This chapter does not describe the phosphorus and sulphur biogeochemical cycles, but phosphorus limitations on carbon sinks are briefly addressed in 6.4.8.2 and future sulphur deposition in 6.4.6.2.

[INSERT FIGURE 6.4 HERE]

Figure 6.4: Schematic of the global nitrogen cycle. The **upper panel (a)** shows the natural and anthropogenic processes that create reactive nitrogen and the corresponding rates of denitrification that convert reactive nitrogen back to N_2 . The **middle panel (b)** shows the flows of the reactive nitrogen species NO_y and NH_x . The **bottom panel (c)** The stratospheric sink of N_2O is the sum of losses via photolysis and reaction with O^1D (Table 6.9). The global magnitude of this sink is adjusted here in order to be equal to the difference between the total sources and the observed growth rate. This value falls within literature estimates (Volk et al., 1997). The atmospheric inventories have been calculated using a conversion factor of $4.79 \text{ TgN (N}_2\text{O) /ppb}$ (Prather et al., 2012).

[START BOX 6.2 HERE]

Box 6.2: Nitrogen Cycle and Climate, Carbon Cycle Feedbacks

Human creation of reactive nitrogen by the Haber-Bosch process (see above and Section 6.3.4), fossil fuel combustion, and agricultural BNF dominate Nr creation relative to biological nitrogen fixation in natural terrestrial ecosystems. This dominance impacts on the radiation balance of the Earth (covered by the IPCC; see e.g., Chapters 7, 8), and affects human health and ecosystem health as well (EPA, 2011b; Sutton et al., 2011).

The Nr creation from 1850 to 2005 is shown in Box 6.2 (Figure 1). After mid-1970s, human production of Nr exceeded natural production. During the 2000s food production (mineral fertilizers, legumes) accounts for three-quarters of Nr created by humans, with fossil fuel combustion and industrial uses accounting equally for the remainder (Galloway et al., 2008; Canfield et al., 2010; Sutton et al., 2011).

[INSERT BOX 6.2, FIGURE 1 HERE]

Box 6.2, Figure 1: Anthropogenic reactive nitrogen (Nr) creation rates (in TgN yr^{-1}) from fossil fuel burning (orange line), cultivation-induced biological nitrogen fixation (blue line), Haber-Bosch process (green line), and total creation (red line). Source: Galloway et al. (2003), Galloway et al. (2008). Note that updates are given in Table 6.9. The only one with significant changes in the more recent literature is cultivation-induced BNF which Herridge et al. (2008) estimated to be 60 Tg N yr^{-1} . The data are only reported since 1850, as no published estimate is available since 1750.

The three most relevant questions regarding the anthropogenic perturbation of the nitrogen cycle with respect to global change are: (1) What are the interactions with the carbon cycle, and the effects on carbon sinks (see Sections 6.3.2.6.5 and 6.4.2.1), (2) What are the effects of increased Nr on the radiative forcing of nitrate aerosols (Chapter 7, 7.3.2) and tropospheric ozone (Chapters 8), (3) What are the impacts of the excess of Nr on humans and ecosystems (health, biodiversity, eutrophication, not treated in this report, but see e.g., EPA, 2011b; Sutton et al., 2011).

Essentially all of the Nr formed by human activity is spread into the environment, either at the point of creation (i.e., fossil fuel combustion) or after it is used in food production and in industry. Once in the environment, Nr has a number of negative impacts, if not converted back into N₂. In addition to its contributions to climate change and stratospheric ozone depletion, Nr contributes to the formation of smog, increases the haziness of the troposphere, contributes to the acidification of soils and fresh waters, increases the productivity in forests, grasslands, open and coastal waters and open ocean, which can lead to eutrophication and reduction in biodiversity in terrestrial and aquatic ecosystems. In addition, Nr-induced increases in nitrogen oxides, aerosols, tropospheric ozone, and nitrates in drinking water have negative impacts on human health (Galloway et al., 2008; Davidson et al., 2012). Once the nitrogen atoms become reactive (e.g., NH₃, NO_x), any given Nr atom can contribute to all of the impacts noted above in sequence. This is called the nitrogen cascade (Galloway et al., 2003; Box 6.2, Figure 2). The nitrogen cascade is the sequential transfer of the same Nr atom through the atmosphere, terrestrial ecosystems, freshwater ecosystems and marine ecosystems that results in multiple effects in each reservoir. Because of the nitrogen cascade, the creation of any molecule of Nr from N₂, at any location, has the potential to affect climate, either directly or indirectly, as explained below. This potential exists until the Nr gets converted back to N₂.

[INSERT BOX 6.2, FIGURE 2 HERE]

Box 6.2, Figure 2: Illustration of the nitrogen cascade showing the sequential effects that a single atom of nitrogen in its various molecular forms can have in various reservoirs after it has been converted from nonreactive N₂ to a reactive form by energy and food production (orange arrows). Once created the reactive nitrogen has the potential to continue to contribute to impacts until it is converted back to N₂. The small black circle indicates that there is the potential for denitrification to occur within that reservoir. Abbreviations: NH₃, ammonia; NH_x, ammonia plus ammonium; NO₃⁻, nitrate; NO_x, nitrogen oxides; NO_y, NO_x and other combinations of nitrogen and oxygen (except N₂O); N₂O, nitrous oxide (adopted with permission from the GEO Yearbook 2003, United Nations Environmental Programme (UNEP), 2004 which was based on Galloway et al., 2003).

The most important processes causing direct links between anthropogenic Nr and climate change include (Erisman et al., 2011): (1) N₂O formation during industrial processes (e.g., fertilizer production), combustion, or microbial conversion of substrate containing nitrogen — notably after fertilizer and manure application to soils. N₂O is a strong greenhouse gas, (2) emission of anthropogenic NO_x leading a) to formation of tropospheric O₃, (which is the third most important greenhouse gas), b) a decrease of CH₄ and c) the formation of nitrate aerosols. Aerosol formation affects radiative forcing, as N-containing aerosols have a direct cooling effect in addition to an indirect cooling effect through cloud formation and 3) NH₃ emission to the atmosphere which contributes to aerosol formation. The first process has a warming effect. The second has both a warming (as a greenhouse gas) and a cooling (through the formation of the OH radical in the troposphere which reacts with CH₄, and through aerosol formation) effect. The net effect of all three NO_x-related contributions is cooling. The third process has a cooling effect.

The most important processes causing an indirect link between anthropogenic Nr and climate change include: (1) nitrogen dependent changes in soil organic matter decomposition and hence CO₂ emissions, affecting heterotrophic respiration, (2) Alteration of the biospheric CO₂ sink due to increased supply of Nr. About half of the carbon that is emitted to the atmosphere is taken up by the biosphere; Nr affects net CO₂ uptake from the atmosphere in terrestrial systems, rivers, estuaries and the open ocean in a positive direction (by increasing productivity or reducing the rate of organic matter breakdown) and negative direction (in situations where it accelerates organic matter breakdown). CO₂ uptake in the ocean causes ocean acidification, which reduces CO₂ uptake, (3) changes in marine primary productivity, generally an increase, in response to Nr deposition, and (4) O₃ formed in the troposphere as a result of NO_x and VOC emissions reduces plant productivity, and therefore reduces CO₂ uptake from the atmosphere. On the global scale the net-influence of the direct and indirect contributions of Nr on the radiative balance was estimated to be -0.24 W m^{-2} (with an uncertainty range of $+0.2$ to -0.5 W m^{-2}) (Erisman et al., 2011).

Nr is required for both plants and soil microorganisms to grow, and plant and microbial processes play important roles in the global carbon cycle. The increasing concentration of atmospheric CO₂ is observed to increase plant photosynthesis (see Box 6.3) and plant growth, which drives an increase of carbon storage in terrestrial ecosystems. Plant growth is however constrained by the availability of Nr in soils (see Section 6.3.2.6.5). This means that in some nitrogen poor ecosystems, insufficient Nr availability will limit carbon sinks, while the deposition of Nr may instead alleviate this limitation and enable larger carbon sinks (see

Section 6.3.2.6.5). Therefore, human production of Nr has the potential to mitigate CO₂ emissions by providing additional nutrients for plant growth in some regions. Microbial growth can also be limited by the availability of Nr, particularly in cold, wet environments, so that human production of Nr also has the potential to accelerate the decomposition of organic matter, increasing release of CO₂. The availability of Nr also changes in response to climate change, generally increasing with warmer temperatures and increased precipitation (see Section 6.4.2.1), but with complex interactions in the case of seasonally inundated environments. This complex network of feedbacks is amenable to study through observation and experimentation (Section 6.3), and Earth System modelling (Section 6.4). Even though we do not yet have a thorough understanding of how nitrogen and carbon cycling will interact with climate change, elevated CO₂ and human Nr production in the future, given scenarios of human activity, current observations and model results all indicate that low nitrogen availability will limit carbon storage on land in the 21st century (see Section 6.4.2.1).

[END BOX 6.2 HERE]

6.1.3.2 Oxygen

Atmospheric oxygen is tightly coupled with the global carbon cycle (sometimes called a mirror of the carbon cycle). The burning of fossil fuels removes oxygen from the atmosphere in a tightly defined stoichiometric ratio depending on fuel carbon content. As a consequence of the burning of fossil fuels, atmospheric O₂ levels have been observed to decrease steadily over the last 20 years (Keeling and Shertz, 1992; Manning and Keeling, 2006) (Figure 6.3b). Compared to the atmospheric oxygen content of ~21% this decrease is very small, however, it provides independent evidence that the rise in CO₂ must be due to an oxidation process, i.e., fossil fuel combustion and/or organic carbon oxidation, and is not caused e.g., by volcanic emissions or by outgassing of dissolved CO₂ from a warming ocean. The atmospheric oxygen measurements furthermore also show the north-south concentration O₂ difference (higher in the south and mirroring the CO₂ north-south concentration difference) as expected from the stronger fossil fuel consumption in the Northern Hemisphere (Keeling et al., 1996).

On land, during photosynthesis and respiration, O₂ and CO₂ are exchanged in nearly a 1:1 ratio. However, with respect to exchanges with the ocean, O₂ behaves quite differently from CO₂, since compared to the atmosphere only a small amount of O₂ is dissolved in the ocean whereas by contrast the oceanic CO₂ content is much larger due to the carbonate chemistry. This different behaviour of the two gases with respect to ocean exchange provides a powerful method to assess independently the partitioning of the uptake of anthropogenic CO₂ by land and ocean (Manning and Keeling, 2006), Section 6.3.2.3.

6.2 Variations in Carbon and Other Biogeochemical Cycles before the Fossil Fuel Era

The Earth System mechanisms that were responsible for past variations in atmospheric CO₂, CH₄, and N₂O will likely operate in the future as well. Past archives of GHG and climate therefore provide useful knowledge, including constraints for biogeochemical models applied to the future projections described in Section 6.4. In addition, past archives of GHG also show that the average rates of increase of CO₂, CH₄ and N₂O are larger during the Industrial Era, as discussed in Section 6.3, than during any comparable period of at least the past 16,000 years (Joos and Spahni, 2008).

6.2.1 Glacial-Interglacial GHG Changes

6.2.1.1 Processes Controlling Glacial CO₂

Ice cores recovered from the Antarctic ice sheet reveal that the concentration of atmospheric CO₂ at the Last Glacial Maximum (LGM, see Glossary) at 21 thousand years ago (21 ka) was about one third lower than during the subsequent interglacial (Holocene) period started at 11.7 ka ago (Delmas et al., 1980; Neftel et al., 1982; Monnin et al., 2001). Longer (to 800 ka) records exhibit similar features, with CO₂ values of ~180–200 ppm during glacial intervals (Petit et al., 1999). Prior to 420 ka, interglacial CO₂ values were 240–260 ppm rather than 270–290 ppm after that date (Lüthi et al., 2008).

A variety of proxy reconstructions as well as models of different complexity from conceptual to complex Earth System Models (ESM, see Glossary) have been used to test hypotheses for the cause of lower LGM atmospheric CO₂ concentrations (e.g., Köhler et al., 2005; Sigman et al., 2010). The mechanisms of the carbon cycle during the LGM, that lead to low atmospheric CO₂, can be broken down by individual drivers (Figure 6.5). It should be recognized however that this separation is potentially misleading, as many of the component drivers shown in Figure 6.5 may combine non-linearly (Bouttes et al., 2011). Only well-established individual drivers are quantified (Figure 6.5), and discussed below.

Reduced land carbon. Despite local evidence of larger carbon storage in permafrost regions during glacial periods (Zimov et al., 2009; Zech et al., 2011), the $\delta^{13}\text{C}$ record of ocean waters as preserved in benthic foraminiferal shells has been used to infer that global terrestrial carbon storage was reduced in glacial times, thus opposite to recorded changes in atmospheric CO₂. Data-based estimates of the deficit between LGM and pre-industrial land carbon storage range from a few hundreds to 1000 PgC (e.g., Bird et al., (1996); Ciais et al., (2012). Dynamic vegetation models tend to simulate values at the higher end (~800 PgC) (Kaplan et al., 2002; Otto et al., 2002) and indicate a role for the physiological effects of low CO₂ on photosynthesis at the LGM at least as large as that of colder and dryer climate conditions in determining the past extent of forests (Prentice and Harrison, 2009).

Lower sea-surface temperatures. Reconstructions of sea-surface temperatures during the LGM suggest that the global surface ocean was on average 3–5°C cooler compared to the Holocene. Because the solubility of CO₂ increases at colder temperature (Zeebe and Wolf-Gladrow, 2001), a colder glacial ocean will hold more carbon. However, uncertainty in reconstructing the LGM pattern of ocean temperature, particularly in the tropics (Archer et al., 2000; Waelbroeck et al., 2009), together with problems in transforming this pattern to the resolution of models in light of the non-linear nature of the CO₂-temperature relationship (Ridgwell, 2001), creates a large spread in modelled estimates. Most ocean general circulation models (OGCM) projections however cluster more tightly and suggest that lower ocean temperatures contribute to lower CO₂ values by 25 ppm during the LGM (Figure 6.5).

Lower sea level and increased salinity. During the LGM, sea level was about ~120 m lower than today, and this change in ocean volume had several well-understood effects on atmospheric CO₂ concentrations. Lower sea level impacts the LGM ocean carbon cycle in two main ways. First, the resulting higher LGM ocean surface salinity causes atmospheric CO₂ to be higher than during the Holocene. Second, the total dissolved inorganic carbon and alkalinity (a measure of the capacity of an aqueous solution to neutralize acid) become more concentrated in equal proportions, and this process also causes atmospheric CO₂ to be higher during the LGM. In total, lower sea level is estimated to contribute to higher CO₂ values by 15 ppm during the LGM (Figure 6.5), implying that other processes must explain the lower CO₂ values measured in ice cores.

Ocean circulation and sea ice. Re-organization in ocean circulation during glacial periods that promoted the retention of dissolved inorganic carbon in the deep ocean during the LGM has become the focus of most research on the glacial-interglacial CO₂ problem. That ocean circulation likely plays a key role in low glacial period atmospheric CO₂ concentration is exemplified by the tight coupling observed between reconstructed deep ocean temperatures and atmospheric CO₂ (Shackleton, 2000). Evidence from marine bore hole sites (Adkins et al., 2002) and from marine sediment cores (Jaccard et al., 2005; Skinner et al., 2010) show that the glacial ocean was highly stratified compared to interglacial conditions and may thus have held a larger store of carbon during glacial times. $\delta^{13}\text{C}$ CO₂ ice core records (Lourantou et al., 2010a; Lourantou et al., 2010b; Schmitt et al., 2012), as well as radiocarbon records from deep-sea corals demonstrate the role of a deep and stratified Southern Ocean in the higher LGM ocean carbon storage. However, conflicting hypotheses exist on the drivers of this increase in the Southern Ocean stratification, e.g., northward shift and weakening of Southern Hemisphere westerly winds (Toggweiler et al., 2006), reduced air-sea buoyancy fluxes (Watson and Garabato, 2006), or massive brine rejections during sea ice formation (Bouttes et al., 2011; Bouttes et al., 2012). Ocean carbon cycle models have simulated a circulation-induced effect on LGM CO₂ that can explain lower values than during interglacial by 3 ppm (Bopp et al., 2003) to 57 ppm (Toggweiler, 1999).

A long-standing hypothesis is that increased LGM sea ice cover acted as a barrier to air-sea gas exchange and hence reduced the 'leakage' of CO₂ during winter months from the ocean to the atmosphere during glacial periods (Broecker and Peng, 1986). However, concurrent changes in ocean circulation and biological

productivity complicate the estimation of the impact of increased sea ice extent on LGM atmospheric CO₂ (Kurahashi-Nakamura et al., 2007). With the exception of the results of an idealized box model (Stephens and Keeling, 2000), ocean carbon models are relatively consistent in projecting a small effect of higher sea ice extent on maintaining atmospheric CO₂ lower during LGM (Archer et al., 2003).

Fe fertilisation. Both marine and terrestrial sediment records indicate higher rates of deposition of dust and hence iron (Fe) supply at the LGM (Mahowald et al., 2006), implying a potential link between Fe fertilisation of marine productivity and lower glacial CO₂ (Martin, 1990). However, despite the fact that ocean carbon cycle models generally employ similar reconstructions of glacial dust fluxes (i.e., Mahowald et al., 1999; Mahowald et al., 2006), there is considerable disagreement among them in the associated CO₂ change. OGCM that include a description of the Fe cycle tend to cluster at the lower end of simulated CO₂ changes between glacial and interglacial (e.g., Archer et al., 2000; Bopp et al., 2003), whereas box models (e.g., Watson et al., 2000) or intermediate complexity models (EMICs, e.g., Brovkin et al., 2007) tend to produce CO₂ changes which are at the higher end (Parekh et al., 2008). An alternative view comes from inferences drawn from the timing and magnitude of changes in dust and CO₂ in ice cores (Röthlisberger et al., 2004), assigning a 20 ppm limit for the lowering of CO₂ during the LGM in response to an Southern Ocean Fe fertilisation effect, and a 8 ppm limit for the same effect in the North Pacific.

Other glacial CO₂ drivers. A number of further aspects of altered climate and biogeochemistry at the LGM are also likely to have affected atmospheric CO₂. Reduced bacterial metabolic rates and remineralization (see Glossary) of organic matter (Matsumoto, 2007; Menviel et al., 2012), increased glacial supply of dissolved silica (required by diatoms to form frustules) (Harrison, 2000), 'silica leakage' (Brzezinski et al., 2002; Matsumoto et al., 2002), changes in net global weathering rates (Berner, 1992; Munhoven, 2002), reduction in coral reef growth and other forms of shallow water CaCO₃ accumulation (Berger, 1982), carbonate compensation (Ridgwell and Zeebe, 2005), and changes in the CaCO₃ to organic matter 'rain ratio' to the sediments (Archer and Maier-Reimer, 1994), will act to amplify or diminish the effect of many of the above drivers on glacial CO₂.

Summary. All of the major drivers of the glacial-to-interglacial atmospheric CO₂ changes (Figure 6.5) are likely to have already been identified. However, Earth System Models have been unable to reproduce the full magnitude of the glacial-to-interglacial CO₂ changes. Significant uncertainties exist in glacial boundary conditions and on some of the primary controls on carbon storage in the ocean and in the land. These uncertainties prevent an unambiguous attribution of individual mechanisms as controllers of the low glacial CO₂ concentrations. Further assessments of the interplay of different mechanisms prior to deglacial transitions or in glacial inceptions will likely provide additional insights into the drivers and processes that caused the glacial decrease of CO₂. Since several of these identified drivers (e.g., organic matter remineralization, ocean stratification) are likely to be sensitive to climate change in general, improved understanding drawn from the glacial-interglacial cycles will help constrain the magnitude of future ocean feedbacks on atmospheric CO₂. Other drivers (e.g., iron fertilization) are involved in geoengineering methods (see Glossary), such that improved understanding could also help constrain the potential and applicability of these methods (see Section 6.5.2).

[INSERT FIGURE 6.5 HERE]

Figure 6.5: Mechanisms contributing to carbon dioxide concentrations changes from LGM to late Holocene (top) and from early/mid Holocene (7 ka) to late Holocene (bottom). Filled black circles represent individual model-based estimates for individual ocean, land, geological or human mechanisms. Solid color bars represent expert judgment (to the nearest 5 ppm) rather than a formal statistical average. References for the different model results used for explaining CO₂ changes from LGM to late Holocene are as per (Kohfeld and Ridgwell, 2009) with excluded model projections in grey. References for the different model results used for explaining CO₂ changes during the Holocene are: Joos et al. (2004), Brovkin et al. (2008), Kleinen et al. (2010), Broecker et al. (1999), Ridgwell et al. (2003), Brovkin et al. (2002), Schurgers et al. (2006), Yu (2011), (Kleinen et al., 2012), Ruddiman (2003), Ruddiman (2007), Strassmann et al. (2008), Olofsson and Hickler (2008), Pongratz et al. (2009), Kaplan et al. (2011), Lemmen (2009), Stocker et al. (2011), Roth and Joos (2012). Confidence levels for each mechanism are indicated in the left column — H for high confidence, M for medium confidence and L for low confidence.

6.2.1.2 Processes Controlling Glacial CH₄ and N₂O

Ice core measurements show that atmospheric CH₄ and N₂O were much lower under glacial conditions compared to interglacial ones. Their reconstructed history encompasses the last 800 ka (Loulergue et al., 2008; Schilt et al., 2010a). Glacial CH₄ mixing ratios are in the 350–400 ppb range during the eight glacial maxima covered by the ice core record. This is about half the levels observed during interglacial conditions. The N₂O concentration amounts to 202 ± 8 ppb at the LGM, compared to the early Holocene levels of about 270 ppb (Flückiger et al., 1999).

CH₄ and N₂O isotopic ratio measurements in ice cores provide important constraints on the mechanisms responsible for their temporal changes. N₂O isotopes suggest a similar increase in marine and terrestrial N₂O emissions during the last deglaciation (Sowers et al., 2003). Marine sediment proxies of ocean oxygenation suggest that most of the observed N₂O deglacial rise was of marine origin (Jaccard and Galbraith, 2011). δD and ¹⁴C isotopic composition measurements of CH₄ have shown that catastrophic methane hydrate degassing events are unlikely to have caused the last deglaciation CH₄ increase (Sowers, 2006; Petrenko et al., 2009; Bock et al., 2010). δ¹³C and δD measurements of CH₄ combined with inter-polar atmospheric CH₄ gradient changes (Greenland minus Antarctica ice cores) suggest that most of the deglacial CH₄ increase was caused by increased emissions from boreal and tropical wetlands and an increase in CH₄ atmospheric residence time due to a reduced oxidative capacity of the atmosphere (Fischer et al., 2008). The biomass burning source apparently changed little on the same time scale, whereas this CH₄ source experienced large fluctuations over the last millennium (Mischler et al., 2009; Wang et al., 2010b). Recent modelling studies however suggest that changes in the atmospheric oxidising capacity of the atmosphere at the LGM are probably negligible compared to changes in sources (Levine et al., 2011) and that tropical temperature influencing tropical wetlands and global vegetation were the dominant controls for CH₄ atmospheric changes on glacial-interglacial time-scales (Konijnendijk et al., 2011).

6.2.1.3 Processes Controlling Changes in CO₂, CH₄ and N₂O During Abrupt Glacial Events

Ice core measurements of CO₂, CH₄ and N₂O show sharp (millennial-scale) changes in the course of glaciations, associated with the so-called Dansgaard/Oeschger (DO) climatic events (see Section 5.6.1), but their amplitude, shape and timing differ. During these millennial scale climate events, atmospheric CO₂ concentrations varied by about 20 ppm, in phase with Antarctic, but not with Greenland temperatures. CO₂ increased during cold (stadial) periods in Greenland, several thousands years before the time of the rapid warming event in Greenland (Ahn and Brook, 2008). CH₄ and N₂O showed rapid transitions in phase with Greenland temperatures with little or no lag. CH₄ changes are in the 50–200 ppb range (Flückiger et al., 2004), in phase with Greenland temperature warming at a decadal time scale (Huber et al., 2006). N₂O changes are large, of same magnitude than glacial-interglacial changes, and for the warmest and longest DO events N₂O starts to increase several centuries before Greenland temperature and CH₄ (Schilt et al., 2010b).

Conflicting hypotheses exist on the drivers of these millennial-scale changes. Some model simulations suggest that both CO₂ and N₂O fluctuations can be explained by changes in the Atlantic meridional overturning ocean circulation (Schmittner and Galbraith, 2008), CO₂ variations being mainly explained by changes in the efficiency of the biological pump which affects deep ocean carbon storage (Bouttes et al., 2011), whereas N₂O variations could be due to changes in productivity and oxygen concentrations in the subsurface ocean (Schmittner and Galbraith, 2008). Other studies, however, suggest that the millennial-scale CO₂ fluctuations can be explained by changes in the land carbon storage (Menviel et al., 2008; Bozbiyik et al., 2011). For CH₄, models have difficulties in reproducing changes in wetland emissions compatible with DO atmospheric variations (Hopcroft et al., 2011), and the changes in the atmospheric oxidizing capacity of the atmosphere during DO events seem to be too weak to explain the CH₄ changes (Levine et al., 2012).

6.2.2 GHG Changes over the Holocene

6.2.2.1 Understanding Processes Underlying Holocene CO₂ Changes

The evolution of the atmospheric CO₂, CH₄, and N₂O concentrations during the Holocene, the interglacial period which began 11.7 ka ago, is known with high certainty from ice core measurements (Figure 6.6). A decrease in atmospheric CO₂ of about 7 ppm is measured in ice cores between 11 to 7 ka, followed by a 20 ppm CO₂ increase until the onset of the Industrial Era in 1750 (Indermühle et al., 1999; Monnin et al., 2004; Elsig et al., 2009). These variations in atmospheric CO₂ over the past 11,000 years preceding

industrialization are more than five times smaller than the CO₂ increase observed during the Industrial Era (see Section 6.3.2.3). Despite the small magnitude of CO₂ variations prior to the Industrial Era, these changes are nevertheless useful for understanding the role of natural forcing in carbon and other biogeochemical cycles during interglacial climate conditions.

[INSERT FIGURE 6.6 HERE]

Figure 6.6: Variations of CO₂, CH₄, and N₂O concentrations during the Holocene. The data are for Antarctic ice cores: EPICA Dome C (Flückiger et al., 2002; Monnin et al., 2004), triangles; EPICA Dronning Maud Land (Schilt et al., 2010b), crosses; Law Dome (MacFarling-Meure et al., 2006), circles; and for Greenland ice core GRIP (Blunier et al., 1995), squares. Lines correspond to spline fits.

Since the IPCC AR4, the mechanisms underlying the observed 20 ppm CO₂ increase between 7 ka and the Industrial Era have been a matter of intensive debate. During three interglacial periods prior to the Holocene, CO₂ did not increase, and this led to a hypothesis that pre-industrial anthropogenic CO₂ emissions could be associated with early land use change and forest clearing (Ruddiman, 2003, 2007). However, ice core CO₂ data (Siegenthaler et al., 2005b) indicate that during Marine Isotope Stage 11 (see Chapter 5, Section 5.2.2), an interglacial period that lasted from 400 to 420 ka, CO₂ increased similarly to the Holocene period. Drivers of atmospheric CO₂ changes during the Holocene can be divided into oceanic and terrestrial processes (Figure 6.5) and their roles are examined below.

Oceanic processes. The change in oceanic carbonate chemistry could explain the slow atmospheric CO₂ increase during the Holocene since 7 ka. Proposed mechanisms include: (1) a shift of oceanic carbonate sedimentation from deep sea to the shallow waters due to sea level rise onto continental shelves causing accumulation of CaCO₃ on shelves including coral reef growth, a process that releases CO₂ to the atmosphere (Ridgwell et al., 2003; Kleinen et al., 2010), (2) a ‘carbonate compensation’ in response to the release of carbon from the deep ocean during deglaciation and to the build-up of terrestrial biosphere in the early Holocene (Broecker et al., 1999; Joos et al., 2004; Elsig et al., 2009; Menviel and Joos, 2012). Proxies for carbonate ion concentration in the deep sea (Yu et al., 2010) and a decrease in modern CaCO₃ preservation in equatorial Pacific sediments (Anderson et al., 2008) support the hypothesis that the ocean was a source of CO₂ to the atmosphere during the Holocene. Changes in sea surface temperatures (SST) over the last 7 ka (Kim et al., 2004) could have contributed to slightly lower (Brovkin et al., 2008) or higher (Menviel and Joos, 2012) atmospheric CO₂ concentration but, very likely, SST-driven CO₂ change represents only a minor contribution to the observed CO₂ increase during the Holocene after 7 ka (Figure 6.5).

Terrestrial processes. The δ¹³C of atmospheric CO₂ trapped in ice cores can be used to infer changes in terrestrial biospheric carbon pools. Calculations based on inferred δ¹³C of atmospheric CO₂ during the Holocene suggest an increase in terrestrial carbon storage of about 300 PgC between 11 and 5 ka and small overall terrestrial changes thereafter (Elsig et al., 2009). Modelling studies suggest that CO₂ fertilization (Box 6.3) in response to increasing atmospheric CO₂ concentration after 7 ka contributed to a substantially increased terrestrial carbon storage (>100 PgC) on Holocene timescales (Kaplan et al., 2002; Joos et al., 2004; Kleinen et al., 2010). Orbitally forced climate variability, including the intensification and decline of the Afro-Asian monsoon and the mid-Holocene warming of the high-latitudes of the Northern Hemisphere are estimated in models to have caused changes in vegetation distribution and hence of terrestrial carbon storage. These climate-induced carbon storage changes are estimated using models to have been smaller than the increase due to CO₂ fertilisation (Brovkin et al., 2002; Schurgers et al., 2006). The Holocene accumulation of carbon in peatland has been reconstructed globally, suggesting a land carbon additional storage of several hundred PgC between the early Holocene and the Industrial Era, although uncertainties remain on this estimate (Tarnocai et al., 2009; Yu, 2011; Kleinen et al., 2012). Volcanic CO₂ emissions to the atmosphere between 12 and 7 ka were estimated to be two to six times higher than during the last millennium, of about 0.1 PgC yr⁻¹ (Huybers and Langmuir, 2009; Roth and Joos, 2012). However, a peak in the inferred volcanic emissions coincides with the period of decreasing atmospheric CO₂ and the *confidence* in changes of volcanic CO₂ emissions is *low*.

Global syntheses of the observational, paleoecological and archaeological records for Holocene land use change are not currently available (Gaillard et al., 2010). Available reconstructions of anthropogenic land use and land cover change (LULCC) prior to the last millennium currently extrapolate using models and

assumptions from single regions to changes in all regions of the world (Goldewijk et al., 2011; Kaplan et al., 2011). Because of regional differences in land use systems and uncertainty in historical population estimates, the *confidence* in spatially explicit LULCC reconstructions is *low*.

Some recent studies focused on reconstructing LULCC and making very simple assumptions regarding the effect of land use on carbon (Olofsson and Hickler, 2008; Lemmen, 2009). Other studies relied on more sophisticated terrestrial biosphere models to simulate carbon storage and loss in response to pre-industrial LULCC during the late Holocene (Strassmann et al., 2008; Pongratz et al., 2009; Stocker et al., 2011). The conclusion of the above studies was that cumulative Holocene carbon emissions as a result of pre-industrial LULCC were not large enough (~50–150 PgC during the Holocene before 1850) to have had an influence larger than an increase of ~10 ppm on late Holocene observed CO₂ concentration increase (Figure 6.5). However, a modelling study by Kaplan et al. (2011) suggested that more than 350 PgC could have been released as a result of LULCC between 8 ka and 1850 as a result of a much stronger loss of soil carbon in response to land use change, than in other studies.

In addition to clearing of forests, large-scale biomass burning activity, inferred from synthesized charcoal records and bog sediments has been hypothesized to correlate with the observed Late Holocene atmospheric CO₂ (Carcaillet et al., 2002). A global extensive synthesis of charcoal records for the last 21,000 years (Power et al., 2008) and updates of those shows that fire activity followed climate variability on global (Marlon et al., 2008; Daniu et al., 2012) and regional scale (Archibald et al., 2009; Mooney et al., 2011; Marlon et al., 2012; Power et al., 2013). There is no evidence, however, for a distinct change in fire activity linked to human activity alone as hypothesized from a regional charcoal record synthesis for the tropical Americas (Nevle and Bird, 2008; Nevle et al., 2011). Fire being a newly studied component, no estimate for its role is given in Figure 6.5.

6.2.2.2 *Holocene CH₄ and N₂O Drivers*

The atmospheric CH₄ levels decreased from the early Holocene to about 6 ka, were lowest at around 5 ka, and increased between 5 ka and year 1750 by about 100 ppb (Figure 6.6). Major Holocene agricultural developments, in particular rice paddy cultivation and widespread domestication of ruminants, have been proposed as an explanation for the Late Holocene CH₄ rise (Ruddiman, 2007). The most recent syntheses of archaeological data point to an increasing anthropogenic CH₄ source from domesticated ruminants after 5 ka and from rice cultivation after 4 ka (Ruddiman, 2007; Fuller et al., 2011). The modeling support for either natural or anthropogenic explanations of the Late Holocene increase in the atmospheric CH₄ concentration is equivocal. A study by Kaplan et al. (2006) suggested that a part of the Late-Holocene CH₄ rise could be explained by anthropogenic sources. Natural wetland CH₄ models driven by simulated climate changes are able (Singarayer et al., 2011) or unable (Konijnendijk et al., 2011) to simulate Late Holocene increase in the CH₄ concentration, reflecting a large spread in present-day CH₄ emissions simulated by this type of models (Melton et al., 2013; see Section 6.3.3.2). The mechanisms causing the N₂O concentration changes during the Holocene are not firmly identified (Flückiger et al., 2002).

6.2.3 *GHG Changes over the Last Millennium*

6.2.3.1 *A Decrease of CO₂ around Year 1600 and Possible Explanations for this Event*

High resolution ice cores records reveal that atmospheric CO₂ during the last millennium varied with a drop in atmospheric CO₂ concentration by 7–10 ppm around year 1600, followed by a CO₂ increase during the 17th century (Trudinger et al., 2002; Siegenthaler et al., 2005a; MacFarling-Meure et al., 2006; Ahn et al., 2012). This is shown in Figure 6.7. The CO₂ decrease during the 17th century was used to evaluate the response of atmospheric CO₂ concentration to a century-scale shift in global temperature (Scheffer et al., 2006; Cox and Jones, 2008; Frank et al., 2010) which was found to be dependent on the choice of global temperature reconstructions used in the model.

[INSERT FIGURE 6.7 HERE]

Figure 6.7: Variations of CO₂, CH₄, and N₂O during 900–1900 from ice cores. The data are for Antarctic ice cores: Law Dome (Etheridge et al., 1996; MacFarling-Meure et al., 2006), circles; West Antarctic Ice Sheet (Mitchell et al.,

2011; Ahn et al., 2012), triangles; Dronning Maud Land (Siegenthaler et al., 2005a), squares. Lines are spline fits to individual measurements.

One of the possible explanations for the drop in atmospheric CO₂ around year 1600 is enhanced land and/or ocean carbon uptake in response to the cooling caused by reduced solar irradiance during the Maunder Minimum (Chapter 5, Section 5.3.5.3). However, simulations using EMIC models (Gerber et al., 2003; Brovkin et al., 2004) and by complex ESM models (Jungclaus et al., 2010) suggest that solar irradiance forcing alone is not sufficient to explain the magnitude of the CO₂ decrease. The drop in atmospheric CO₂ around year 1600 could also be caused by a cooling from increased volcanic eruptions (Jones and Cox, 2001; Brovkin et al., 2010; Frölicher et al., 2011). A third hypothesis calls for a link between CO₂ and epidemics and wars associated with forest regrowth over abandoned lands and increased carbon storage, especially in Central America. Here, results are model- and scenario dependent. Simulations by Pongratz et al. (2011a) do not reproduce a decrease in CO₂, while simulations by Kaplan et al. (2011) suggest a considerable increase in land carbon storage around year 1600. The temporal resolution of Central American charcoal and pollen records is insufficient to support or falsify these model results (e.g., Nevle and Bird, 2008; Marlon et al., 2008).

Ensemble simulations over the last 1200 years have been conducted using an ESM (Jungclaus et al., 2010) and EMICs (Eby et al., 2013) including a fully-interactive carbon cycle. The sensitivity of atmospheric CO₂ concentration to Northern Hemisphere temperature changes in ESM was modeled to be of 2.7–4.4 ppm K⁻¹, while EMICs show on average a higher sensitivity of atmospheric CO₂ to global temperature changes of 8.6 ppm K⁻¹. These sensitivities fall within the range of 1.7–21.4 ppm K⁻¹ of a recent reconstruction based on tree-ring Northern Hemisphere temperature reconstructions (Frank et al., 2010).

6.2.3.2 Mechanisms Controlling CH₄ and N₂O during the Last Millennium

Recent high-resolution ice core records confirm a CH₄ decrease in the late 16th century by about 40 ppb (MacFarling-Meure et al., 2006; Mitchell et al., 2011), as shown in Figure 6.7. Correlations between this drop in atmospheric CH₄ and the lower temperatures reconstructed during the 15th and 16th centuries suggest that climate change may have reduced CH₄ emissions by wetlands during this period. Additionally to changes in the wetland CH₄ source, changes in biomass burning have been invoked to explain the Last Millennium CH₄ record (Ferretti et al., 2005; Mischler et al., 2009), ice core CO and CO isotopes (Wang et al., 2010b) and global charcoal depositions (Marlon et al., 2008). Changes in anthropogenic CH₄ emissions during times of war and plague hypothetically contributed to variability in atmospheric CH₄ concentration (Mitchell et al., 2011). Ice core δ¹³CH₄ measurements suggested pronounced variability in both natural and anthropogenic CH₄ sources over the 1000–1800 period (Sapart et al., 2012). No studies are known about mechanisms of N₂O changes for the last millennium.

6.3 Evolution of Biogeochemical Cycles Since the Industrial Revolution

6.3.1 CO₂ Emissions and Their Fate Since 1750

Prior to the Industrial Era, that began in 1750, the concentration of atmospheric CO₂ fluctuated roughly between 180 ppm and 290 ppm for at least 2.1 million years (see Chapter 5, Section 5.2.2 and Hönisch et al., 2009; Lüthi et al., 2008; Petit et al., 1999). Between 1750 and 2011, the combustion of fossil fuels (coal, gas, oil, and gas flaring) and the production of cement have released 365 ± 30 PgC (1 Pg C = 10¹⁵ gC) to the atmosphere (Table 6.1; Boden et al., 2011). Land use change activities, mainly deforestation, has released an additional 180 ± 80 PgC (Table 6.1). This carbon released by human activities is called anthropogenic carbon.

Table 6.1: Global anthropogenic CO₂ budget, accumulated since the Industrial Revolution (onset in 1750) and averaged over the 1980s, 1990s, 2000s, as well as the last ten years until 2011. By convention, a negative ocean or land to atmosphere CO₂ flux is equivalent to a gain of carbon by these reservoirs. The table does not include natural exchanges (e.g., rivers, weathering) between reservoirs. The uncertainty range of 90% confidence interval presented here differs from how uncertainties were reported in AR4 (68%).

1750–2011 Cumulative	1980–1989	1990–1999	2000–2009	2002–2011
-------------------------	-----------	-----------	-----------	-----------

	PgC	PgC yr ⁻¹	PgC yr ⁻¹	PgC yr ⁻¹	PgC yr ⁻¹
Atmospheric increase ^a	240 ± 10 ^f	3.4 ± 0.2	3.1 ± 0.2	4.0 ± 0.2	4.3 ± 0.2
Fossil fuel combustion and cement production ^b	365 ± 30 ^f	5.5 ± 0.4	6.4 ± 0.5	7.8 ± 0.6	8.3 ± 0.7
Ocean-to-atmosphere flux ^c	-155 ± 30 ^f	-2.0 ± 0.7	-2.2 ± 0.7	-2.3 ± 0.7	-2.4 ± 0.7
Land-to-atmosphere flux	30 ± 45 ^f	-0.1 ± 0.8	-1.1 ± 0.9	-1.5 ± 0.9	-1.6 ± 1.0
<i>Partitioned as follows</i>					
Net land use change ^d	180 ± 80 ^{f,g}	1.4 ± 0.8	1.6 ± 0.8	1.1 ± 0.8	0.9 ± 0.8
Residual terrestrial flux ^e	-150 ± 90 ^f	-1.5 ± 1.1	-2.7 ± 1.2	-2.6 ± 1.2	-2.5 ± 1.3

Notes:

(a) Data from Charles D. Keeling, (<http://scrippsco2.ucsd.edu/data/data.html>), Thomas Conway and Pieter Tans, NOAA/ESRL (www.esrl.noaa.gov/gmd/ccgg/trends/) using a conversion factor of 2.120 Pg C per ppm (Prather et al., 2012). Prior to the atmospheric record in 1960, ice core data is used (Neftel et al., 1982; Friedli et al., 1986; Etheridge et al., 1996).

(b) Estimated by the Carbon Dioxide Information Analysis Center (CDIAC) based on UN energy statistics for fossil fuel combustion (up to 2009) and US Geological Survey for cement production (Boden et al., 2011), and updated to 2011 using BP energy statistics.

(c) Based on observations for 1990–1999, with the trends based on existing global estimates (see 6.3.2.5 and Table 6.4).

(d) Based on the “bookkeeping” land use change flux accounting model of Houghton et al. (2012) until 2010, and assuming constant LUC emissions for 2011, consistent with satellite-based fire emissions (Le Quéré et al., 2013; see 6.3.2.2. and Table 6.2).

(e) Calculated as the sum of the Land-to-atmosphere flux minus Net land use change flux, assuming the errors on each term are independent and added quadratically.

(f) The 1750–2011 estimate and its uncertainty is rounded to the nearest 5 PgC.

(g) Estimated from the cumulative net land use change emissions of Houghton et al. (2012) during 1850–2011 and the average of four publications (Pongratz et al., 2009; van Minnen et al., 2009; Shevliakova et al., 2009; and Zaehle et al., 2011) during 1750–1850.

[INSERT FIGURE 6.8 HERE]

Figure 6.8: Annual anthropogenic CO₂ emissions and their partitioning among the atmosphere, land and ocean (PgC yr⁻¹) from 1750 to 2011. (Top) Fossil fuel and cement CO₂ emissions by category, estimated by the Carbon Dioxide Information Analysis Center (CDIAC) based on UN energy statistics for fossil fuel combustion and US Geological Survey for cement production (Boden et al., 2011). (Bottom) Fossil fuel and cement CO₂ emissions as above. CO₂ emissions from net land use change, mainly deforestation, are based on land cover change data and estimated for 1750–1850 from the average of four models (Pongratz et al., 2009; Shevliakova et al., 2009; van Minnen et al., 2009; Zaehle et al., 2011) before 1850 and from Houghton et al. (2012) after 1850 (see Table 6.2). The atmospheric CO₂ growth rate (term in light blue “atmosphere from measurements” in the figure) prior to 1959 is based on a spline fit to ice core observations (Neftel et al., 1982; Friedli et al., 1986; Etheridge et al., 1996) and a synthesis of atmospheric measurements from 1959 (Ballantyne et al., 2012). The fit to ice core observations does not capture the large interannual variability in atmospheric CO₂ and is represented with a dashed line. The ocean CO₂ sink prior to 1960 (term in dark blue “ocean from indirect observations and models” in the figure) is from Khatiwala et al. (2009) and from a combination of models and observations from 1960 from (Le Quéré et al., 2013). The residual terrestrial sink (term in green in the figure) is computed from the residual of the other terms. The emissions and their partitioning only include the fluxes that have changed since 1750, and not the natural CO₂ fluxes (e.g., atmospheric CO₂ uptake from weathering, outgassing of CO₂ from lakes and rivers, and outgassing of CO₂ by the ocean from carbon delivered by rivers; see Figure 6.1) between the atmosphere, land and ocean reservoirs that existed before that time and still exist today. The uncertainties in the various terms are discussed in the text and reported in Table 6.1 for decadal mean values.

Of the 545 ± 85 PgC of anthropogenic carbon emitted to the atmosphere from fossil fuel and cement and land use change, less than half have accumulated in the atmosphere (240 ± 10 PgC) (Table 6.1). The remaining anthropogenic carbon has been absorbed by the ocean and in terrestrial ecosystems: the carbon ‘sinks’ (Figure 6.8). The ocean stored 155 ± 30 PgC of anthropogenic carbon since 1750 (see Section 6.3.2.5.3 and Box 6.1). Terrestrial ecosystems that have not been affected by land use change since 1750, have accumulated 150 ± 90 PgC of anthropogenic carbon since 1750 (Table 6.1), thus not fully compensating the net CO₂ losses from terrestrial ecosystems to the atmosphere from land use change during the same period estimated of 180 ± 80 PgC (Table 6.1). The net balance of all terrestrial ecosystems, those affected by land use change and the others, is thus close to neutral since 1750, with an average loss of 30 ± 45 (see Figure 6.1). This increased storage in terrestrial ecosystems not affected by land use change is likely

to be caused by enhanced photosynthesis at higher CO₂ levels and N deposition, and changes in climate favouring carbon sinks such as longer growing seasons in mid-to-high latitudes. Forest area expansion and increased biomass density of forests that result from changes in land use change are also carbon sinks, and they are accounted in Table 6.1 as part of the net flux from land use change. The increased terrestrial carbon storage in ecosystems not affected by land use change is called the Residual terrestrial sink in Table 6.1 because it is inferred from mass balance as the difference between fossil and net land use change emissions and measured atmospheric and oceanic storage increase.

6.3.2 Global CO₂ Budget

Since the IPCC AR4 (Denman et al., 2007), a number of new advancements in data availability and data-model synthesis have allowed the establishment of a more constrained anthropogenic CO₂ budget and better attribution of its flux components. The advancements are: (1) revised data on the rates of land use change conversion from country statistics (FAO, 2010) now providing an arguably more robust estimate of the land use change flux (Houghton et al., 2012; Section 6.3.2.2); (2) a new global compilation of forest inventory data that provides an independent estimate of the amount of carbon that has been gained by forests over the past two decades, albeit with very scarce measurements for tropical forest (Pan et al., 2011); (3) over 2 million new observations of the partial pressure of CO₂ at the ocean surface (pCO₂) have been taken and added to the global databases (Takahashi et al., 2009; Pfeil et al., 2013) and used to quantify ocean CO₂ sink variability and trends (Section 6.3.2.5) and to evaluate and constrain models (Schuster et al., 2013; Wanninkhof et al., 2013); and (4) the use of multiple constraints with atmospheric inversions and combined atmosphere-ocean inversions (so called top down approaches; Jacobson et al., 2007) and the up-scaling of reservoir-based observations using models (so called bottom up approaches) provides new coarse scale consistency checks on CO₂ flux estimates for land and ocean regions (McGuire et al., 2009; Piao et al., 2009b; Schulze et al., 2009; Ciais et al., 2010; Schuster et al., 2013). The causes of the year-to-year variability observed in the annual atmospheric CO₂ accumulation shown in Figure 6.8 are estimated with a *medium to high confidence* to be mainly driven by terrestrial processes occurring in tropical latitudes as inferred from atmospheric CO₂ inversions and supported by ocean data and models (Bousquet et al., 2000; Raupach et al., 2008; Sarmiento et al., 2010) (Figures 6.9 and 6.13; Section 6.3.2.5) and land models (Figure 6.16; Section 6.3.2.6).

[INSERT FIGURE 6.9 HERE]

Figure 6.9: Interannual surface CO₂ flux anomalies from inversions of the TRANSCOM project for the period 1981–2010 (Peylin et al., 2013). The ensemble of inversion results contains up to 17 atmospheric inversion models. The orange bars in the bottom panel indicate the number of available inversion models for each time period. The ensemble mean is bounded by the 1 sigma inter-model spread in ocean-atmosphere (blue) and land-atmosphere (green) CO₂ fluxes (PgC yr⁻¹) grouped into large latitude bands, and the global. For each flux and each region, the CO₂ flux anomalies were obtained by subtracting the long-term mean flux from each inversion and removing the seasonal signal. Grey shaded regions indicate El Niño episodes, and the black bars indicate the cooling period following the Mt. Pinatubo eruption, during which the growth rate of CO₂ remained low. A positive flux means a larger than normal source of CO₂ to the atmosphere (or a smaller CO₂ sink).

6.3.2.1 CO₂ Emissions from Fossil Fuel Combustion and Cement Production

Global CO₂ emissions from the combustion of fossil fuels used for this chapter are determined from national energy consumption statistics and converted to emissions by fuel type (Marland and Rotty, 1984). Estimated uncertainty for the annual global emissions are on the order of ±8% (converted from ±10% uncertainty for 95% confidence intervals in Andres et al. (2012) to the 90% confidence intervals used here). The uncertainty has been increasing in recent decades because a larger fraction of the global emissions originate from emerging economies where energy statistics and emission factors per fuel type are more uncertain (Gregg et al., 2008). CO₂ emissions from cement production were 4% of the total emissions during 2000–2009, compared to 3% in the 1990s (Boden et al., 2011). Additional emissions from gas flaring represent <1% of the global emissions.

Global CO₂ emissions from fossil fuel combustion and cement production were 7.8 ± 0.6 PgC yr⁻¹ on average during 2000–2009, 6.4 ± 0.5 PgC yr⁻¹ during 1990–1999, and 5.5 ± 0.4 PgC yr⁻¹ during 1980–1989 (Table 6.1; Figure 6.8). Global fossil fuel CO₂ emissions increased by 3.2% yr⁻¹ on average during the decade 2000–2009 compared to 1.0% yr⁻¹ in the 1990s and 1.9% yr⁻¹ in the 1980s. Francey et al. (2013)

recently suggested a cumulative underestimation of 8.8 PgC emissions during the period 1993–2004, which would reduce the contrast in emissions growth rates between the two decades. The global financial crisis in 2008–2009 induced only a short-lived drop in global emissions in 2009 (–0.3%), with the return to high annual growth rates of 5.1% and 3.0% in 2010 and 2011, respectively, and fossil fuel and cement CO₂ emissions of 9.2 ± 0.8 PgC in 2010 and 9.5 ± 0.8 PgC in 2011 (Peters et al., 2013).

6.3.2.2 Net Land Use Change CO₂ Flux

CO₂ is emitted to the atmosphere by land use and land use change activities, in particular deforestation, and taken up from the atmosphere by other land uses such as afforestation (the deliberate creation of new forests) and vegetation regrowth on abandoned lands. A critical distinction in estimating land use change is the existence of gross and net fluxes. Gross fluxes are the individual fluxes from multiple processes involved in land use change that can be either emissions to or removals from the atmosphere occurring at different time scales. For example, gross emissions include instantaneous emissions from deforestation fires and long-term emissions from the decomposition of organic carbon; and they also include the long-term CO₂ uptake by forest regrowth and soil carbon storage on abandoned agricultural lands, afforestation and storage changes of wood products (Houghton et al., 2012; Mason Earles et al., 2012). The net flux of land use change is the balance among all source and sink processes involved in a given timeframe. The net flux of land use change is globally a net source to the atmosphere (Table 6.1; Figure 6.8).

Approaches to estimate global net CO₂ fluxes from land use fall into three categories: (1) the ‘bookkeeping’ method that tracks carbon in living vegetation, dead plant material, wood products and soils with cultivation, harvesting and reforestation using country-level reports on changes in forest area and biome-averaged biomass values (Houghton, 2003); (2) process-based terrestrial ecosystem models that simulate on a grid-basis the carbon stocks (biomass, soils) and exchange fluxes between vegetation, soil, and atmosphere (see references in Table 6.2); and (3) detailed regional (primarily tropical forests) analyses based on satellite data that estimate changes in forest area or biomass (DeFries et al., 2002; Achard et al., 2004; Baccini et al., 2012; Harris et al., 2012). Satellite-derived estimates of CO₂ emissions to the atmosphere from so-called deforestation fires (van der Werf et al., 2010) provide additional constraints on the spatial attribution and variability of land use change gross emissions. Most global estimates do not include emissions from peat burning or decomposition after a land use change, which are estimated to be 0.12 PgC yr^{–1} over 1997–2006 for peat fires (van der Werf et al., 2008) and between 0.10 and 0.23 PgC yr^{–1} from the decomposition of drained peat (Hooijer et al., 2010). The processes and time scales captured by these methods to estimate net land use change CO₂ emissions are diverse, creating difficulties with comparison of different estimates (Houghton et al., 2012; Table 6.2). The bookkeeping method of Houghton et al. (2012) was used for Table 6.1 because it is closest to observations and includes the most extensive set of management practices (Table 6.2). Methods that do not include long-term ‘legacy’ fluxes from soils caused by deforestation (Table 6.2) underestimate net land use change CO₂ emissions by 13–62% depending on the starting year and decade (Ramankutty et al., 2006), and methods that do not include the fate of carbon wood harvest and shifting cultivation underestimate CO₂ emissions by 25–35% (Houghton et al., 2012).

Table 6.2: Estimates of net land to atmosphere CO₂ flux from land use change covering recent decades (PgC yr^{–1}). Positive values indicate CO₂ losses to the atmosphere. Various forms of land management are also included in the different estimates, including W=wood harvest, C=shifting cultivation, and H=harvesting of crops, and P=peat burning and peat drainage. All methods include the vegetation degradation after land clearance. Additional processes included are I=initial biomass loss during the year of deforestation, D=decomposition of slash and soil carbon during the year of initial loss, R=regrowth, S=change in storage in wood products pools, C=the effect of increasing CO₂, M=the effect of observed climate variability between decades, L=‘legacy’ long-term decomposition flux carried over from land use change transitions prior to start of time period used for reporting in the table. In the absence of data on L in the assessed estimates, the studies have either assumed I = instantaneous loss of all biomass and soil carbon (a committed future flux) or did not consider the legacy flux L. Satellite-based methods have examined LUC emissions in the tropical regions only. Numbers in parentheses are ranges in uncertainty provided in some studies.

Notes:

(a) References for the databases used: FAO (2010) as applied in Houghton et al. (2012); FAO (2005) as applied in Houghton (2003), updated; GFED (van der Werf et al., 2009); HYDE (Goldewijk et al., 2011), SAGE (Ramankutty and Foley, 1999). Landsat and AVHRR are satellite-based data and GFED is derived from satellite products as described in the references.

(b) Based on average estimates by biomes compiled from literature data (see details in corresponding references).

(c) 1990–1997 only.

(d) Legacy fluxes for land cover change prior to 1980 are not included and are estimated to add about 0.2 PgC yr⁻¹ to the 1980s and 0.1 PgC yr⁻¹ to the 1990s estimates, based on Ramankutty et al. (2006).

(e) The vegetation and soil biomass is computed using a vegetation model described in the reference.

(f) 1997–2006 average based on estimates of carbon emissions from deforestation and degradation fires, including peat fires and oxidation. Estimates were doubled to account for emissions other than fire including respiration of leftover plant materials and soil carbon following deforestation following (Olivier et al., 2005).

(g) Method as described in the reference but updated to 2010 using the land cover change data listed in column 2.

- (h) The large variability produced by the calculation method is removed for comparison with other studies by averaging the flux over the two decades.
- (i) Average of estimates from all process models and 90% confidence uncertainty interval; note that the spread of the different estimates does not follow a Gaussian distribution.

Global net CO₂ emissions from land use change are estimated at 1.4, 1.5, and 1.1 PgC yr⁻¹ for the 1980s, 1990s and 2000s, respectively, by the bookkeeping method of Houghton et al. (2012) (Table 6.2; Figure 6.10). This estimate is consistent with global emissions simulated by process-based terrestrial ecosystem models using mainly three land cover change data products as input for time-varying maps of land use change (Table 6.2). The bookkeeping method estimate is also generally consistent although higher than the satellite-based methods (tropics only). Part of the discrepancy can be accounted for by emissions from extratropical regions (~0.1 PgC yr⁻¹; Table 6.3) and by legacy fluxes for land cover change prior to 1980s (~0.2 PgC yr⁻¹) that are not covered by satellite-based methods used in Table 6.2, and by the fact that the bookkeeping method accounts for degradation and shifting agriculture CO₂ losses not detected in the satellite-based method reported in Table 6.2. We adopt an uncertainty of ±0.8 PgC yr⁻¹ as representative of 90% uncertainty intervals. This is identical to the uncertainty of ±0.5 PgC yr⁻¹ representing ±1 sigma interval (68% if Gaussian distributed error) from Houghton et al. (2012). This uncertainty of ±0.8 PgC yr⁻¹ on net land use change CO₂ fluxes is smaller than the one that was reported in AR4 of 0.5 to 2.7 PgC yr⁻¹ for the 1990s (68% confidence interval). In this chapter, uncertainty is estimated based on expert judgment of the available evidence, including improved accuracy of land cover change incorporating satellite data, the larger number of independent methods to quantify emissions and the consistency of the reported results (Table 6.2; Figure 6.10).

Different estimates of net land use change CO₂ emissions are shown in Figure 6.10. The lower net land use change CO₂ emissions reported in the 2000s compared to the 1990s, by 0.5 PgC yr⁻¹ in the bookkeeping method based on FAO (2010), and by 0.3–0.5 PgC yr⁻¹ from five process-based ecosystem models based on the HYDE land cover change data updated to 2009 (Goldewijk et al., 2011), is within the error bar of the data and methods. The bookkeeping method suggests that most of the LUC emissions originates from Central and South America, Africa and Tropical Asia since the 1980s (Table 6.3). The process models based on the HYDE database allocate about 30% of the global land use change emissions to East Asia, but this is difficult to reconcile with the large afforestation programmes reported in this region. Inconsistencies in the available land cover change reconstructions and in the modelling results prevent a firm assessment of recent trends and their partitioning among regions (see regional data in Table 6.3).

[INSERT FIGURE 6.10 HERE]

Figure 6.10: Net land use change CO₂ emissions (PgC yr⁻¹). All methods are based on land cover change data (see Table 6.2) and are smoothed with a 10 year filter to remove interannual variability. The bookkeeping estimate of Houghton et al. (2012) (thick black over 1850–2011) and the average of four process models (dash black) over 1750–1850 (see 6.3.2.2) are used in Table 6.1. The process model results for net land use change CO₂ emissions from Table 6.2 are shown in blue. Satellite-based methods are available for the tropics only, from (red) van der Werf et al. (2010), (blue) DeFries et al. (2002), and (green) Achard et al. (2004). Note that the definitions of land use change fluxes vary between models (Table 6.2).

Table 6.3: Estimates of net land to atmosphere flux from land use change (PgC yr⁻¹; except where noted) for decadal periods from 1980s to 2000s by region. Positive values indicate net CO₂ losses from land ecosystems affected by land use change to the atmosphere. Uncertainties are reported as 90% confidence interval (unlike 68% in AR4). Numbers in parentheses are ranges in uncertainty provided in some studies. Tropical Asia includes the Middle East, India and surrounding countries, Indonesia and Papua New Guinea. East Asia includes China, Japan, Mongolia and Korea. N/A indicates not available from the study cited.

Notes:

(a) Method as described in the reference but updated to 2010 using the HYDE land cover change data.

(b) 1997–2006 average based on estimates of CO₂ emissions from deforestation and degradation fires, including peat carbon emissions. Estimates were doubled to account for emissions other than fire including respiration of leftover plant materials and soil carbon following deforestation following (Olivier et al., 2005). Estimates include peat fires and peat soil oxidation. If peat fires are excluded, estimate in tropical Asia is 0.23 and Pan-tropical total is 0.71.

(c) CO₂ estimates were summed for dry and humid tropical forests, converted to C and normalized to annual values. Estimates are based on satellite-derived deforestation area (Hansen et al., 2010), and assume 0.6 fraction of biomass emitted with deforestation. Estimates do not include carbon uptake by regrowth or legacy fluxes from historical deforestation. Estimates cover emissions from 2000 to 2005.

(d) Includes China only.

(e) East Asia and Oceania are averaged in one region. The flux is split in two equally for computing the average; North Africa and the Middle East are combined with Eurasia.

In this chapter, we do not assess individual gross fluxes that sum up to make the net land use change CO₂ emission, because there are too few independent studies. Gross emissions from tropical deforestation and degradation were 3.0 ± 0.5 PgC yr⁻¹ for the 1990s and 2.8 ± 0.5 PgC yr⁻¹ for the 2000s using forest inventory

data, FAO (2010), and the bookkeeping method (Pan et al., 2011). These gross emissions are about double the net emissions because of the presence of a large regrowth that compensates for about half of the gross emissions. A recent analysis estimated a lower gross deforestation of 0.6–1.2 PgC yr⁻¹ (Harris et al., 2012). That study primarily estimated permanent deforestation and excluded additional gross emissions from degraded forests, shifting agriculture and some carbon pools. In fact, gross emissions from permanent deforestation are in agreement between the bookkeeping method of Houghton et al. (2012) and the satellite data analysis of Harris et al. (2012).

Over the 1750–2011 period, cumulative net CO₂ emissions from land use change of 180 ± 80 PgC are estimated (Table 6.1). The uncertainty is based on the spread of the available estimates (Figure 6.10). The cumulative net CO₂ emissions from land use change have been dominated by deforestation and other land use change in the mid northern latitudes prior to 1980s, and in the tropics since the 1980s, largely from deforestation in tropical America and Asia with smaller contributions from tropical Africa. Deforestation from 800 to 1750 has been estimated at 27 PgC using a process-based ecosystem model (Pongratz et al., 2009).

6.3.2.3 Atmospheric CO₂ Concentration Growth Rate

Since the beginning of the Industrial Era (1750), the concentration of CO₂ in the atmosphere has increased by 40%, from 278 ± 5 ppm to 390.5 ± 0.1 ppm in 2011 (Figure 6.11; updated from Ballantyne et al. (2012), corresponding to an increase in CO₂ of 240 ± 10 PgC in the atmosphere. Atmospheric CO₂ grew at a rate of 3.4 ± 0.2 PgC yr⁻¹ in the 1980s, 3.1 ± 0.2 PgC yr⁻¹ in the 1990s, and 4.0 ± 0.2 PgC yr⁻¹ in the 2000s (Conway and Tans, 2011) (Table 6.1). The increase of atmospheric CO₂ between 1750 and 1957, prior to direct measurements in the atmosphere, is established from measurements of CO₂ trapped in air bubbles in ice cores (e.g., Etheridge et al., 1996). After 1957, the increase of atmospheric CO₂ is established from highly precise continuous atmospheric CO₂ concentration measurements at background stations (e.g., Keeling et al., 1976).

[INSERT FIGURE 6.11 HERE]

Figure 6.11: Atmospheric CO₂, CH₄, and N₂O concentrations history over the industrial era (right hand side panels) and from the year 0 to the year 1750 (left hand side panels), determined from air enclosed in ice cores and firm air (color symbols) and from direct atmospheric measurements (blue lines, measurements from the Cape Grim observatory) (MacFarling-Meure et al., 2006).

The ice core record of atmospheric CO₂ during the past century exhibits interesting variations, which can be related to climate induced-changes in the carbon cycle. Most conspicuous is the interval from about 1940 to 1955, during which atmospheric CO₂ concentration stabilized (Trudinger et al., 2002), and the CH₄ and N₂O growth slowed down (MacFarling-Meure et al., 2006), possibly caused by slightly decreasing temperatures over land in the Northern Hemisphere (Rafelski et al., 2009).

There is substantial evidence (e.g., from ¹³C carbon isotopes in atmospheric CO₂, Keeling et al., (2005) that source/sink processes on land generate most of the interannual variability in the atmospheric CO₂ growth rate (Figure 6.12). The strong positive anomalies of the CO₂ growth rate in El Niño years (e.g., 1986/1988 and 1997/1998) originated in tropical latitudes (see Sections 6.3.6.3 and 6.3.2.5.4), while the anomalies in 2003 and 2005 originated in northern mid- latitudes, perhaps reflecting the European heat wave in 2003 (Ciais et al., 2005). Volcanic forcing also contributes to multi-annual variability in carbon storage on land and in the ocean (Jones and Cox, 2001; Gerber et al., 2003; Brovkin et al., 2010; Frölicher et al., 2011).

[INSERT FIGURE 6.12 HERE]

Figure 6.12: (Top) Global average atmospheric CO₂ growth rate, computed from the observations of the SIO network (light green line, Keeling et al., (2005), updated) and from the marine boundary layer air reference measurements of the NOAA-GMD network (dark green line; Conway et al., 1994; Dlugokencky and Tans, 2013). (Bottom) Atmospheric growth rate of CO₂ as a function of latitude determined from the NOAA-ESRL network, representative of stations located in the marine boundary layer at each given latitude (Masarie and Tans, 1995; Dlugokencky and Tans, 2013). Sufficient observations are available only since 1979.

With a *very high level* of confidence, the increase in CO₂ emissions from fossil fuel burning and those arising from land use change are the dominant cause of the observed increase in atmospheric CO₂ concentration. Several lines of evidence support this conclusion:

- The observed decrease in atmospheric O₂ content over past two decades and the lower O₂ content in the northern compared to the southern hemisphere are consistent with the burning of fossil fuels (see Figure 6.3 and Section 6.1.3.2; Keeling et al., 1996; Manning and Keeling, 2006).
- CO₂ from fossil fuels and from the land biosphere has a lower ¹³C/¹²C stable isotope ratio than the CO₂ in the atmosphere. This induces a decreasing temporal trend in the atmospheric ¹³C/¹²C ratio of atmospheric CO₂ concentration as well as, on annual average, slightly lower ¹³C/¹²C values in the Northern Hemisphere (Figure 6.3). These signals are measured in the atmosphere.
- Because fossil fuel CO₂ is devoid of radiocarbon (¹⁴C), reconstructions of the ¹⁴C/C isotopic ratio of atmospheric CO₂ from tree rings show a declining trend, as expected from the addition of fossil CO₂ (Stuiver and Quay, 1981; Levin et al., 2010). Yet nuclear weapon tests in the 1950s and 1960s have been offsetting that declining trend signal by adding ¹⁴C to the atmosphere. After this nuclear weapon induced ¹⁴C pulse in the atmosphere has been ending, the ¹⁴C/C isotopic ratio of atmospheric CO₂ is observed to resume its declining trend (Naegler and Levin, 2009; Graven et al., 2012).
- Most of the fossil fuel CO₂ emissions take place in the industrialized countries north of the equator. Consistent with this, on annual average, atmospheric CO₂ measurement stations in the Northern Hemisphere record increasingly higher CO₂ concentrations than stations in the Southern Hemisphere, as witnessed by the observations from Mauna Loa, Hawaii, and the South Pole (see Figure 6.3). The annually averaged concentration difference between the two stations has increased in proportion of the estimated increasing difference in fossil fuel combustion emissions between the hemispheres (Figure 6.13; Keeling et al., 1989; Tans et al., 1989; Fan et al., 1999).
- The rate of CO₂ emissions from fossil fuel burning and land use change was almost exponential, and the rate of CO₂ increase in the atmosphere was also almost exponential and about half that of the emissions, consistent with a large body of evidence about changes of carbon inventory in each reservoir of the carbon cycle presented in this chapter.

[INSERT FIGURE 6.13 HERE]

Figure 6.13: Blue points: Annually averaged CO₂ concentration difference between the station Mauna Loa in the northern hemisphere and the station South Pole in the southern hemisphere (vertical axis; Keeling et al., 2005, updated) versus the difference in fossil fuel combustion CO₂ emissions between the hemispheres (Boden et al., 2011). Dark red dashed line: regression line fitted to the data points.

6.3.2.4 CO₂ Airborne Fraction

Until recently, the uncertainty in CO₂ emissions from land use change emissions was large and poorly quantified which led to the use of an airborne fraction (see Glossary) based on CO₂ emissions from fossil fuel only (e.g., Figure 7.4 in AR4 and Figure 6.26 of this Chapter). However, reduced uncertainty of emissions from land use change and larger agreement in its trends over time (Section 6.3.2.2) allow to make use of an airborne fraction that includes all anthropogenic emissions. The airborne fraction will increase if emissions are too fast for the uptake of CO₂ by the carbon sinks (Bacastow and Keeling, 1979; Gloor et al., 2010; Raupach, 2013). It is thus controlled by changes in emissions rates, and by changes in carbon sinks driven by rising CO₂, changes in climate and all other biogeochemical changes.

A positive trend in airborne fraction of ~0.3% yr⁻¹ relative to the mean of 0.44 ± 0.06 (or about 0.05 increase over 50 years) was found by all recent studies (Raupach et al., 2008, and related papers; Knorr, 2009; Gloor et al., 2010) using the airborne fraction of total anthropogenic CO₂ emissions over the ~1960–2010 period (for which the most accurate atmospheric CO₂ data are available). However, there is no consensus on the significance of the trend because of differences in the treatment of uncertainty and noise (Raupach et al., 2008; Knorr, 2009). There is also no consensus on the cause of the trend (Canadell et al., 2007b; Raupach et al., 2008; Gloor et al., 2010). Land and ocean carbon cycle model results attributing the trends of fluxes to underlying processes suggest that the effect of climate change and variability on ocean and land sinks have had a significant influence (Le Quéré et al., 2009), including the decadal influence of volcanic eruptions (Frölicher et al., 2013).

6.3.2.5 Ocean CO₂ Sink

6.3.2.5.1 Global ocean sink and decadal change

The estimated mean anthropogenic ocean CO₂ sink assessed in AR4 was 2.2 ± 0.7 PgC yr⁻¹ for the 1990s based on observations (McNeil et al., 2003; Manning and Keeling, 2006; Mikaloff-Fletcher et al., 2006), and is supported by several contemporary estimates (see Chapter 3). Note that the uncertainty of ± 0.7 PgC yr⁻¹ reported here (90% confidence interval) is the same as the ± 0.4 PgC yr⁻¹ uncertainty reported in AR4 (68% confidence intervals). The uptake of anthropogenic CO₂ by the ocean is primarily a response to increasing CO₂ in the atmosphere and is limited mainly by the rate at which anthropogenic CO₂ is transported from the surface waters into the deep ocean (Sarmiento et al., 1992; Graven et al., 2012). This anthropogenic ocean CO₂ sink occurs on top of a very active natural oceanic carbon cycle. Recent climate trends, such as ocean warming, changes in ocean circulation and changes in marine ecosystems and biogeochemical cycles, can have affected both the anthropogenic ocean CO₂ sink as well as the natural air-sea CO₂ fluxes. We report a decadal mean uptake of 2.0 ± 0.7 PgC yr⁻¹ for the 1980s and of 2.3 ± 0.7 PgC yr⁻¹ for the 2000s (Table 6.4). The methods used are: (1) an empirical Green's function approach fitted to observations of transient ocean tracers (Khatiwala et al., 2009), (2) a model-based Green's function approach fitted to anthropogenic carbon reconstructions (Mikaloff-Fletcher et al., 2006), (3) estimates based on empirical relationships between observed ocean surface pCO₂ and temperature and salinity (Park et al., 2010), and (4) process-based global ocean biogeochemical models forced by observed meteorological fields (Doney et al., 2009; Assmann et al., 2010; Le Quéré et al., 2010; Graven et al., 2012). All these different methods suggest that in the absence of recent climate change and climate variability, the ocean anthropogenic CO₂ sink should have increased by 0.23 ± 0.15 PgC yr⁻¹ between the 1980s and the 1990s, and by 0.33 ± 0.13 PgC yr⁻¹ between the 1990s and the 2000s (Figure 6.14). The decadal estimates in the ocean CO₂ sink reported in Table 6.4 as 'CO₂ effects only' are entirely explained by the faster rate of increase of atmospheric CO₂ in the later decade. On the other hand, 'climate effects only' in Table 6.4 are assessed to have no noticeable effect on the sink difference between the 1980s and the 1990s (0.02 ± 0.05 PgC yr⁻¹), but are estimated to have reduced the ocean anthropogenic CO₂ sink by 0.19 ± 0.18 PgC yr⁻¹ between the 1990s and the 2000s (Table 6.4).

Table 6.4: Decadal changes in the ocean CO₂ sink from models and from data-based methods (a positive change between two decades means an increasing sink with time). It is reminded that the total CO₂ sink for the 1990s is estimated at 2.2 ± 0.7 PgC yr⁻¹ based on observations.

Notes:

(a) As published by Sarmiento et al. (2010).

(b) Average of all estimates ±90% confidence interval. The average includes results by Le Quéré et al. (2010) – NCEP only because the other Le Quéré et al. model versions do not differ sufficiently to be considered separately.

(c) Based on observed patterns of atmospheric minus oceanic pCO₂, assuming the difference increases with time following the increasing atmospheric CO₂.

(d) Ocean inversion, assuming constant oceanic transport through time.

(e) Based on observed fit between the variability in temperature and pCO₂, and observed variability in temperature.

[INSERT FIGURE 6.14 HERE]

Figure 6.14: Anomalies in the ocean CO₂ ocean-to-atmosphere flux in response to: (a) changes in climate, (b) increasing atmospheric CO₂, and (c) the combined effects of increasing CO₂ and changes in climate (PgC yr⁻¹). All estimates are shown as anomalies with respect to the 1990–2000 averages. Estimates are updates from ocean models (in colours) and from indirect methods based on observations (Khatiwala et al., 2009; Park et al., 2010). A negative ocean-to-atmosphere flux represents a sink of CO₂, as in Table 6.1.

6.3.2.5.2 Regional changes in ocean dissolved inorganic carbon

Observational-based estimates for the global ocean inventory of anthropogenic carbon are obtained from shipboard repeated hydrographic cross sections (Sabine et al., 2004; Waugh et al., 2006; Khatiwala et al., 2009). These estimates agree well among each other, with an average value of 155 ± 30 PgC of increased dissolved inorganic carbon for the period 1750–2011 (See Chapter 3). The uptake of anthropogenic carbon into the ocean is observed to be larger in the high latitudes than in the tropics and subtropics over the entire Industrial Era, because of the more vigorous ocean convection in the high latitudes (Khatiwala et al., 2009). A number of ocean cross sections have been repeated over the last decade and the observed changes in carbon storage (Table 6.5), suggest that some locations have rates of carbon accumulation that are higher and others that are lower than the global average estimated by Khatiwala et al. (2009). Model results suggest that there may be an effect of climate change and variability in the storage of total inorganic carbon in the ocean (Table 6.4), but that this effect is small (~2 PgC over the past 50 years; Figure 6.14) compared to the cumulative uptake of anthropogenic carbon during the same period.

6.3.2.5.3 Interannual variability in air-sea CO₂ fluxes

The interannual variability in the global ocean CO₂ sink is estimated to be of about ±0.2 PgC yr⁻¹ (Wanninkhof et al., 2013) which is small compared to the interannual variability of the terrestrial CO₂ sink (see Sections 6.3.2.3 and 6.3.2.6.3; Figure 6.12). In general, the ocean takes up more CO₂ during El Niño episodes (Park et al., 2010) because of the temporary suppression of the source of CO₂ to the atmosphere over the eastern Pacific upwelling. Interannual variability of ~0.3 PgC yr⁻¹ has been reported for the North Atlantic ocean region alone (Watson et al., 2009) but there is no agreement among estimates regarding the exact magnitude of driving factors of air-sea CO₂ flux variability in this region (Schuster et al., 2013). Interannual variability of 0.1–0.2 PgC yr⁻¹ was also estimated by models and one atmospheric inversion in the Southern Ocean (Le Quéré et al., 2007), possibly driven by the Southern Annular Mode of climate variability (Lenton and Matear, 2007; Lovenduski et al., 2007; Lourantou and Metzl, 2011).

6.3.2.5.4 Regional ocean pCO₂ trends

Observations of the partial pressure of CO₂ at the ocean surface (pCO₂) show that ocean pCO₂ has been increasing generally at about the same rate as CO₂ in the atmosphere when averaged over large ocean regions during the past two to three decades (Yoshikawa-Inoue and Ishii, 2005; Takahashi et al., 2009; McKinley et al., 2011). However, analyses of regional observations highlight substantial regional and temporal variations around the mean trend.

In the North Atlantic, repeated observations show ocean pCO₂ increasing regionally either at the same rate or faster than atmospheric CO₂ between about 1990 and 2006 (Schuster et al., 2009) thus indicating a constant or decreasing sink for CO₂ in that region, in contrast to the increasing sink expected from the response of the ocean to increasing atmospheric CO₂ alone. The anomalous North Atlantic trends appear to be related to sea surface warming and its effect on solubility (Corbière et al., 2007) and/or changes in ocean circulation (Schuster and Watson, 2007; Schuster et al., 2009) and deep convection (Metzl et al., 2010). Recent changes have been associated with decadal variability in the North Atlantic Oscillation (NAO) and the Atlantic Multidecadal Variability (AMV) (Thomas et al., 2007; Ullman et al., 2009; McKinley et al., 2011; Tjiputra et al., 2012). A systematic analysis of trends estimated in this region show no agreement regarding the drivers of change (Schuster et al., 2013).

In the Southern Ocean, an approximately constant sink was inferred from atmospheric (Le Quéré et al., 2007) and oceanic (Metzl, 2009; Takahashi et al., 2009) CO₂ observations but the uncertainties are large (Law et al., 2008). Most ocean biogeochemistry models reproduce the constant sink and attribute it as a response to an increase in Southern Ocean winds driving increased upwards transport of carbon-rich deep waters (Lenton and Matear, 2007; Verdy et al., 2007; Lovenduski et al., 2008; Le Quéré et al., 2010). The increase in winds has been attributed to the depletion of stratospheric ozone (Thompson and Solomon, 2002) with a contribution from greenhouse gases (Fyfe and Saenko, 2006).

Large decadal variability has been observed in the Equatorial Pacific (Ishii et al., 2009) associated with changes in the phasing of the Pacific Decadal Oscillation (see Glossary) and its impact on gas transfer velocity (Feely et al., 2006; Valsala et al., 2012). By contrast, ocean pCO₂ appears to have increased at a slower rate than atmospheric CO₂ (thus a growing ocean CO₂ sink in that region) in the northern North

Pacific Ocean (Takahashi et al., 2006). There is less evidence available to attribute the observed changes in other regions to changes in underlying processes or climate change and variability.

6.3.2.5.5 *Processes driving variability and trends in air-sea CO₂ fluxes*

Three type of processes are estimated to have an important effect on the air-sea CO₂ fluxes on century time scales: (1) the dissolution of CO₂ at the ocean surface and its chemical equilibrium with other forms of carbon in the ocean (mainly carbonate and bicarbonate), (2) the transport of carbon between the surface and the intermediate and deep ocean, and 3) changes in the cycling of carbon through marine ecosystem processes (the ocean biological pump; see Section 6.1.1.1). The surface dissolution and equilibration of CO₂ with the atmosphere is well understood and quantified. It varies with the surface ocean conditions, in particular with temperature (solubility effect) and alkalinity. The capacity of the ocean to take up additional CO₂ for a given alkalinity decreases at higher temperature (4.23% per degree warming; Takahashi et al., 1993) and at elevated CO₂ concentrations (about 15% per 100 ppm, computed from the so called Revelle factor; Revelle and Suess, 1957).

Recent changes in nutrient supply in the ocean are also thought to have changed the export of organic carbon from biological processes below the surface layer, and thus the ocean CO₂ sink (Duce et al., 2008).

Anthropogenic reactive nitrogen Nr (see Box 6.2) entering the ocean via atmospheric deposition or rivers acts as a fertilizer and may enhance carbon export to depth and hence the CO₂ sink. This Nr contribution has been estimated to be between 0.1 and 0.4 PgC yr⁻¹ around the year 2000 using models (Duce et al., 2008; Reay et al., 2008; Krishnamurthy et al., 2009; Suntharalingam et al., 2012). Similarly, increases in iron deposition over the ocean from dust generated by human activity is estimated to have enhanced the ocean cumulative CO₂ uptake by 8 PgC during the 20th century (or about 0.05 PgC yr⁻¹ in the past decades) (Mahowald et al., 2010). Although changes in ocean circulation and in global biogeochemical drivers have the potential to alter the ocean carbon fluxes through changes in marine ecosystems, modeling studies show only small variability in ocean biological pump, which has not significantly impacted the response of the ocean carbon cycle over the recent period (Bennington et al., 2009).

Model studies suggest that the response of the air-sea CO₂ fluxes to climate change and variability in recent decades has decreased the rate at which anthropogenic CO₂ is absorbed by the ocean (Sarmiento et al. (2010), Figure 6.14 and Table 6.4). This result is robust to the model or climate forcing used (Figure 6.13), but no formal attribution to anthropogenic climate change has been made. There is insufficient data coverage to separate the impact of climate change on the global ocean CO₂ sink directly from observations, though the regional trends described in Section 6.3.2.5.4 suggest that surface ocean pCO₂ responds to changes in ocean properties in a significant and measurable way.

6.3.2.5.6 *Model evaluation of global and regional ocean carbon balance*

Ocean process-based carbon cycle models are capable of reproducing the mean air-sea fluxes of CO₂ derived from pCO₂ observations (Takahashi et al., 2009), including their general patterns and amplitude (Sarmiento et al., 2000), the anthropogenic uptake of CO₂ (Orr et al., 2001; Wanninkhof et al., 2013), and the regional distribution of air-sea fluxes (Gruber et al., 2009). The spread between different model results for air-sea CO₂ fluxes is the largest in the Southern Ocean (Matsumoto et al., 2004), where intense convection occurs. Tracer observations (Schmittner et al., 2009) and water mass analysis (Iudicone et al., 2011) have been used to reduce the model uncertainty associated with this process and improve the simulation of carbon fluxes. The models reproduce the observed seasonal cycle of pCO₂ in the sub-tropics but generally do poorly in sub-polar regions where the balance of processes is more difficult to simulate well (McKinley et al., 2006; Schuster et al., 2013). Less information is available to evaluate specifically the representation of biological fluxes in the models, outside of their realistic representation of surface ocean chlorophyll distributions. Ocean process-based carbon cycle models used in AR5 reproduce the relatively small interannual variability inferred from observations (Figure 6.12; Wanninkhof et al., 2013). See also Chapter 9, Section 9.4.5.2.

Sensitivity of modelled air-sea fluxes to CO₂. Data-based studies estimated a cumulative carbon uptake of $\sim 155 \pm 30$ PgC across studies for the 1750–2011 time period (Sabine et al., 2004; Waugh et al., 2006; Khatiwala et al., 2009), a mean anthropogenic CO₂ sink of 2.2 ± 0.7 Pg C yr⁻¹ for the 1990s, and decadal trends of 0.13 PgC yr⁻¹ per decade during the two decades 1990–2009 (Wanninkhof et al., 2013; from atmospheric inversions), respectively. Models that have estimated these quantities give a total ocean uptake of 170 ± 25 PgC for 1750–2011 (from the model ensemble of Orr et al., (2005) until 1994, plus an additional

40 Pg C from estimates in Table 6.4 for 1995–2011), a mean anthropogenic CO₂ sink of 2.1 ± 0.6 PgC yr⁻¹ for 1990–1999 (Le Quéré et al., 2013), and a decadal trend of 0.14 PgC yr⁻¹ per decade for 1990–2009 (Wanninkhof et al., 2013). Therefore, although the ocean models do not reproduce all the details of the regional structure and changes in air-sea CO₂ fluxes, their globally integrated ocean CO₂ sink and decadal rate of change of this sink is in good agreement with the available observations.

Sensitivity of modelled air-sea fluxes to climate. The relationship between air-sea CO₂ flux and climate is strongly dependent on the oceanic region and on the time-scale. Ocean carbon cycle models of the type used in AR5 estimate a reduction in cumulative ocean CO₂ uptake of 1.6–5.4 PgC over the period 1959–2008 (1.5–5.4%) in response to climate change and variability compared to simulations with no changes in climate (Figure 6.14), partly due to changes in the equatorial Pacific and to changes in the Southern Ocean. The only observational-based estimate available to evaluate the climate response of the global air-sea CO₂ flux is from Park et al. (2010), which is at the low end of the model estimate for the past two decades (Table 6.4). However this estimate does not include the non-linear effects of changes in ocean circulation and warming on the global air-sea CO₂ flux, which could amplify the response of the ocean CO₂ sink to climate by 20–30% (Le Quéré et al., 2010; Zickfeld et al., 2011).

Processes missing in ocean models. The most important processes missing in ocean carbon cycle models used in the AR5 are those representing explicitly small-scale physical circulation (e.g., eddies, brine formation), which are parameterised in models. These processes have an important influence on the vertical transport of water, heat, salt and carbon (Loose and Schlosser, 2011; Sallée et al., 2012). In particular, changes in vertical transport in the Southern Ocean are thought to explain part of the changes in atmospheric CO₂ between glacial and interglacial conditions, a signal that is not entirely reproduced by models (Section 6.2) suggesting that the sensitivity of ocean models could be underestimated.

Processes related to marine ecosystems in global ocean models are also limited to the simulation of lower trophic levels, with crude parameterizations for sinking processes, bacterial and other loss processes at the surface and in the ocean interior, and their temperature-dependence (Kwon et al., 2009). Projected changes in carbon fluxes from the response of marine ecosystems to changes in temperature (Beaugrand et al., 2010), ocean acidification (Riebesell et al., 2009) (see Glossary), and pressure from fisheries (Pershing et al., 2010) are all considered potentially important, though not yet quantified. Several processes have been specifically identified that could lead to changes in the ocean CO₂ sink, in particular the temperature effects on marine ecosystem processes (Riebesell et al., 2009; Taucher and Oschlies, 2011) and the variable nutrient ratios induced by ocean acidification or ecosystem changes (Tagliabue et al., 2011). Coastal ocean processes are also poorly represented in global and may influence the ocean CO₂ sink. Nevertheless, the fit of ocean model results to the integrated CO₂ sink and decadal trends discussed above suggest that, up to now, the missing processes have not had a dominant effect on ocean CO₂ beyond the limits of the uncertainty of the data.

6.3.2.6 Land CO₂ Sink

6.3.2.6.1 Global residual terrestrial sink and atmosphere-to-land CO₂ flux

The residual terrestrial CO₂ sink, i.e., the uptake of CO₂ in ecosystems excluding the effects of land use change, is 1.5 ± 1.1 , 2.7 ± 1.2 and 2.6 ± 1.2 PgC yr⁻¹ for the 1980s, 1990s, and 2000s, respectively (Table 6.1). After including the net land use change emissions, the atmosphere-to-land flux of CO₂ (Table 6.1) corresponds to a net sink of CO₂ by all terrestrial ecosystems. This sink has intensified globally from a neutral CO₂ flux of 0.1 ± 0.8 PgC yr⁻¹ in the 1980s to a net CO₂ sink of 1.1 ± 0.9 PgC yr⁻¹ and 1.5 ± 0.9 PgC yr⁻¹ during the 1990s and 2000s, respectively (Table 6.1; Sarmiento et al., 2010). This growing land sink is also supported by an atmospheric inversion (Gurney and Eckels, 2011) and by process-based models (Le Quéré et al., 2009).

6.3.2.6.2 Regional atmosphere-to-land CO₂ fluxes

The results from atmospheric CO₂ inversions, terrestrial ecosystem models and forest inventories consistently show that there is a large net CO₂ sink in the northern extra-tropics, albeit the very limited availability of observations in the tropics (Jacobson et al., 2007; Gurney and Eckels, 2011; Pan et al., 2011). Inversion estimates of atmosphere-land CO₂ fluxes show net atmosphere-to-land CO₂ flux estimates ranging from neutral to a net source of 0.5–1.0 PgC yr⁻¹ (Jacobson et al., 2007; Gurney and Eckels, 2011) (Figure 6.15). However, Stephens et al. (2007) selected from an ensemble of inversion models those that were

consistent with independent aircraft cross-validation data, and constrained an atmosphere-to-land CO₂ flux of 0.1 ± 0.8 PgC yr⁻¹ during the period 1992–1996, and a Northern Hemisphere net CO₂ sink of 1.5 ± 0.6 PgC yr⁻¹. These results shows that after subtracting emissions from land use change, tropical land ecosystems might also be large CO₂ sinks.

[INSERT FIGURE 6.15 HERE]

Figure 6.15: (Top) Bar plots showing decadal average CO₂ fluxes for 11 land regions (1) as estimated by 10 different atmospheric CO₂ inversions for the 1990s (yellow) and 2000s (red) (Peylin et al., 2013; data source: <http://transcom.lscce.ipsl.fr/>), and (2) as simulated by 10 dynamic vegetation models (DGVMs) for the 1990s (green) and 2000s (light green) (Piao et al., 2013; data source: <http://www-lscceodds.cea.fr/invsat/RECCAP/>). The divisions of land regions are shown in the map. (Bottom) Bar plots showing decadal average CO₂ fluxes for 11 ocean regions (1) as estimated by 10 different atmospheric CO₂ inversions for the 1990s (yellow) and 2000s (red) (data source: <http://transcom.lscce.ipsl.fr/>), (2) inversion of contemporary interior ocean carbon measurements using 10 ocean transport models (dark blue) (Gruber et al., 2009), and (3) surface ocean pCO₂ measurements based air-sea exchange climatology (Takahashi et al., 2009). The divisions of 11 ocean regions are shown in the map.

Based on repeated forest biomass inventory data, estimated soil carbon changes, and CO₂ emissions from land use change from the bookkeeping method of Houghton et al. (2012), Pan et al. (2011) estimated a global forest carbon accumulation of 0.5 ± 0.1 PgCyr⁻¹ in boreal forests, and of 0.8 ± 0.1 PgC yr⁻¹ in temperate forests for the period 2000–2007. Tropical forests were found to be near neutral with net emissions from land use change being compensated by sinks in established tropical forests (forests not affected by land use change), therefore consistent with the Stephens et al. (2007) inversion estimate of tropical atmosphere-land CO₂ fluxes.

Since AR4, a number of studies have compared and attempted to reconcile regional atmosphere-to-land CO₂ flux estimates from multiple approaches and so providing further spatial resolution of the regional contributions of carbon sources and sinks (Table 6.6). A synthesis of regional contributions estimated a 1.7 PgC yr⁻¹ sink in the Northern Hemisphere regions above 20°N with consistent estimates from terrestrial models and inventories (uncertainty: ± 0.3 PgC yr⁻¹) and atmospheric CO₂ inversions (uncertainty: ± 0.7 PgC yr⁻¹) (Ciais et al., 2010).

Table 6.6: Regional CO₂ budgets using top-down estimates (atmospheric inversions) and bottom-up estimates (inventory data, biogeochemical modelling, eddy-covariance), excluding fossil fuel emissions. A positive sign indicates a flux from the atmosphere to the land (i.e., a land sink).

Region	CO ₂ Sink (PgC yr ⁻¹)	Uncertainty ^a	Period	Reference
Arctic Tundra	0.1	$\pm 0.3^b$	2000–2006	McGuire et al. (2012)
Australia	0.04	± 0.03	1990–2009	Haverd et al. (2013)
East Asia	0.25	± 0.1	1990–2009	Piao et al. (2012)
Europe	0.9	± 0.2	2001–2005	Luysaert et al. (2012)
North America	0.6	± 0.02	2000–2005	King et al. (2012)
Russia	0.6	-0.3 to -1.3	1990–2007	Dolman et al. (2012)
South Asia	0.15	± 0.24	2000–2009	Patra et al. (2013)
South America	-0.3	± 0.3	2000–2005	Gloor et al. (2012)

6.3.2.6.3 Interannual variability in atmosphere-to-land CO₂ fluxes

The interannual variability of the residual CO₂ land sink shown in Figures 6.12 and 6.16 accounts for most of the interannual variability of the atmospheric CO₂ growth rate (see Section 6.3.2.3). Atmospheric CO₂ inversion results suggest that tropical land ecosystems dominate the global CO₂ variability, with positive anomalies during El Niño episodes (Bousquet et al., 2000; Rödenbeck et al., 2003; Baker et al., 2006), which is consistent with the results of one inversion of atmospheric ¹³C and CO₂ measurements (Rayner et al., 2008). A combined ENSO-Volcanic index time series explains 75% of the observed variability (Raupach et al., 2008). A positive phase of ENSO (El Niño, see Glossary) is generally associated with enhanced land

CO₂ source, and a negative phase (La Niña) with enhanced land CO₂ sink (Jones and Cox, 2001; Peylin et al., 2005). Observations from eddy covariance networks suggest that interannual carbon flux variability in the tropics and temperate regions is dominated by precipitation, while boreal ecosystem fluxes are more sensitive to temperature and shortwave radiation variation (Jung et al., 2011), in agreement with the results from process-based terrestrial ecosystem models (Piao et al., 2009a). Terrestrial biogeochemical models suggest that interannual net biome productivity (NBP) variability is dominated by Gross Primary Production (GPP, see Glossary) rather than terrestrial ecosystem respiration (Piao et al., 2009b; Jung et al., 2011).

6.3.2.6.4 Carbon fluxes from inland water

Global analyses estimate that inland waters receive about 1.7–2.7 PgC yr⁻¹ emitted by soils to rivers headstreams, of which, 0.2–0.6 PgC yr⁻¹ is buried in aquatic sediments, 0.8–1.2 PgC yr⁻¹ returns to the atmosphere as CO₂, and 0.9 PgC yr⁻¹ is delivered to the ocean (Cole et al., 2007; Battin et al., 2009; Aufdenkampe et al., 2011). Estimates of the transport of carbon from land ecosystems to the coastal ocean by rivers are ~0.2 PgC yr⁻¹ for Dissolved Organic Carbon (DOC), 0.3 PgC yr⁻¹ for Dissolved Inorganic Carbon (DIC), and 0.1–0.4 PgC yr⁻¹ for Particulate Organic Carbon (POC) (Seitzinger et al., 2005; Syvitski et al., 2005; Mayorga et al., 2010). For the DIC fluxes, only ~2/3 of it originates from atmospheric CO₂ and the rest of the carbon is supplied by weathered carbonate rocks (Suchet and Probst, 1995; Gaillardet et al., 1999; Oh and Raymond, 2006; Hartmann et al., 2009). Regional DIC concentrations in rivers has increased during the Industrial Era (Oh and Raymond, 2006; Hamilton et al., 2007; Perrin et al., 2008). Agricultural practices coupled with climate change can lead to large increases in regional scale DIC export in watersheds with a large agricultural footprint (Raymond et al., 2008). Furthermore, regional urbanization also elevates DIC fluxes in rivers (Baker et al., 2008; Barnes and Raymond, 2009) which suggest that anthropogenic activities have contributed a significant portion of the annual global river DIC flux to the ocean.

Land clearing and management are thought to produce an acceleration of POC transport, much of which is trapped in alluvial and colluvial deposition zones, lakes, reservoirs, and wetlands (Stallard, 1998; Smith et al., 2001b; Syvitski et al., 2005). Numerous studies have demonstrated an increase in the concentration of DOC in rivers in the Northeastern United States and northern/central Europe over the past 2–4 decades (Worrall et al., 2003; Evans et al., 2005; Findlay, 2005; Monteith et al., 2007; Lepistö et al., 2008). Due to the important role of wetlands in DOC production, the mobilization of DOC due to human-induced changes in wetlands likely represents an important cause of changes in global river DOC fluxes to date (Seitzinger et al., 2005), although a global estimate of this alteration is not available. A robust partitioning between natural and anthropogenic carbon fluxes in freshwater systems is not yet possible, nor a quantification of the ultimate fate of carbon delivered by rivers to the coastal and open oceans.

6.3.2.6.5 Processes driving terrestrial atmosphere-to-land CO₂ fluxes

Assessment of experimental data, observations, and model results suggest that the main processes responsible for the residual terrestrial CO₂ sink include the CO₂ fertilisation effect on photosynthesis (see Box 6.3), nitrogen fertilisation by increased deposition (Norby, 1998; Thornton et al., 2007; Bonan and Levis, 2010; Zaehle and Dalmonech, 2011) and climate effects (Nemani et al., 2003; Gloor et al., 2009). Processes responsible for the net atmosphere-to-land CO₂ sink on terrestrial ecosystems include, in addition, forest regrowth and afforestation (Myneni et al., 2001; Pacala et al., 2001; Houghton, 2010; Bellassen et al., 2011; Williams et al., 2012a), changes in forest management and reduced harvest rates (Nabuurs et al., 2008).

[START BOX 6.3 HERE]

Box 6.3: The CO₂ Fertilization Effect

Elevated atmospheric CO₂ concentrations lead to higher leaf photosynthesis and reduced canopy transpiration, which in turn lead to increased plant water use efficiency and reduced fluxes of surface latent heat. The increase leaf photosynthesis with rising CO₂, the so called CO₂ fertilization effect, plays a dominant role in terrestrial biogeochemical models to explain the global land carbon sink (Sitch et al., 2008), yet it is one of most unconstrained process in those models.

Field experiments provide a direct evidence of increased photosynthesis rates and water use efficiency (plant carbon gains per unit of water loss from transpiration) in plants growing under elevated CO₂. This

physiological changes translate into a broad range of higher plant carbon accumulation in more than 2/3 of the experiments and with increased net primary production (NPP) of about 20–25% at double CO₂ from pre-industrial concentrations (Ainsworth and Long, 2004; Luo et al., 2004; Nowak et al., 2004; Norby et al., 2005; Luo et al., 2006; Canadell et al., 2007a; Denman et al., 2007; Ainsworth et al., 2012; Wang et al., 2012a). Since the AR4, new evidence is available from long-term Free-air CO₂ Enrichment (FACE) experiments in temperate ecosystems showing the capacity of ecosystems exposed to elevated CO₂ to sustain higher rates of carbon accumulation over multiple years (Liberloo et al., 2009; McCarthy et al., 2010; Aranjuelo et al., 2011; Dawes et al., 2011; Lee et al., 2011; Zak et al., 2011). However, FACE experiments also show the diminishing or lack of CO₂ fertilization effect in some ecosystems and for some plant species (Dukes et al., 2005; Adair et al., 2009; Bader et al., 2009; Norby et al., 2010; Newingham et al., 2013). This lack of response occurs despite increased water use efficiency, also confirmed with tree ring evidence (Gedalof and Berg, 2010; Peñuelas et al., 2011).

Nutrient limitation is hypothesized as primary cause for reduced or lack of CO₂ fertilization effect observed on NPP in some experiments (Luo et al., 2004; Dukes et al., 2005; Finzi et al., 2007; Norby et al., 2010). Nitrogen and phosphorus (P) are very likely to play the most important role in this limitation of the CO₂ fertilization effect on net primary productivity (NPP), with nitrogen limitation prevalent in temperate and boreal ecosystems, and phosphorus limitation in the tropics (Luo et al., 2004; Vitousek et al., 2010; Wang et al., 2010a; Goll et al., 2012). Micronutrients interact in diverse ways with other nutrients in constraining NPP such as molybdenum and phosphorus in the tropics (Wurzburger et al., 2012). Thus, with *high confidence*, the CO₂ fertilization effect will lead to enhanced NPP, but significant uncertainties remain on the magnitude of this effect, given the lack of experiments outside of temperate climates.

[END BOX 6.3 HERE]

Process attribution of the global land CO₂ sink is difficult due to limited availability of global datasets and biogeochemical models that include all major processes. However, regional studies shed light on key drivers and their interactions. The European and North American carbon sinks are explained by the combination of forest regrowth in abandoned lands and decreased forest harvest along with the fertilization effects of rising CO₂ and nitrogen deposition (Pacala et al., 2001; Ciais et al., 2008; Sutton et al., 2008; Schulze et al., 2010; Bellassen et al., 2011; Williams et al., 2012a). In the tropics, there is evidence from forest inventories that increasing forest growth rates are not explained by the natural recovery from disturbances, suggesting that increasing atmospheric CO₂ and climate change play a role in the observed sink in established forests (Lewis et al., 2009; Pan et al., 2011). There is also recent evidence of tropical nitrogen deposition becoming more notable although its effects on the net carbon balance have not been assessed (Hietz et al., 2011).

The land carbon cycle is very sensitive to climate changes (e.g., precipitation, temperature, diffuse vs. direct radiation), and thus the changes in the physical climate from increasing GHGs as well as in the diffuse fraction of sunlight are likely to be causing significant changes in the carbon cycle (Jones et al., 2001; Friedlingstein et al., 2006; Mercado et al., 2009). Changes in the climate are also associated with disturbances such as fires, insect damage, storms, droughts and heat waves which are already significant processes of inter-annual variability and possibly trends of regional land carbon fluxes (Page et al., 2002; Ciais et al., 2005; Chambers et al., 2007; Kurz et al., 2008b; Clark et al., 2010; van der Werf et al., 2010; Lewis et al., 2011) (see Section 6.3.2.2).

Warming (and possibly the CO₂ fertilization effect) has also been correlated with global trends in satellite greenness observations, which resulted in an estimated 6% increase of global NPP, or the accumulation of 3.4 PgC on land over the period 1982–1999 (Nemani et al., 2003). This enhanced NPP was attributed to the relaxation of climatic constraints to plant growth, particularly in high latitudes. Concomitant to the increased of NPP with warming, global soil respiration also increased between 1989 and 2008 (Bond-Lamberty and Thomson, 2010) reducing the magnitude of the net land sink. A recent study suggests a declining NPP trend over 2000–2009 (Zhao and Running, 2010) although the model used to reconstruct NPP trends from satellite observation has not been widely accepted (Medlyn, 2011; Samanta et al., 2011).

6.3.2.6.6 Model evaluation of global and regional terrestrial carbon balance

Evaluation of global process-based land carbon models was performed against ground and satellite observations including: (1) measured CO₂ fluxes and carbon storage change at particular sites around the

world, in particular sites from the Fluxnet global network (Baldocchi et al., 2001; Jung et al., 2007; Stöckli et al., 2008; Schwalm et al., 2010; Tan et al., 2010), (2) observed spatio-temporal change in leaf area index (LAI) (Lucht et al., 2002; Piao et al., 2006), and (3) interannual and seasonal change in atmospheric CO₂ (Randerson et al., 2009; Cadule et al., 2010).

Figure 6.16 compares the global land CO₂ sink driven by climate change and rising CO₂ as simulated by different process based carbon cycle models (without land use change), with the residual terrestrial sink computed as the sum of fossil fuel and cement emissions and land use change emissions minus the sum of CO₂ growth rate and ocean sink (Le Quéré et al., 2009; Friedlingstein et al., 2010). Although these two quantities are not the same, the multi-model mean reproduce well the trend and interannual variability of the residual sink which is dominated by climate variability and climate trends and CO₂, respectively, both represented in models (Table 6.7). Limited availability of in-situ measurements, particularly in the tropics, limits the progress towards reducing uncertainty on model parameterizations.

Table 6.7: Estimates of the land CO₂ sink from process-based terrestrial ecosystem models driven by rising CO₂ and by changes in climate. The land sink simulated by these models is close to but not identical to the terrestrial CO₂ sink from Table 6.1 because the models calculate the effect of CO₂ and climate over managed land, and many do not include nitrogen limitation and disturbances.

Model Name	Nitrogen Limitation	Natural Fire CO ₂ Emissions	1980–1989	1990–1999	2000–2009
	(Yes/No)	(Yes/No)	PgC yr ⁻¹	PgC yr ⁻¹	PgC yr ⁻¹

[INSERT FIGURE 6.16 HERE]

Figure 6.16: Time series for the residual terrestrial CO₂ land-to-atmosphere flux (PgC yr⁻¹). The black line and gray shading represent the estimated value and its uncertainty from Table 6.1, which is calculated from the difference between emissions from fossil fuel and land use change plus emissions from net land use change, minus the atmospheric growth rate and the ocean sink. The process models from Table 6.7 are shown in thin green, and their average in thick green. A negative land-to-atmosphere flux represents a sink of CO₂. The definition of the land-to-

atmosphere flux simulated by the models is close to but not identical to the terrestrial CO₂ sink from Table 6.1 (see Table 6.7).

Regional and local measurements can be used to evaluate and improve global models. Regionally, forest inventory data show that the forest carbon sink density over Europe is of $-89 \pm 19 \text{ gC m}^{-2} \text{ yr}^{-1}$, which is compatible with model estimates with afforestation ($-63 \text{ gC m}^{-2} \text{ yr}^{-1}$; Luysaert et al., 2010), while modelled NPP was 43% larger than the inventory estimate. In North America, the ability of 22 terrestrial carbon cycle models to simulate the seasonal cycle of land-atmosphere CO₂ exchange from 44 eddy covariance flux towers was poor with a difference between observations and simulations of ten times the observational uncertainty (Schwalm et al., 2010). Model shortcomings included spring phenology, soil thaw, snow pack melting, and lag responses to extreme climate events (Keenan et al., 2012). In China, the magnitude of the carbon sink estimated by five terrestrial ecosystem models (-0.22 to $-0.13 \text{ PgC yr}^{-1}$) was compatible to the observation-based estimate ($-0.18 \pm 0.73 \text{ PgC yr}^{-1}$; Piao et al., 2009a), but modelled interannual variation was weakly correlated to observed regional land-atmosphere CO₂ fluxes (Piao et al., 2011).

Sensitivity of the terrestrial carbon cycle to rising atmospheric CO₂. An inter-comparison of ten process-based models showed increased NPP by 3% to 10% over the last three decades, during which CO₂ increased by ~50 ppm (Piao et al., 2013). These results are consistent within the broad range of responses from experimental studies (see Box 6.3). However, Hickler et al. (2008) suggested that currently available FACE results (largely from temperate regions) are not applicable to vegetation globally since there may be large spatial heterogeneity in vegetation responses to CO₂ fertilization.

Sensitivity of terrestrial carbon cycle to climate trends and variability. Warming exerts a direct control on the net land-atmosphere CO₂ exchange since both photosynthesis and respiration are sensitive to changes in temperature. From estimates of interannual variations in the residual land sink, 1°C of positive global temperature anomaly leads to a decrease of 4 PgC yr⁻¹ of the global land CO₂ sink (Figure 6.17). This observed interannual response is close to the response of the models listed in Table 6.7 ($-3.5 \pm 1.5 \text{ PgC yr}^{-1} \text{ } ^\circ\text{C}^{-1}$ in Piao et al., 2013), albeit individual models show a range going from -0.5 to $-6.2 \text{ PgC yr}^{-1} \text{ } ^\circ\text{C}^{-1}$. The sensitivity of atmospheric CO₂ concentration to century scale temperature change was estimated at about 3.6–45.6 PgC °C⁻¹ (or 1.7–21.4 ppm CO₂ °C⁻¹) using the ice core observed CO₂ drop during the Little Ice Age (see Section 6.2; Frank et al., 2010).

Terrestrial carbon cycle models used in AR5 generally underestimate GPP in the water limited regions, implying that these models do not correctly simulate soil moisture conditions, or that they are too sensitive to changes in soil moisture (Jung et al., 2007). Most models (Table 6.7) estimated that the interannual precipitation sensitivity of the global land CO₂ sink to be higher than that of the observed residual land sink ($-0.01 \text{ PgC yr}^{-1} \text{ mm}^{-1}$; Figure 6.17).

[INSERT FIGURE 6.17 HERE]

Figure 6.17: The response of interannual land CO₂ flux anomaly to per 1°C interannual temperature anomaly and per 100 mm interannual precipitation anomaly during 1980–2009. Black circle show climate sensitivity of land CO₂ sink estimated from the residual land sink (see Figure 6.15 and Table 6.1), which is the sum of fossil fuel and cement emissions and land use change emissions minus the sum of observed atmospheric CO₂ growth rate and modeled ocean sink (Le Quéré et al., 2009; Friedlingstein and Prentice, 2010). Colored circles show land CO₂ sink estimated by 10 process-based terrestrial carbon cycle models (CLM4C, CLM4CN, HYLAND, LPJ, LPJ-GUESS, OCN, ORCHIDEE, SDGVM, TRIFFID and VEGAS). Error bars show standard error of the sensitivity estimates. Dashed error bars indicate the estimated sensitivity by the regression approach are statistically insignificant ($P > 0.05$). Grey area denoted the area bounded by the estimated climate sensitivity of the residual land sink \pm the standard error of the estimated climate sensitivity of the residual land sink. The sensitivity of land CO₂ sink interannual variations to interannual variations of temperature (or precipitation) is estimated as the regression coefficient of temperature (or precipitation) in a multiple regression of detrended anomaly of land CO₂ sink against detrended anomaly of annual mean temperature and annual precipitation.

Processes missing in terrestrial carbon cycle models. First, many models do not explicitly take into account the various forms of disturbances or ecosystem dynamics: migration, fire, logging, harvesting, insect outbreaks and the resulting variation in forest age structure which is known to affect the net carbon exchange (Kurz et al., 2008c; Bellassen et al., 2010; Higgins and Harte, 2012). Second, many key processes relevant to decomposition of carbon are missing in models (Todd-Brown et al., 2012), and particularly for permafrost

carbon and for carbon in boreal and tropical wetlands and peatlands, despite the large amount of carbon stored in these ecosystems and their vulnerability to warming and land use change (Tarnocai et al., 2009; Hooijer et al., 2010; Page et al., 2011). However, progress has been made (Wania et al., 2009; Koven et al., 2011; Schaefer et al., 2011). Third, nutrient dynamics are only taken into account by few models despite it is well established that nutrient constrains NPP and nitrogen deposition enhances NPP (Elser et al., 2007; Magnani et al., 2007; LeBauer and Treseder, 2008), Section 6.3.2.6.5. Very few models have phosphorus dynamics (Zhang et al., 2011; Goll et al., 2012). Fourth, the negative effects of elevated tropospheric ozone on NPP have not been taken into account by most of current carbon cycle models (Sitch et al., 2007). Fifth, transfer of radiation, water and heat in the vegetation-soil-atmosphere continuum are treated very simply in the global ecosystem models. Finally, process that transport carbon at the surface (e.g., water and tillage erosion; Quinton et al., 2010) and human managements including fertilization and irrigation (Gervois et al., 2008) are poorly or not represented at all. Broadly, models are still at their early stages in dealing with land use, land use change, and forestry.

6.3.3 Global CH₄ Budget

AR5 is the first IPCC assessment report providing a consistent synthesis of the CH₄ budget per decade using multiple atmospheric CH₄ inversion models (top-down) and process-based models and inventories (bottom-up). Table 6.8 shows the budgets for the decades of 1980s, 1990s and 2000s. Uncertainties on emissions and sinks are listed using minimum and maximum of each published estimate for each decade. Bottom-up approaches are used to attribute decadal budgets to individual processes emitting CH₄ (see Section 6.1.1.2 for a general overview). Top-down inversions provide an atmospheric-based constraint mostly for the total CH₄ source per region, and the use of additional observations (e.g., isotopes) allows inferring emissions per source type. Estimates of CH₄ sinks in the troposphere by reaction with tropospheric OH, in soils and in the stratosphere are also presented. Despite significant progress since the AR4, large uncertainties remain in the present knowledge of the budget and its evolution over time.

6.3.3.1 Atmospheric Changes

Since the beginning of the Industrial Era, the atmospheric CH₄ concentration increased by a factor of 2.5 (from 722 ppb to 1803 ppb in 2011). CH₄ is currently measured by a network of more than 100 surface sites (Blake et al., 1982; Cunnold et al., 2002; Langenfelds et al., 2002; Dlugokencky et al., 2011), aircraft profiles (Brenninkmeijer et al., 2007; Wecht et al., 2012; Worden et al., 2012), and before 1979 from analyses of firm air and ice cores (see Chapter 5, Section 5.2.2 and Section 6.2, and Figure 6.11). The growth of CH₄ in the atmosphere is largely in response to increasing anthropogenic emissions. The vertically averaged atmospheric CH₄ concentration field can be mapped by remote sensing from the surface using Fourier Transform Infrared Spectroscopy (FTIR) instruments (Total Carbon Column Observing Network, TCCON, <http://www.tccon.caltech.edu/>) and from space by several satellite instruments: AIRS (since 2002; <http://airs.jpl.nasa.gov/>), TES (since 2004; <http://tes.jpl.nasa.gov/>), IASI (since 2006; Crévoisier et al., 2009), SCIAMACHY (2003–2012; Frankenberg et al., 2008), and GOSAT-TANSO-FTS (since 2009; Morino et al., 2011). As an example, SCIAMACHY shows the column CH₄ gradient between the two hemispheres as well as increased concentrations over South East Asia, due to emissions from agriculture, wetlands, waste, and energy production (Frankenberg et al., 2008). *In situ* observations provide very precise measurements (~0.2%) but unevenly located at the surface of the globe. Satellite data offer a global coverage at the cost of a lower precision on individual measurements (~2%) and possible biases (Bergamaschi et al., 2009).

The growth rate of CH₄ has declined since the mid-1980s and a near zero growth rate (quasi-stable concentrations) was observed during 1999–2006 suggesting an approach to steady state where the sum of emissions are in balance with the sum of sinks (Dlugokencky et al., 2003; Khalil et al., 2007; Patra et al., 2011; Figure 6.18). The reasons for this growth rate decline after the mid-1980s are still debated, and results from various studies provide possible scenarios: (1) a reduction of anthropogenic emitting activities such as coal mining, gas industry and/or animal husbandry, especially in the countries of the former Soviet Union (Dlugokencky et al., 2003; Chen and Prinn, 2006; Savolainen et al., 2009; Simpson et al., 2012), (2) a compensation between increasing anthropogenic emissions and decreasing wetland emissions (Bousquet et al., 2006; Chen and Prinn, 2006), (3) significant (Rigby et al., 2008) to small (Montzka et al., 2011) changes in OH concentrations, and/or, based on two different ¹³CH₄ datasets, (4) reduced emissions from rice paddies

attributed to changes in agricultural practices (Kai et al., 2011), or (5) stable microbial and fossil fuel emissions from 1990 to 2005 (Levin et al., 2012).

[INSERT TABLE 6.8 HERE]

Table 6.8: Global CH₄ budget for the past three decades (in Tg(CH₄) yr⁻¹). The bottom-up estimates for the decade of 2000–2009 are used in the Executive Summary and in Figure 6.2. T-D stands for Top-Down inversions and B-U for Bottom-Up approaches. Only studies covering at least five years of each decade have been used. Reported values correspond to the mean of the cited references and therefore not always equal (max-min)/2; likewise, ranges [in brackets] represent minimum and maximum values of the cited references. The sum of sources and sinks from B-U approaches does not automatically balance the atmospheric changes. For B-U studies, individual source types are also presented. For T-D inversions, the 1980s decade starts in 1984. As some atmospheric inversions did not reference their global sink, balance with the atmosphere and the sum of the sources has been assumed. One biomass burning estimate (Schultz et al., 2007) excludes biofuels (a). Stratospheric loss for B-U is the sum of the loss by OH radicals, a 10 Tg yr⁻¹ loss due to O¹D radicals (Neef et al., 2010) and a 20–35% contribution due to Cl radicals (Allan et al., 2007).

Since 2007, atmospheric CH₄ is observed to increase again (Rigby et al., 2008; Dlugokencky et al., 2009) with positive anomalies of emissions of 21 Tg(CH₄) yr⁻¹ and 18 Tg(CH₄) yr⁻¹ estimated by inversions during 2007 and 2008, respectively (Bousquet et al., 2011) as compared to the 1999–2006 period. The increase of emissions in 2007–2008 was dominated by tropical regions (Bousquet et al., 2011) with a major contribution from tropical wetlands, and some contribution from high latitude wetlands during the 2007 anomaly (Dlugokencky et al., 2009; Bousquet et al., 2011). This increase is suggested by the growth rate over latitude in Figure 6.18 (Dlugokencky et al., 2009). The recent increase of CH₄ concentration since 2007 is also consistent with anthropogenic emission inventories, which show more (EDGAR v4.2) or less (EPA, 2011a) rapidly increasing anthropogenic CH₄ emissions in the period 2000–2008. This is related to increased energy production in growing Asian economies (EDGAR, edgar.jrc.ec.europa.eu; EPA, <http://www.epa.gov/nonco2/econ-inv/international.html>). The atmospheric increase has continued after 2009, at a rate of 4–5 ppb yr⁻¹ (Sussmann et al., 2012).

[INSERT FIGURE 6.18 HERE]

Figure 6.18: Upper panel: Globally averaged growth rate of atmospheric CH₄ in ppb yr⁻¹ determined from the NOAA/ESRL network, representative for the marine boundary layer. Lower panel: Atmospheric growth rate of CH₄ as a function of latitude (Masarie and Tans, 1995; Dlugokencky and Tans, 2013).

6.3.3.2 CH₄ Emissions

The CH₄ growth rate results from the balance between emissions and sinks. Methane emissions around the globe are biogenic, thermogenic or pyrogenic in origin (Neef et al., 2010), and they can be the direct result of either human activities and/or natural processes (see Section 6.1.1.2 and Table 6.8). Biogenic sources are due to degradation of organic matter in anaerobic conditions (natural wetlands, ruminants, waste, landfills, rice paddies, fresh waters, termites). Thermogenic sources come from the slow transformation of organic matter into fossil fuels on geological timescales (natural gas, coal, oil). Pyrogenic sources are due to incomplete combustion of organic matter (biomass and biofuel burning). Some sources can eventually combine a biogenic and a thermogenic origin (e.g., natural geological sources such as oceanic seeps, mud volcanoes or hydrates). Each of these three types of emissions is characterized by ranges in their isotopic composition in ¹³C-CH₄: typically –55 to –70‰ for biogenic, –25 to –45‰ for thermogenic, and –13 to –25‰ for pyrogenic. These isotopic distinctions provide a basis for attempting to separate the relative contribution of different methane sources using the top-down approach (Bousquet et al., 2006; Neef et al., 2010; Monteil et al., 2011).

During the decade of the 2000s, natural sources of CH₄ account for 35–50% of the decadal mean global emissions (Table 6.8). The single most dominant CH₄ source of the global flux and inter-annual variability is CH₄ emissions from wetlands (177–284 Tg(CH₄) yr⁻¹). The term ‘wetlands’ denotes here a variety of ecosystems emitting CH₄ in the tropics and the high latitudes: wet soils, swamps, bogs and peatlands. These emissions are highly sensitive to climate change and variability, as shown, for instance, from the high CH₄ growth rate in 2007–2008 that coincides with positive precipitation and temperature anomalies (Dlugokencky et al., 2009). Several process-based models of methane emissions from wetlands have been developed and improved since AR4 (Hodson et al., 2011; Ringeval et al., 2011; Spahni et al., 2011; Melton et al., 2013), yet the confidence in modeled wetland CH₄ emissions remains low particularly because of

limited observational datasets available for model calibration and evaluation. Spatial distribution and temporal variability of wetlands also remains highly unconstrained in spite the existence of some remote sensing products (Papa et al., 2010). It has been observed that wetland CH₄ emissions increase in response to elevated atmospheric CO₂ concentrations (van Groenigen et al., 2011) which also attributes such an increase in CH₄ emissions from natural wetlands to increasing soil moisture due to the reduced plant demand for water under higher CO₂. However, the sign and magnitude of the CH₄ emission response to changes in temperature and precipitation vary among models but show, on average, a decrease of wetland area and CH₄ flux with increasing temperature, especially in the tropics, and a modest (~4%) increase of wetland area and CH₄ flux with increasing precipitation (Melton et al., 2013).

In AR4, natural geological sources were estimated between 4 and 19 Tg(CH₄) yr⁻¹. Since then, Etiope et al. (2008) provided improved emission estimates from terrestrial (13–29 Tg(CH₄) yr⁻¹) and marine (~20 Tg(CH₄) yr⁻¹) seepages, mud volcanoes (6–9 Tg(CH₄) yr⁻¹), hydrates (5–10 Tg(CH₄) yr⁻¹) and geothermal and volcanic areas (3–6 Tg(CH₄) yr⁻¹) which represent altogether between 42 and 64 Tg(CH₄) yr⁻¹ (see Table 6.8 for full range of estimates). This contribution from natural, geological, and partly fossil CH₄ is larger than in AR4 and consistent with a ¹⁴CH₄ re-analysis showing natural and anthropogenic fossil contributions to the global CH₄ budget to be around 30% (Lassey et al., 2007) and not around 20% as previously estimated (e.g., AR4). However, such a large percentage was not confirmed by an analysis of the global atmospheric record of ethane (Simpson et al., 2012) which is co-emitted with geological CH₄.

Of the natural sources of CH₄, emissions from thawing permafrost and CH₄ hydrates in the northern circumpolar region will become potentially important in the 21st century because they could increase dramatically due to the rapid climate warming of the Arctic and the large C pools stored there (Tarnocai et al., 2009; Walter Anthony et al., 2012) (see Section 6.4.3.4). Hydrates are however estimated to represent only a very small emission, between 2 to 9 Tg(CH₄) yr⁻¹ under the current time period (Table 6.8). Super saturation of dissolved CH₄ at the bottom and surface waters in the East Siberian Arctic Shelf indicate some CH₄ activity across the region, with a net sea-air flux of 10.5 Tg(CH₄) yr⁻¹ which is similar in magnitude to the flux for the entire ocean (Shakhova et al., 2010) but it is not possible to say whether this source has always been present or is a consequence of recent Arctic changes. The ebullition of CH₄ from decomposing, thawing lake sediments in north Siberia with an estimated flux of ~4 Tg(CH₄) yr⁻¹ is another demonstration of the activity of this region and of its potential importance in the future (Walter et al., 2006; van Huissteden et al., 2011). The sum of all natural emission estimates other than wetlands is still very uncertain based on bottom-up studies [see Table 6.8, Range of 238–484 Tg(CH₄) yr⁻¹ for 2000–2009].

Pyrogenic sources of CH₄ (biomass burning in Table 6.8) are assessed to have a small contribution in the global flux for the 2000s (32–39 Tg(CH₄) yr⁻¹). Biomass burning of tropical and boreal forests (17–21 Tg(CH₄) yr⁻¹) play a much smaller role than wetlands in inter-annual variability of emissions, except during intensive fire periods (Langenfjelds et al., 2002; Simpson et al., 2006). Only during the 1997–1998 record strong El Niño, burning of forests and peatland that took place in Indonesia and Malaysia, released ~12 Tg(CH₄) and contributed to the observed growth rate anomaly (Langenfjelds et al., 2002; van der Werf et al., 2004). Other smaller fire CH₄ emissions positive anomalies were suggested over the northern mid-latitudes in 2002–2003, in particular over Eastern Siberia in 2003 (van der Werf et al., 2010) and Russia in 2010. Traditional biofuel burning is estimated to be a source of 14–17 Tg(CH₄) yr⁻¹ (Andreae and Merlet, 2001; Yevich and Logan, 2003).

Keppler et al. (2006) reported that plants under aerobic conditions were able to emit CH₄, and thus potentially could constitute a large additional emission, that had not been previously considered in the global CH₄ budget. Later studies do not support plant emissions as a widespread mechanism (Dueck et al., 2007; Wang et al., 2008; Nisbet et al., 2009) or show small to negligible emissions in the context of the global CH₄ budget (Vigano et al., 2008; Nisbet et al., 2009; Bloom et al., 2010). Alternative mechanisms have been suggested to explain an apparent aerobic CH₄ production, which involve (1) adsorption and desorption (Kirschbaum and Walcroft, 2008; Nisbet et al., 2009), (2) degradation of organic matter under strong UV light (Dueck et al., 2007; Nisbet et al., 2009), and (3) methane in the groundwater emitted through internal air spaces in tree bodies (Terazawa et al., 2007). Overall, a significant emission of CH₄ by plants under aerobic conditions is very unlikely, and this source is not reported in Table 6.8.

Anthropogenic CH₄ sources are estimated to range between 50% and 65% of the global emissions for the 2000s (Table 6.8). They include rice-paddies agriculture, ruminant animals, sewage and waste, landfills, and fossil fuel extraction, storage, transformation, transportation and use (coal mining, gas and oil industries). Anthropogenic sources are dominant over natural sources in top-down inversions (~65%) but they are of the same magnitude in bottom-up models and inventories (Table 6.8). Rice paddies emit between 33 and 40 Tg(CH₄) yr⁻¹ and 90% of these emissions come from tropical Asia, with more than 50% from China and India (Yan et al., 2009). Ruminant livestock, such as cattle, sheep, goats, etc. produce CH₄ by food fermentation in their anoxic rumens with a total estimate of between 87 and 94 Tg(CH₄) yr⁻¹. Major regional contributions of this flux come from India, China, Brazil, and the US (EPA, 2006; Olivier and Janssens-Maenhout, 2012), EDGAR v4.2. India, with the world's largest livestock population emitted 11.8 Tg(CH₄) yr⁻¹ in 2003, including emission from enteric fermentation (10.7 Tg(CH₄) yr⁻¹) and manure management (1.1 Tg(CH₄) yr⁻¹; Chhabra et al., 2013). Methanogenesis in landfills, livestock manure and waste waters produces between 67 and 90 Tg(CH₄) yr⁻¹ due to anoxic conditions and a high availability of acetate, CO₂ and H₂. Loss of natural gas (~90% CH₄) is the largest contributor to fossil fuel related fugitive emissions estimated between 85 and 105 Tg(CH₄) yr⁻¹ US (EPA, 2006; Olivier and Janssens-Maenhout, 2012), EDGAR v4.2.

6.3.3.3 Sinks of Atmospheric CH₄

The main sink of atmospheric CH₄ is its oxidation by OH radicals, a chemical reaction that takes place mostly in the troposphere and stratosphere (Table 6.8). OH removes each year an amount of CH₄ equivalent to 90% of all surface emissions (Table 6.8), i.e., 9% of the total burden of CH₄ in the atmosphere, which defines a partial atmospheric lifetime with respect to OH of 7–11 years for an atmospheric burden of 4800 Tg(CH₄) (4700–4900 TgCH₄ as computed by ACCMIP atmospheric chemistry models in Voulgarakis et al. (2013) thus slightly different from Figure 6.2; see Chapter 8, Section 8.2.3.3 for ACCMIP models). A recent estimate of the CH₄ lifetime is 9.1 to –0.9 years (Prather et al., 2012). A small sink of atmospheric CH₄ is suspected, but still debated, in the marine boundary layer due to a chemical reaction with chlorine (Allan et al., 2007). Another small sink is the reaction of CH₄ with Cl radicals and O(¹D) in the stratosphere (Shallcross et al., 2007; Neef et al., 2010). Finally, oxidation in upland soils (with oxygen) by methanotrophic bacteria removes about 9–47 Tg(CH₄) yr⁻¹ (Curry, 2007; Dutaur and Verchot, 2007; Spahni et al., 2011; Ito and Inatomi, 2012).

There have been a number of published estimates of global OH concentrations and variations over the past decade (Prinn et al., 2001; Dentener et al., 2003; Bousquet et al., 2005; Prinn et al., 2005; Rigby et al., 2008; Montzka et al., 2011). The very short lifetime of OH makes it almost impossible to measure directly global OH concentrations in the atmosphere. Chemistry transport models (CTMs), chemistry climate models (CCMs), or proxy methods have to be used to obtain a global mean value and time variations. For the 2000s, CTMs and CCMs (Young et al., 2013) estimate a global chemical loss of methane due to OH of 604 Tg(CH₄) yr⁻¹ (509–764 Tg(CH₄) yr⁻¹). This loss is larger, albeit compatible considering the large uncertainties, with a recent extensive analysis by Prather et al. (2012) inferring a global chemical loss of 554 ± 56 Tg(CH₄) yr⁻¹. Top-down inversions using methyl-chloroform (MCF) measurements to infer OH provide a smaller chemical loss of 518 Tg(CH₄) yr⁻¹ with a more narrow range of 510–538 Tg(CH₄) yr⁻¹ in the 2000s. However, inversion estimates probably do not account for all sources of uncertainties (Prather et al., 2012).

CCMs and CTMs simulate small inter-annual variations of OH radicals, typically of 1–3% (standard deviation over a decade) due to a high buffering of this radical by atmospheric photochemical reactions (Voulgarakis et al., 2013; Young et al., 2013). Atmospheric inversions show much larger variations for the 1980s and the 1990s (5–10%), likely because of their oversensitivity to uncertainties on methyl-chloroform emissions, when measurements of this tracer are used to reconstruct OH (Montzka et al., 2011), although reduced variations are inferred after 1998 by Prinn et al. (2005). For the 2000s, the reduction of MCF in the atmosphere, due to the Montreal protocol (1987) and its further amendments, allows a consistent estimate of small OH variations between atmospheric inversions (<±5%) and CCMs/CTMs (<±3%). However, the very low atmospheric values reached by MCF (few ppt in 2010) impose the need to find another tracer to reconstruct global OH in the upcoming years. Finally, evidence for the role of changes in OH concentrations in explaining the increase in atmospheric methane since 2007 is variable, ranging from a significant contribution (Rigby et al., 2008) to only a small role (Bousquet et al., 2011).

6.3.3.4 Global CH₄ Budget for the 2000s

Based on the inversion of atmospheric measurements of CH₄ from surface stations, global CH₄ emissions for the 2000s are of 548 Tg(CH₄) yr⁻¹, with a range of 526–569 Tg(CH₄) yr⁻¹ (Table 6.8). The total loss of atmospheric methane is of 540 Tg(CH₄) yr⁻¹ with a range of 514–560 Tg(CH₄) yr⁻¹, determining a small imbalance of about 8 Tg(CH₄) yr⁻¹, in line with the small growth rate of 6 Tg(CH₄) yr⁻¹ observed for the 2000s.

Based on bottom-up models and inventories, a larger global CH₄ emissions of 678 Tg(CH₄) yr⁻¹ are found, mostly because of the still debated upward re-evaluation of geological (Etiope et al., 2008) and fresh water (Walter et al., 2007; Bastviken et al., 2011) emission sources. An averaged total loss of 632 Tg(CH₄) yr⁻¹ is found, by an ensemble of Atmospheric Chemistry models (Lamarque et al., 2013) leading to an imbalance of about 45 Tg(CH₄) yr⁻¹ during the 2000s, as compared to the observed mean growth rate of 6 Tg(CH₄) yr⁻¹ (Table 6.8; Dlugokencky et al., 2011). There is no constraint that applies to the sum of emissions in the bottom-up approach, unlike for top-down inversions when these have constrained OH fields (e.g., from MCF). Therefore, top-down inversions can help constrain global CH₄ emissions in the global budget, although they do not resolve the same level of detail in the mix of sources than the bottom up approaches, and thus provide more limited information about processes (Table 6.8).

6.3.4 Global Nitrogen Budgets and Global N₂O Budget in the 1990s

The atmospheric abundance of N₂O has been increasing mainly as a result of agricultural intensification to meet the food demand for a growing human population. Use of synthetic fertilizer (primarily from the Haber-Bosch process) use and manure applications increase the production of N₂O in soils and sediments, via nitrification and denitrification pathways, leading to increased N₂O emissions to the atmosphere. Increased emissions do not only occur in agricultural fields, but also in aquatic systems after nitrogen leaching and runoff, and in natural soils and ocean surface waters as a result of atmospheric deposition of nitrogen originating from agriculture, fossil fuel combustion and industrial activities. Food production is likely responsible for 80% of the increase in atmospheric N₂O (Kroeze et al., 1999; Davidson, 2009; Williams and Crutzen, 2010; Syakila and Kroeze, 2011; Zaehle et al., 2011; Park et al., 2012), via the addition of N-fertilizers. Global emissions of N₂O are difficult to estimate due to heterogeneity in space and time. Table 6.9 presents global emissions based on upscaling of local flux measurements at the surface. Modeling of the atmospheric life-time of N₂O and atmospheric inversions constrain global and regional N₂O budgets (Hirsch et al., 2006; Huang et al., 2008; Rhee et al., 2009; Prather et al., 2012), although there is uncertainty in these estimates because of uncertainty in the dominant loss term of N₂O, i.e., the destruction of N₂O by photolysis and reaction with O(1D) in the stratosphere. The long atmospheric lifetime of N₂O (118–131 years, Fleming et al., 2011; Volk et al., 1997; Hsu and Prather, 2010; see Chapter 8) implies that it will take more than a century before atmospheric abundances stabilize after the stabilization of global emissions. This is of concern not only because of its contribution to the radiative forcing (see Glossary), but also because the relative importance of N₂O and other greenhouse gases in affecting the ozone layer (Ravishankara et al., 2009; Fleming et al., 2011).

[INSERT TABLE 6.9 HERE]

Table 6.9: Section 1 gives the global nitrogen budget (TgN yr⁻¹): a) creation of reactive nitrogen, b) emissions of NO_x, NH₃ in 2000s to atmosphere, c) deposition of nitrogen to continents and oceans, d) discharge of total nitrogen to coastal ocean and e) conversion of Nr to N₂ by denitrification. Section 2 gives the N₂O budget for the year 2006, and for the 1990s compared to AR4. Unit: Tg(N₂O-N) yr⁻¹.

Since AR4 (Table 6.9 for the 1990s), a number of studies allow us to update some of the N₂O emission estimates. First and most importantly, the IPCC Guidelines were revised in 2006 (De Klein et al., 2007) and in particular emission factors for estimating agricultural N₂O emissions. Applying these 2006 emission factors to global agricultural statistics results in higher direct emissions from agriculture (from fertilized soils and animal production) than in AR4, but into indirect emissions (associated with leaching and runoff of Nr resulting in N₂O emissions from groundwater, riparian zones and surface waters) that are considerably lower than reported in AR4 (Table 6.9). It should be noted that emissions of N₂O show large uncertainties when default emission factors are applied at the global scale (Crutzen et al., 2008; Davidson, 2009; Smith et al., 2012). Second, estimates of the anthropogenic source of N₂O from the open ocean have been made for the

first time. These emissions result from atmospheric deposition of anthropogenic Nr (nitrogen oxides and ammonia/ammonium) (Duce et al., 2008; Suntharalingam et al., 2012). This anthropogenic ocean N₂O source was implicitly included as part of the natural ocean N₂O source in AR4, but is now given as a separate anthropogenic source of 0.2 (0.1–0.4) TgN yr⁻¹ in Table 6.9. Finally, a first estimate of global N₂O uptake at the surface is now available (Syakila et al., 2010; Syakila and Kroeze, 2011), based on reviews of measurements of N₂O uptake in soils and sediments (Chapuis-Lardy et al., 2007; Kroeze et al., 2007). The uncertainty in this sink of N₂O is large. On the global scale, this surface sink is negligible, but at the local scale it may not be irrelevant.

6.3.4.1 Atmosphere N₂O Burden and Growth Rate

The concentration of N₂O is currently 20% higher than pre-industrial levels (Figure 6.11; MacFarling-Meure et al., 2006). Figure 6.19 shows the annual growth rate of atmospheric N₂O estimated from direct measurements (NOAA/GMD network of surface stations). On decadal time scales, the concentration of N₂O has been increasing at a rate of 0.73 ± 0.03 ppb yr⁻¹. The inter-annual variability in mid to high latitude N₂O abundance in both the Northern and Southern hemispheres was found to correlate with the strength of the stratospheric Brewer-Dobson circulation (Nevison et al., 2011). Variability in stratosphere to troposphere air mass exchange, coupled with the stratospheric N₂O sink is likely to be responsible for a fraction of the inter-annual variability in tropospheric N₂O, but the understanding of this process is poor (Huang et al., 2008). This removal process signal is obscured in the southern hemisphere by the timing of oceanic thermal and biological ventilation signals (Nevison et al., 2011) and terrestrial sources (Ishijima et al., 2009). These two factors may thus also be important determinants of seasonal and inter-annual variability of N₂O in the atmosphere. Quantitative understanding of terrestrial N₂O emissions variability is poor, although emissions are known to be sensitive to soil water content (Ishijima et al., 2009). A first process model-based estimate suggests that the mainly climate-driven variability in the terrestrial source may account for only 0.07 ppb yr⁻¹ variability in atmospheric N₂O growth rate, which would be difficult to detect in the observed growth rate (Zaehle et al., 2011).

[INSERT FIGURE 6.19 HERE]

Figure 6.19: Upper panel: Globally averaged growth rate of atmospheric N₂O in ppb yr⁻¹ representative for the marine boundary layer. Lower panel: Atmospheric growth rate of N₂O as a function of latitude. Sufficient observations are only available since the year 2002. Observations from the NOAA/ESRL network (Masarie and Tans, 1995; Dlugokencky and Tans, 2013).

Most N₂O is produced by biological (microbial) processes such as nitrification and denitrification in terrestrial and aquatic systems, including rivers, estuaries, coastal seas and the open ocean (Table 6.9; Freing et al., 2012). In general, more N₂O is formed when more reactive nitrogen is available. The production of N₂O shows large spatial and temporal variability. Emission estimates for tropical regions and for aquatic systems are relatively uncertain. Inverse modeling studies show that the errors in emissions are large, especially in (sub)-tropical regions (e.g., Hirsch et al., 2006; Huang et al., 2008). Emissions from rivers, estuaries and continental shelves have been subject of debate for many years (Seitzinger and Kroeze, 1998; De Klein et al., 2007). Recent studies confirm that rivers can be important sources of N₂O which could be a reason to reconsider recent estimates of aquatic N₂O emissions (Beaulieu et al., 2011; Rosamond et al., 2012).

Table 6.9 does not include the formation of atmospheric N₂O from abiotic decomposition of ammonium nitrate in the presence of light, appropriate relative humidity and a surface. This process has been recently proposed as a potentially important source of N₂O (Rubasinghege et al., 2011), however, a global estimate does not yet exist. Table 6.9 indicates that the global N₂O emissions in the mid-1990s amount to 17.5 (8.1–30.7) TgN (N₂O) yr⁻¹. The uncertainty range is consistent with that of atmospheric inversions studies (14.1–17.8) by Huang et al. (2008). The estimates of anthropogenic N₂O emissions of Table 6.9 are in line with the top-down estimates by Prather et al. (2012) of 6.5 ± 1.3 TgN (N₂O) yr⁻¹, and somewhat higher than their estimates for natural (9.1 ± 1.3 TgN (N₂O) yr⁻¹) and total (15.7 ± 1.1 TgN (N₂O) yr⁻¹) emissions. Anthropogenic emissions have steadily increased over the last two decades and were 6.9 (2.7–11.1) TgN (N₂O) yr⁻¹ in 2006 or 6% higher than the value in mid-1990s (Davidson, 2009; Zaehle et al., 2011) (see also Figure 6.4c). Overall, anthropogenic N₂O emissions are now a factor of 8 greater than their estimated level in 1900. These trends are consistent with observed increases in atmospheric N₂O (Syakila et al., 2010). Human

activities strongly influence the source of N₂O, since N-fertilizer used in agriculture is now the main source of nitrogen for nitrification and denitrification (Opdyke et al., 2009). Nitrogen stable isotope ratios confirm that fertilised soils are primarily responsible for the historic increase in N₂O (Röckmann and Levin, 2005; Sutka et al., 2006; Park et al., 2012).

6.3.4.2 Sensitivity of N₂O Fluxes to Climate and Elevated CO₂

Previous studies suggested a considerable positive feedback between N₂O and climate (Khalil and Rasmussen, 1989) supported by observed glacial-interglacial increases of ~70 ppb in atmospheric N₂O (Flückiger et al., 1999). Climate change influence marine and terrestrial N₂O sources, but their individual contribution and even the sign of their response to long-term climate variations are difficult to estimate (see Section 6.2). Simulations by terrestrial biosphere models suggest a moderate increase of global N₂O emissions with recent climatic changes, mainly related to changes in land temperature (Zaehle and Dalmonech, 2011; Xu-Ri et al., 2012), thus suggesting a possible positive feedback to the climate system. Nonetheless, the recent change in atmospheric N₂O is largely dominated to anthropogenic reactive nitrogen (Nr) and industrial emissions (Holland et al., 2005; Davidson, 2009; Zaehle and Dalmonech, 2011). Stocker et al. (2013) have found using a global coupled model of climate and biogeochemical cycles, that future climate change will amplify terrestrial N₂O emissions resulting from anthropogenic Nr additions, consistent with empirical understanding (Butterbach-Bahl and Dannenmann, 2011). This result suggests that the use of constant emission factors might underestimate future N₂O emission trajectories. Significant uncertainty remains in the N₂O-climate feedback from land ecosystems, given the poorly known response of emission processes to the changes in seasonal and frequency distribution of precipitation, and also because agricultural emissions themselves may also be sensitive to climate.

N₂O production will be affected by climate change through the effects on the microbial nitrification and denitrification processes (Barnard et al., 2005; Singh et al., 2010; Butterbach-Bahl and Dannenmann, 2011). Warming experiments tend to show enhanced N₂O emission (Lohila et al., 2010; Brown et al., 2011; Chantarel et al., 2011; Larsen et al., 2011). Elevated CO₂ predominantly increases N₂O emissions (van Groenigen et al., 2011), however, reductions have also been observed (Billings et al., 2002; Mosier et al., 2002), induced by changes in soil moisture, plant productivity and nitrogen uptake, as well as activity and composition of soil microbial and fungal communities (Barnard et al., 2005; Singh et al., 2010). The effect of interacting climate and atmospheric CO₂ change modulates and potentially dampens the individual responses to each driver (Brown et al., 2011). A terrestrial biosphere model that integrates the interacting effects of temperature, moisture and CO₂ changes is capable of qualitatively reproducing the observed sensitivities to these factors and their combinations (Xu-Ri et al., 2012). Thawing permafrost soils under particular hydrological settings may liberate reactive nitrogen and turn into significant sources of N₂O, however, the global significance of this source is not established (Elberling et al., 2010).

6.3.4.3 Global Nitrogen Budget

For base year 2005, anthropogenic activities created ~210 (190–230) TgN of reactive nitrogen Nr from N₂, more than 3 times the reactive nitrogen from natural terrestrial sources of ~58 TgN (50–100 TgN yr⁻¹) (Table 6.9, Section 1a). Note that the estimate of natural terrestrial biological fixation (58 TgN yr⁻¹) is lower than former estimates (100 TgN yr⁻¹, Galloway et al., 2004), but the ranges overlap, 50–100 TgN yr⁻¹, vs. 90–120 TgN yr⁻¹, respectively). Of this created reactive nitrogen, NO_x and NH₃ emissions from anthropogenic sources are ~4-fold greater than natural emissions (Table 6.9, Section 1b). A greater portion of the NH₃ emissions are deposited to the continents rather than to the oceans, relative to the deposition of NO_y, due to the longer atmospheric residence time of the latter. These deposition estimates are lower limits, as they do not include organic nitrogen species. New model and measurement information (Kanakidou et al., 2012) suggest that incomplete inclusion of emissions and atmospheric chemistry of reduced and oxidized organic nitrogen components in current models may lead to systematic underestimates of total global reactive nitrogen deposition by up to 35% (Table 6.9, Section 1c). Discharge of reactive nitrogen to the coastal oceans is ~45 TgN yr⁻¹ (Table 6.9, Section 1d). Denitrification converts Nr back to atmospheric N₂. Current estimate for the production of atmospheric N₂ is 110 Tg N yr⁻¹ (Bouwman et al., 2013). Thus of the ~280 TgN yr⁻¹ of Nr from anthropogenic and natural sources, ~40% gets converted to N₂ each year. The remaining 60% is stored in terrestrial ecosystems, transported by rivers and by atmospheric transport and deposition to the ocean, or emitted as N₂O (a small fraction of total Nr only despite the important forcing of increasing

N_2O emissions for climate change). For the oceans, denitrification producing atmospheric N_2 is 200–400 TgN yr^{-1} , which is larger than the current uptake of atmospheric N_2 by ocean biological fixation of 140–177 TgN yr^{-1} (Table 6.9 Section 1e; Figure 6.4a).

6.4. Projections of Future Carbon and Other Biogeochemical Cycles

6.4.1 Introduction

In this section, we assess coupled model projections of changes in the evolution of CO_2 , CH_4 and N_2O fluxes, and hence the role of carbon and other biogeochemical cycles in future climate under socio-economic emission scenarios (see Box 6.4). AR4 reported how climate change can affect the natural carbon cycle in a way which could feed back onto climate itself. A comparison of 11 coupled climate-carbon cycle models of different complexity (Coupled Climate-Carbon Cycle Model Intercomparison Project; C4MIP; Friedlingstein et al., 2006) showed that all 11 models simulated a positive feedback. There is substantial quantitative uncertainty in future CO_2 and temperature, both across coupled carbon-climate models (Friedlingstein et al., 2006; Plattner et al., 2008) and within each model parametrizations (Falloon et al., 2011; Booth et al., 2012; Higgins and Harte, 2012). This uncertainty on the coupling between carbon cycle and climate is of comparable magnitude to the uncertainty caused by physical climate processes discussed in Chapter 12 of this report (Denman et al., 2007; Gregory et al., 2009; Huntingford et al., 2009).

Other biogeochemical cycles and feedbacks play an important role in the future of the climate system, although the carbon cycle represents the strongest of these. Natural CH_4 emissions from wetland and fires are sensitive to climate change (Section 6.2; Sections 6.4.7 and 6.3.3.2). The fertilizing effects of nitrogen deposition and rising CO_2 also likely affect CH_4 emissions by wetlands through increased plant productivity (Stocker et al., 2013). Changes in the nitrogen cycle, in addition to interactions with CO_2 sources and sinks, are very likely to affect the emissions of N_2O both on land and from the ocean (Section 6.3.4.2; Section 6.4.6) and potentially on the rate of CH_4 oxidation (Gärdenäs et al., 2011). A recent review highlighted the complexity of terrestrial biogeochemical feedbacks on climate change (Arneth et al., 2010) and used the methodology of Gregory et al. (2009) to express their magnitude in common units of $\text{W m}^{-2} \text{K}^{-1}$ (Figure 6.20). A similar degree of complexity exists in the ocean and in interactions between land, atmosphere and ocean cycles. Many of these processes are not yet represented in coupled climate-biogeochemistry models. Leuzinger et al. (2011) observed a trend from manipulation experiments for higher-order interactions between feedbacks to reduce the magnitude of response. *Confidence* in the magnitude, and sometimes even the sign, of many of these feedbacks between climate and carbon and other biogeochemical cycles is *low*.

[INSERT FIGURE 6.20 HERE]

Figure 6.20: A synthesis of the magnitude of biogeochemical feedbacks on climate. Gregory et al. (2009) proposed a framework for expressing non-climate feedbacks in common units ($\text{W m}^{-2} \text{K}^{-1}$) with physical feedbacks, and Arneth et al. (2010) extended this beyond carbon cycle feedbacks to other terrestrial biogeochemical feedbacks. The figure shows the results compiled by Arneth et al. (2010), with ocean carbon feedbacks from the C4MIP coupled climate-carbon models used for AR4 also added. Some further biogeochemical feedbacks are also shown but this list is not exhaustive. Black dots represent single estimates, and coloured bars denote the simple mean of the dots with no weighting or assessment being made to likelihood of any single estimate. There is *low confidence* in the magnitude of the feedbacks in the lower portion of the figure, especially for those with few, or only one, dot. The role of nitrogen limitation on terrestrial carbon sinks is also shown — this is not a separate feedback, but rather a modulation to the climate-carbon and concentration-carbon feedbacks. These feedback metrics are also likely to be state or scenario dependent and so cannot always be compared like-for-like (see Section 6.4.2.2). Results have been compiled from (a) Arneth et al. (2010), (b) Friedlingstein et al. (2006), (c) HadGEM2-ES (Collins et al., 2011) simulations, (d) Burke et al. (2012), (e) von Deimling et al. (2012), (f) Stocker et al. (2013). Note the different x-axis scale for the lower portion of the figure.

The response of land and ocean carbon storage to changes in climate, atmospheric CO_2 and other anthropogenic activities (e.g., land use change; Table 6.2) varies strongly on different timescales. This chapter has assessed carbon cycle changes across many timescales from millennial (see Section 6.2) to inter-annual and seasonal (see Section 6.3), and these are summarised in Table 6.10. A common result is that an increase in atmospheric CO_2 will *always* lead to an *increase* in land and ocean carbon storage, all other things being held constant. Cox et al. (2013) find an empirical relationship between short term inter-annual variability and long-term land tropical carbon cycle sensitivity which may offer an observational constraint on the climate-carbon cycle response over the next century. Generally, however, changes in climate on

different timescales do not lead to a consistent sign and magnitude of the response in carbon storage change due to the very many different mechanisms that operate. Thus, changes in carbon cycling on one timescale cannot be extrapolated to make projections on different timescales, but can provide valuable information on the processes at work and can be used to evaluate and improve models.

[INSERT TABLE 6.10 HERE]

Table 6.10: Comparison of the sign and magnitude of changes in carbon storage (PgC) by land and ocean over different timescales. These changes are shown as approximate numbers to allow a comparison across timescales. For more details see the indicated chapter section. An indication, where known, of what causes these changes (climate, CO₂, land use change) is also given with an indication of the sign: ‘+’ means that an increase in CO₂ or global-mean temperature is associated with an increase in carbon storage (positive β or γ — see Section 6.4.2), and a ‘–’ means an increase in CO₂ or global-mean temperature is associated with a decrease in carbon storage (negative β or γ). The processes which operate to drive these changes can vary markedly, e.g., from seasonal phenology of vegetation to long-term changes in ice sheet cover or ocean circulation impacting carbon reservoirs. Some of these processes are ‘reversible’ in the context that they can increase and decrease cyclically, whereas some are ‘irreversible’ in the context that changes in one sense might be much longer than in the opposite direction.

[START BOX 6.4 HERE]

Box 6.4: Climate-Carbon Cycle Models and Experimental Design

What are coupled climate-carbon cycle models and why do we need them?

Atmosphere-Ocean general circulation models (AO-GCMs, see Glossary) have long been used for making climate projections, and have formed the core of previous IPCC climate projection chapters (e.g., Meehl et al. (2007), see also Chapters 1, 9, 12). For the 5th Coupled Model Intercomparison Project (CMIP5), many models now have an interactive carbon cycle. What exactly does this mean, how do they work and how does their use differ from previous climate models? Atmosphere-ocean GCMs typically represent the physical behaviour of the atmosphere and oceans but atmospheric composition, such as the amount of CO₂ in the atmosphere, is prescribed as an input to the model. This approach neglects the fact that changes in climate might affect the natural biogeochemical cycles, which control atmospheric composition, and so there is a need to represent these processes in climate projections.

At the core of coupled climate-carbon cycle models is the physical climate model, but additional components of land and ocean biogeochemistry respond to the changes in the climate conditions to influence in return the atmospheric CO₂ concentration. Input to the models comes in the form of anthropogenic CO₂ emissions, which can increase the CO₂ and then the natural carbon cycle exchanges CO₂ between the atmosphere and land and ocean components. These ‘climate-carbon cycle models’ (‘Earth System Models’, ESMs — see Glossary) provide a predictive link between fossil fuel CO₂ emissions and future CO₂ concentrations and climate and are an important part of the CMIP5 experimental design (Hibbard et al., 2007; Taylor et al., 2012).

Apart from Earth System GCMs, so called Earth System models of intermediate complexity (EMICs) are often used to perform similar experiments (Claussen et al., 2002; Plattner et al., 2008). EMICs have reduced resolution or complexity but run much more quickly and can be used for longer experiments or large ensembles.

How are these models used?

The capability of ESMs to simulate carbon cycle processes and feedbacks and in some models other biogeochemical cycles, allows for a greater range of quantities to be simulated such as changes in natural carbon stores, fluxes or ecosystem functioning. There may also be applications where it is desirable for the user to pre-define the pathway of atmospheric CO₂ and prescribe it as a forcing to the ESMs. Thus, numerical simulations with ESM models can be either ‘concentration driven’ or ‘emissions driven’.

Concentration-driven simulations follow the ‘traditional’ approach of prescribing the time-evolution of atmospheric CO₂ as an input to the model. This is shown schematically in Box 6.4 Figure 1 (left hand side). Atmospheric CO₂ concentration is prescribed as input to the model from a given scenario and follows a pre-

defined pathway regardless of changes in the climate or natural carbon cycle processes. The processes between the horizontal dashed lines in the figure represent the model components which are calculated during the concentration-driven simulation. Externally prescribed changes in atmospheric CO₂ concentration, which drive climate change, affect land and ocean carbon storage. By construction, changes in land and ocean storage, however, do not feedback on the atmospheric CO₂ concentration nor on climate. The changes in natural carbon fluxes and stores are output by the model.

So called ‘compatible fossil fuel emissions’, E , can be diagnosed afterwards from mass conservation by calculating the residual between the prescribed CO₂ pathway and the natural fluxes:

$$E = \frac{dCO_2}{dt}_{prescribed} + (land_carbon_uptake + ocean_carbon_uptake) \quad (6.1)$$

Land use change emissions cannot be diagnosed separately from a single simulation (see Section 6.4.3.2).

[INSERT BOX 6.4, FIGURE 1 HERE]

Box 6.4, Figure 1: Schematic representation of carbon cycle numerical experimental design. Concentration-driven (left hand side) and emissions-driven (right hand side) simulation experiments make use of the same ESM models, but configured differently. Concentration-driven simulations prescribe atmospheric CO₂ as a pre-defined input to the climate and carbon cycle model components, but their output does not affect the CO₂. Compatible emissions can be calculated from the output of the concentration driven simulations. Emissions-driven simulations prescribe CO₂ emissions as the input and atmospheric CO₂ is an internally calculated element of the Earth system model.

Emissions-driven simulations allow the full range of interactions in the models to operate and determine the evolution of atmospheric CO₂ and climate as an internal part of the simulation itself (Box 6.4, Figure 1, right hand side). In this case emissions of CO₂ are the externally prescribed input to the model and the subsequent changes in atmospheric CO₂ concentration are simulated by it.

In *emissions-driven* experiments, the global atmospheric CO₂ growth rate is calculated within the model due to the net balance between the anthropogenic emissions, E , and natural fluxes:

$$\frac{dCO_2}{dt}_{simulated} = E - (land_carbon_uptake + ocean_carbon_uptake) \quad (6.2)$$

The effect of climate change on the natural carbon cycle will manifest itself either through changes in atmospheric CO₂ in the *emissions-driven* experiments or in the compatible emissions in the *concentration-driven* experiments.

Concentration-driven simulation experiments have the advantage that they can also be performed by GCMs without an interactive carbon cycle and have been used extensively in previous assessments (e.g., Prentice et al., 2001). For this reason, most of the RCP simulations (see Chapter 1) presented later in this Chapter with carbon cycle models and in Chapter 12 with models that do not all have an interactive carbon cycle, are performed this way. Emissions-driven simulations have the advantage of representing the full range of interactions in the coupled climate-carbon cycle models. The RCP8.5 pathway was repeated by many ESM models as an emissions-driven simulation (Chapter 12).

Feedback Analysis

The Earth System models are made up of many ‘components’, corresponding to different processes or aspects of the system. In order to understand their behaviour techniques have been applied to assess different aspects of the models' sensitivities (Friedlingstein et al., 2003; Friedlingstein et al., 2006; Arora et al., 2013). The two dominant emerging interactions are the sensitivity of the carbon cycle to changes in CO₂ and its sensitivity to changes in climate. These can be measured using two metrics: ‘beta’ (β) measures the strength of changes in carbon fluxes by land or ocean in response to changes in atmospheric CO₂; ‘gamma’ (γ) measure the strength of changes in carbon fluxes by land or ocean in response to changes in climate. These

metrics can be calculated as cumulative changes in carbon storage (as in Friedlingstein et al., 2006) or instantaneous rates of change (Arora et al., 2013).

It is not possible to calculate these sensitivities in a single simulation, so it is necessary to perform ‘decoupled’ simulations where some processes in the models are artificially disabled in order to be able to evaluate the changes in other processes. See Box 6.4 Table 1.

Box 6.4, Table 1: Configurations of simulations designed for feedback analysis by allowing some carbon-climate interactions to operate but holding others constant. The curves denote whether increasing or constant CO₂ values are input to the radiation and carbon cycle model components. In a fully coupled simulation, the carbon cycle components of the models experience both changes in atmospheric CO₂ (see Box 6.3 on fertilization) and changes in climate. In “biogeochemically” coupled experiments, the atmospheric radiation experiences constant CO₂ (i.e., the radiative forcing of increased CO₂ is not activated in the simulation) while the carbon cycle model components experience increasing CO₂. This experiment quantifies the strength of the effect of rising CO₂ concentration alone on the carbon cycle (β). In a radiatively coupled experiment, the climate model's radiation scheme experiences an increase in the radiative forcing of CO₂ (and hence produces a change in climate) but CO₂ concentration is kept fixed to pre-industrial value as input to the carbon cycle model components. This simulation quantifies the effect of climate change alone on the carbon cycle (γ).

	CO ₂ input to radiation scheme	CO ₂ input to carbon-cycle scheme	Reason
Fully coupled			Simulates the fully coupled system
“Biogeochemically” coupled 'esmFixClim'			Isolates the carbon-cycle response to CO ₂ (β) for land and oceans
Radiatively coupled 'esmFdbk'			Isolates carbon-cycle response to climate change (γ) for land and for oceans

A large positive value of β denotes that a model responds to increasing CO₂ by simulating large increases in natural carbon sinks. Negative values of γ denote that a model response to climate warming is to reduce CO₂ uptake from the atmosphere, whilst a positive value means warming acts to increase CO₂ uptake. β and γ values are not specified in a model, but are properties that emerge from the suite of complex processes represented in the model. The values of the β and γ metrics diagnosed from simulations can vary from place to place within the same model (see Section 6.4.2.3) although it is the average over the whole globe that determines the global extent of the climate-carbon cycle feedback.

Such an idealised analysis framework should be seen as a technique for assessing relative sensitivities of models and understanding their differences, rather than as absolute measures of invariant system properties. By design, these experiments exclude land use change.

The complex ESMs have new components and new processes beyond conventional atmosphere-ocean GCMs and thus require additional evaluation to assess their ability to make climate projections. Evaluation of the carbon cycle model components of ESMs is presented in Sections 6.3.2.5.6 for ocean carbon models and 6.3.2.6.6 for land carbon models. Evaluation of the fully coupled ESMs is presented in Chapter 9.

[END BOX 6.4 HERE]

6.4.2 Carbon Cycle Feedbacks in CMIP5 Models

6.4.2.1 Global Analysis

The carbon cycle response to future climate and CO₂ changes can be viewed as two strong and opposing feedbacks (Gregory et al., 2009). The climate-carbon response (γ) determines changes in carbon storage due to changes in climate, and the concentration-carbon response (β) determines changes in storage due to elevated CO₂. Climate-carbon cycle feedback responses have been analyzed for 8 CMIP5 ESMs which performed idealized simulations involving atmospheric CO₂ increasing at a prescribed rate of 1% per year (Arora et al., 2013; Box 6.4). There is *high confidence* that increased atmospheric CO₂ will lead to increased land and ocean carbon uptake but by an uncertain amount. Models agree on the sign of land and ocean response to rising CO₂ but show only medium and low agreement for the magnitude of ocean and land carbon uptake respectively (Figure 6.21). Future climate change will decrease land and ocean carbon uptake compared to the case with constant climate (*medium confidence*). Models agree on the sign, globally, of land and ocean response to climate change but show low agreement on the magnitude of this response, especially for the land. Land and ocean carbon uptake may differ in sign between different regions and between models (Section 6.4.2.3). Inclusion of N-cycle processes in two of the land carbon cycle model components out of these 8 reduces the magnitude of the sensitivity to both CO₂ and climate (Section 6.4.6.3) and increases the spread across the CMIP5 ensemble. The CMIP5 spread in ocean sensitivity to CO₂ and climate appears reduced compared with C4MIP.

[INSERT FIGURE 6.21 HERE]

Figure 6.21: Comparison of carbon cycle feedback metrics between the C4MIP ensemble of 7 GCMs and 4 EMICs under the SRES-A2 scenario (Friedlingstein et al., 2006) and the 8 CMIP5 models (Arora et al., 2013) under the 140-year 1% CO₂ increase per year scenario. Black dots represent a single model simulation and coloured bars the mean of the multi-model results, grey dots are used for models with a coupled terrestrial nitrogen cycle. The comparison with C4MIP is for context, but these metrics are known to be variable across different scenarios and rates of change (see Section 6.4.2.2). Some of the CMIP5 models are derived from models that contributed to C4MIP and some are new to this analysis. Table 6.11 lists the main attributes of each CMIP5 model used in this analysis. The SRES A2 scenario is closer in rate of change to a 0.5% yr⁻¹ scenario and as such it should be expected that the CMIP5 γ terms are comparable, but the β terms are likely to be around 20% smaller for CMIP5 than for C4MIP due to lags in the ability of the land and ocean to respond to higher rates of CO₂ increase (Gregory et al., 2009). This dependence on scenario (Section 6.4.2.2) reduces confidence in any quantitative statements of how CMIP5 carbon cycle feedbacks differ from C4MIP. CMIP5 Models used: MPI-ESM-LR, BCC-CSM1, HadGEM2-ES, IPSL-CM5A-LR, CanESM2, NorESM-ME, CESM1-BGC, MIROC-ESM.

[INSERT TABLE 6.11 HERE]

Table 6.11: CMIP5 model descriptions in terms of carbon cycle attributes and processes.

The role of the idealized experiment presented here is to study model processes and understand what causes the differences between models. Arora et al. (2013) assessed the global carbon budget from these idealized simulations and found that the CO₂ contribution to changes in land and ocean carbon storage sensitivity is typically 4–5 times larger than the sensitivity to climate across the CMIP5 ESMs. The land carbon-climate response (γ) is larger than the ocean carbon-climate response in all models. Whilst land and ocean contribute equally to the total carbon-concentration response (β), the model spread in the land response is greater than for the ocean.

6.4.2.2 Scenario Dependence of Feedbacks

The values of carbon-cycle feedback metrics can vary markedly for different scenarios and as such cannot be used to compare model simulations over different time periods, nor inter-compare model simulations with different scenarios (Arora et al., 2013). Gregory et al. (2009) demonstrated how sensitive the feedback metrics are to the rate of change of CO₂ for two models: faster rates of CO₂ increase lead to reduced beta values as the carbon uptake (especially in the ocean) lags further behind the forcing. γ is much less sensitive to the scenario, as both global temperature and carbon uptake lag the forcing.

6.4.2.3 Regional Feedback Analysis

The linear feedback analysis with the β and γ metrics of Friedlingstein et al. (2006) has been applied at the regional scale to future carbon uptake by Roy et al. (2011), Yoshikawa et al. (2008). Figure 6.22 shows this analysis extended to land and ocean points for the CMIP5 models under the 1% yr⁻¹ CO₂ simulations.

[INSERT FIGURE 6.22 HERE]

Figure 6.22: The spatial distributions of multi model-mean land and ocean β and γ for 7 CMIP5 models using the *concentration-driven* idealised 1% per year CO₂ simulations. For land and ocean, β and γ are defined from changes in terrestrial carbon storage and changes in air-sea integrated fluxes respectively, from 1xCO₂ to 4xCO₂, relative to global (not local) CO₂ and temperature change. In the zonal mean plots, the solid lines show the multi-model mean and shaded areas denote ± 1 standard deviation. Models used are: BCC-CSM1-1, CanESM2, CESM1-BGC, HadGEM2-ES, IPSL-CM5A-LR, MPI-ESM-LR, NorESM1-ME. The dashed lines show the models that include a land carbon component with an explicit representation of N-cycle processes (CESM1-BGC, NorESM1-ME).

6.4.2.3.1 Regional ocean response

Increased CO₂ is projected by the CMIP5 models to increase oceanic CO₂ sinks almost everywhere (positive β) (*high confidence*) with the exception of some very limited areas (Figure 6.22). The spatial distribution of the CO₂ ocean response, β_o , is consistent between the models and with the Roy et al. (2011) analysis. On average, the regions with the strongest increase of oceanic CO₂ sinks in response to higher atmospheric CO₂ are the North Atlantic and the Southern Ocean. The magnitude and distribution of β_o in the ocean closely resemble the distribution of historical anthropogenic CO₂ flux from inversion studies and forward modelling studies (Gruber et al., 2009), with the dominant anthropogenic CO₂ uptake in the Southern Ocean (Section 6.3.2.5).

Climate warming is projected by the CMIP5 models to reduce oceanic carbon uptake in most oceanic regions (negative γ) (*medium confidence*) consistent with the Roy et al. (2011) analysis (Figure 6.22). This sensitivity of ocean CO₂ sinks to climate, γ_o , is mostly negative (i.e., a reduced regional ocean CO₂ sink in response to climate change) but with regions of positive values in the Arctic, the Antarctic and in the equatorial Pacific (i.e., climate change increases ocean CO₂ sink in these regions). The North Atlantic Ocean and the mid-latitude Southern Ocean have the largest negative γ_o values. Reduced CO₂ uptake in response to climate change in the sub-polar Southern Ocean and the tropical regions has been attributed to warming induced decreased CO₂ solubility, reduced CO₂ uptake in the mid-latitudes to decreased CO₂ solubility and decreased water mass formation which reduces the absorption of anthropogenic CO₂ in intermediate and deep waters (Roy et al., 2011). Increased uptake in the Arctic and the polar Southern Ocean is partly associated with a reduction in the fractional sea ice coverage (Roy et al., 2011).

6.4.2.3.2 Regional land response

Increased CO₂ is projected by the CMIP5 models to increase land CO₂ sinks everywhere (positive β) (*medium confidence*). This response, β_L , has the largest values over tropical land, in humid rather than arid regions, associated with enhanced carbon uptake in forested areas of already high biomass. In the zonal totals, there is a secondary peak of high β_L values over Northern Hemisphere temperate and boreal ecosystems, partly due to a greater land area there but also coincident with large areas of forest. Models agree on the sign of response but have low agreement on the magnitude.

The climate effect alone is projected by the CMIP5 models to reduce land CO₂ sinks in tropics and mid-latitudes (negative γ) (*medium confidence*). CMIP5 models show medium agreement that warming may increase land carbon uptake in high latitudes but none of these models include representation of permafrost carbon pools which are projected to decrease in warmer conditions (Section 6.4.3.3), therefore confidence is low regarding the sign and magnitude of future high-latitude land carbon response to climate change. Matthews et al. (2005) showed that vegetation productivity is the major cause of C4MIP model spread, but this manifests itself as changes in soil organic matter (Jones and Falloon, 2009).

6.4.3 Implications of the Future Projections for the Carbon Cycle and Compatible Emissions

6.4.3.1 The RCP Future CO₂ Concentration and Emissions Scenarios

The CMIP5 simulations include 4 future scenarios referred to as ‘Representative Concentration Pathways’ or RCPs (see Glossary) (Moss et al., 2010): RCP2.6, RCP4.5, RCP6.0, RCP8.5 (see Chapter 1). These future scenarios include CO₂ concentration and emissions, and have been generated by four Integrated Assessment

Models (IAMs) and are labelled according to the approximate global radiative forcing level at 2100. These scenarios are described in more detail in Chapter 1 (Figure 1.16) and chapter 12 (12.3) and also documented in Annex II.

van Vuuren et al. (2011) showed that the basic climate and carbon cycle responses of IAMs is generally consistent with the spread of climate and carbon cycle responses from ESMs. For the physical and biogeochemical components of the RCP scenarios 4.5, 6.0 and 8.5, the underlying IAMs are closely related. Only the IMAGE IAM, which created RCP2.6, differs markedly by using a more sophisticated carbon cycle sub-model for land and ocean. The MAGICC6 simple climate model was subsequently used to generate the CO₂ pathway for all 4 RCP scenarios using the CO₂ emissions output by the 4 IAMs (Meinshausen et al., 2011).

6.4.3.2 Land Use Changes in Future Scenarios

ESMs and IAMs use a diversity of approaches for representing land use changes, including different land use classifications, parameter settings, and geographical scales. To implement land use change in a consistent manner across ESMs, a ‘harmonized’ set of annual gridded land use change during the period 1500–2100 was developed for input to the CMIP5 ESMs (Hurtt et al., 2011).

Not all the CMIP5 ESMs used the full range of information available from the land use change scenarios, such as wood harvest projections or sub-grid scale shifting cultivation. Sensitivity studies indicated that these processes along with the start date of the simulation all strongly affect estimated carbon fluxes (Hurtt et al., 2011; Sentman et al., 2011).

Land use has been in the past and will be in the future a significant driver of forest land cover change and terrestrial carbon storage. Land use trajectories in the RCPs show very distinct trends and cover a wide-range of projections. These land use trajectories are very sensitive to assumptions made by each individual IAM regarding the amount of land needed for food production (Figure 6.23). The area of cropland and pasture increases in RCP8.5 with the MESSAGE IAM model, mostly driven by an increasing global population, but cropland area also increases in the RCP2.6 with the IMAGE IAM model, as a result of bio-energy production and increased food demand as well. RCP6 with the AIM model shows an expansion of cropland but a decline in pasture land. RCP4.5 with the GCAM IAM is the only scenario to show a decrease in global cropland. Several studies (Wise et al., 2009; Thomson et al., 2010; Tilman et al., 2011) highlight the large sensitivity of future land use requirements to assumptions such as increases in crop yield, changes in diet, or how agricultural technology and intensification is applied.

Within the IAMs, land use change is translated into land use CO₂ emissions as shown in Figure 6.23(b). Cumulative emissions for the 21st century (Figure 6.23c) vary markedly across RCPs, with increasing cropland and pastureland areas in RCP2.6 and RCP8.5 giving rise to the highest emissions from land use change, RCP4.5 to intermediate emissions, and RCP6.0 to close to zero net emissions. All scenarios suggest that 21st century land use emissions will be less than half of those from 1850 to present day as rate of change of land conversion stabilises in future.

The adoption of widely differing approaches among ESMs for the treatment and diagnosis of land use and land cover change (LULCC) processes in terrestrial carbon cycle models leads to substantial between-model variation in the simulated impact on land carbon stocks. It is not yet possible to fully quantify LULCC fluxes from the CMIP5 model simulations. The harmonization process applied to LULCC datasets for CMIP5 has been an important step toward consistency among IAMs, however, among ESMs, and between IAMs and ESMs, assignment of meaningful uncertainty ranges to present-day and future LULCC fluxes and states remains a critical knowledge gap with implications for compatible emissions to achieve CO₂ pathways (Section 6.4.3.3; Jones et al., 2013).

[INSERT FIGURE 6.23 HERE]

Figure 6.23: Land use trends and CO₂ emissions according to the four different integrated assessment models (IAMs) used to define the RCP scenarios. Global changes in croplands and pasture from the historical record and the RCP scenarios (top left), and associated annual land use emissions of CO₂ (bottom left). Bars (right panel) show cumulative land use emissions for the historical period (defined here as 1850–2005) and the 4 RCP scenarios from 2006 to 2100.

6.4.3.3 Projections of Future Carbon Cycle Response by ESMs Under the RCP Scenarios

Simulated changes in land and ocean carbon uptake and storage under the four RCP scenarios are presented here using results from CMIP5 ESMs concentration-driven simulations (see Box 6.4). The implications of these changes on atmospheric CO₂ and climate as simulated by CMIP5 emissions-driven simulations are presented in Chapter 12.

The results of the *concentration-driven* CMIP5 ESMs simulations show medium agreement on the magnitude of cumulative ocean carbon uptake from 1850 to 2005 (Figure 6.24a): average 127 ± 28 PgC (1 standard deviation). The models show low agreement on the sign and magnitude of changes in land carbon storage (Figure 6.24a): average 2 ± 74 PgC (1 standard deviation). These central estimates are very close to observational estimates of 125 ± 25 PgC for the ocean and -5 ± 40 PgC for the net cumulative land-atmosphere flux respectively (see Table 6.12), but show a large spread across models. For all four RCP scenarios all models project continued ocean uptake throughout the 21st century. For RCP4.5, all the models also project an increase in land carbon uptake, but for RCP2.6, RCP6.0 and RCP8.5 a minority of models (4 out of 11 for RCP2.6, 1 out of 8 for RCP6.0 and 4 out of 15 for RCP8.5; Jones et al., 2013) project a decrease in land carbon storage at 2100 relative to 2005. Model spread in land carbon projections is much greater than model spread in ocean carbon projections at least in part due to different treatment of land use change. Decade mean land and ocean fluxes are documented in Annex II, Table AII.3.1a, b. Important processes missing from many or all CMIP5 land carbon cycles include the role of nutrient cycles, permafrost, fire and ecosystem acclimation to changing climate. For this reason we assign *low confidence* to quantitative projections of future land uptake.

[INSERT FIGURE 6.24 HERE]

Figure 6.24: Cumulative land and ocean carbon uptake simulated for the historical period 1850–2005 (top panel) and for the four RCP scenarios up to 2100 (panels b–e). Mean (thick line) and 1 standard deviation (shaded). Vertical bars on the right show the full model range as well as standard deviation. Black bars show observationally derived estimates for 2005. Models used: CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MIROC-ESM-CHEM, MIROC-ESM, MPI-ESM-LR, NorESM1-ME, INMCM4, CESM1-BGC, BCC-CSM1.1. Not every model performed every scenario simulation.

The *concentration-driven* ESM simulations can be used to quantify the compatible fossil fuel emissions required to follow the four RCP CO₂ pathways (Jones et al., 2013; see Box 6.4, Figure 6.25, Table 6.12, Annex II, Table AII.2.1a). There is significant spread between ESMs, but general consistency between ESMs and compatible emissions estimated by IAMs to define each RCP scenario. However, for RCP8.5 on average, the CMIP5 models project lower compatible emissions than the MESSAGE IAM. The IMAGE IAM predicts that global negative emissions are required to achieve the RCP2.6 decline in radiative forcing from 3 W m^{-2} to 2.6 W m^{-2} by 2100. All models agree that strong emissions reductions are required to achieve this after about 2020 (Jones et al., 2013). An average emission reduction of 50% (range 14–96%) is required by 2050 relative to 1990 levels. There is disagreement between those ESMs which performed this simulation over the necessity for global emissions in the RCP2.6 to become negative by the end of the 21st century to achieve this, with 6 ESMs simulating negative compatible emissions and 4 ESM models simulating positive emissions from 2080 to 2100. The RCP2.6 scenario achieves this negative emission rate through use of large-scale bio-energy with carbon-capture and storage (BECCS). This would be classed as a carbon dioxide removal (CDR) form of geoengineering under the definition used in this IPCC report, and is discussed further in Section 6.5.2. The ESMs themselves make no assumptions about how the compatible emissions could or would be achieved, but merely compute the global total emission that is required to follow the CO₂ concentration pathway, accounting for the carbon cycle response to climate and CO₂, and for land use change CO₂ emissions.

Table 6.12: The range of compatible fossil fuel emissions (PgC) simulated by the CMIP5 models for the historical period and the 4 RCP scenarios, expressed as cumulative fossil fuel emission. In order to be consistent with Table 6.1 budgets are calculated up to 2011 for historical and 2012–2100 for future scenarios, and values are rounded to the nearest 5 PgC.

Compatible Fossil Fuel Emissions Diagnosed from <i>Concentration-</i>	Land Carbon Changes	Ocean Carbon Changes
--	---------------------	----------------------

<i>Driven CMIP5 Simulations</i>									
	Historical / RCP Scenario	CMIP5 ESM Mean	CMIP5 ESM Range	Historical / RCP Scenario	CMIP5 ESM Mean	CMIP5 ESM Range	Historical / RCP Scenario	CMIP5 ESM Mean	CMIP5 ESM Range
1850– 2011	365 ^a	350	235–455	5 ± 40 ^b	10	–125–160	140 ± 25 ^b	140	110–220
RCP2.6	275	270	140–410	^c	65	–50–195	^c	150	105–185
RCP4.5	735	780	595–1005		230	55–450		250	185–400
RCP6.0	1165	1060	840–1250		200	–80–370		295	265–335
RCP8.5	1855	1685	1415–1910		180	–165–500		400	320–635

Notes:

(a) Historical estimates of fossil fuel are as prescribed to all CMIP5 ESM models in the *emissions-driven* simulations (Andres et al., 2011).

(b) Estimate of historical net land and ocean carbon uptake from Table 6.1 but over the shorter 1850–2011 time period.

(c) IAM breakdown of future carbon changes by land and ocean are not available.

[INSERT FIGURE 6.25 HERE]

Figure 6.25: Compatible fossil fuel emissions simulated by the CMIP5 ESM models for the 4 RCP scenarios. Top: time series of compatible emission rate (PgC yr⁻¹). Dashed lines represent the historical estimates and emissions calculated by the integrated assessment models (IAM) used to define the RCP scenarios, solid lines and plumes show results from CMIP5 ESMs (model mean, with 1 standard deviation shaded). Bottom: cumulative emissions for the historical period (1860–2005) and 21st century (defined in CMIP5 as 2006–2100) for historical estimates and RCP scenarios. Dots denote individual ESM results, bars show the multi-model mean. In the CMIP5 model results, total carbon in the land-atmosphere-ocean system can be tracked and changes in this total must equal fossil fuel emissions to the system (see Box 6.4). Models used: CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MIROC-ESM-CHEM, MIROC-ESM, MPI-ESM-LR, NorESM1-ME, INMCM4, CESM1-BGC, BCC-CSM1.1. Not every model performed every scenario simulation.

The dominant cause of future changes in the airborne fraction of fossil fuel emissions (see Section 6.3.2.4) is the emissions scenario and not carbon cycle feedbacks (Jones et al., 2013; Figure 6.26). Models show high agreement that 21st century cumulative airborne fraction will increase under rapidly increasing CO₂ in RCP8.5 and decreases under the peak-and-decline RCP2.6 scenarios. The airborne fraction declines slightly under RCP4.5 and remains of similar magnitude in the RCP6.0 scenario. Between-model spread in changes in the land-fraction is greater than between-scenario spread. Models show high agreement that the ocean fraction will increase under RCP2.6 and remain of similar magnitude in the other RCP scenarios.

[INSERT FIGURE 6.26 HERE]

Figure 6.26: Changes in atmospheric, land and ocean fraction of fossil fuel carbon emissions. The fractions are defined as the changes in storage in each component (atmosphere, land, ocean) divided by the compatible fossil fuel emissions derived from each CMIP5 simulation for the 4 RCP scenarios. Solid circles show the observed estimate based on Table 6.1 for the 1990s. The coloured bars denote the cumulative uptake fractions for the 21st century under the different RCP scenarios for each model. Multi-model mean values are shown as star symbols and the multi-model range (min-to-max) and standard deviation are shown by thin and thick vertical lines respectively. Due to the difficulty of estimating land use emissions from the ESMs this figure uses a fossil fuel definition of airborne fraction, rather than the preferred definition of fossil and land use emissions discussed in Section 6.3.2.4. 21st century cumulative atmosphere, land and ocean fractions are shown here in preference to the more commonly shown instantaneous fractions because for RCP2.6 emissions reach and cross zero for some models and so an instantaneous definition of AF becomes singular at that point. Models used: CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MIROC-ESM-CHEM, MIROC-ESM, MPI-ESM-LR, NorESM1-ME, CESM1-BGC. Not every model performed every scenario simulation.

Several studies (Jones et al., 2006; Matthews, 2006; Plattner et al., 2008; Miyama and Kawamiya, 2009) have shown that climate-carbon cycle feedbacks affect the compatible fossil fuel CO₂ emissions that are consistent with a given CO₂ concentration pathway. Using decoupled RCP4.5 simulations (see Box 6.4) five CMIP5 ESMs agree that the climate impact on carbon uptake by both land and oceans will reduce the compatible fossil fuel CO₂ emissions for that scenario by between 6% and 29% between 2006 and 2100 respectively (Figure 6.27) equating to an average of 157 ± 76 PgC (1 standard deviation) less carbon that can be emitted from fossil fuel use if climate feedback (see Glossary) is included. Compatible emissions would

be reduced by a greater degree under higher CO₂ scenarios which exhibit a greater degree of climate change (Jones et al., 2006).

[INSERT FIGURE 6.27 HERE]

Figure 6.27: Compatible fossil fuel emissions for the RCP4.5 scenario (top panel) in the presence (red) and absence (blue) of the climate feedback on the carbon cycle, and the difference between them (bottom panel). Multi-model mean, 10-year smoothed values are shown, with 1 standard deviation shaded. This shows the impact of climate change on the compatible fossil fuel CO₂ emissions to achieve the RCP4.5 CO₂ concentration pathway. Models used: CanESM2, GFDL-ESM2M, HadGEM2-ES, IPSL-CM5A-LR and MIROC-ESM.

6.4.3.4 Permafrost Carbon

Current estimates of permafrost soil carbon stocks are ~1700 PgC (Tarnocai et al., 2009), the single largest component of the terrestrial carbon pool. Terrestrial carbon models project a land CO₂ sink with warming at high northern latitudes, however none of the models participating in C4MIP or CMIP5 included explicit representation of permafrost soil carbon decomposition in response to future warming. Including permafrost carbon processes into an ESM may change the sign of the high northern latitude carbon cycle response to warming from a sink to a source (Koven et al., 2011). The magnitude of the source of CO₂ to the atmosphere from decomposition of permafrost carbon in response to warming varies widely by 2100 according to different techniques and scenarios. Process-models provide different estimates of the cumulative loss of permafrost carbon: 7–17 PgC (Zhuang et al., 2006), 55–69 Pg (Koven et al., 2011), 126–254 PgC (Schaefer et al., 2011) and 68–508 PgC (MacDougall et al., 2012). Combining observed vertical soil C profiles with modeled thaw rates provides an estimate that the total quantity of newly-thawed soil carbon by 2100 will be 246 PgC for RCP4.5 and 436 PgC for RCP8.5 (Harden et al., 2012), although not all of this will be released to the atmosphere on that timescale. Uncertainty estimates suggest the cumulative loss of permafrost carbon could range from 33 to 114 PgC (68% range) under RCP8.5 warming (Schneider von Deimling et al., 2012), or 50–270 PgC (5th–95th percentile range; Burke et al., 2012). The best estimate range for carbon released from thawed permafrost by 2100 is from 50 to more than 250 PgC for RCP8.5. Sources of uncertainty for the permafrost carbon feedback include the physical thawing rates, the fraction of carbon that is released after being thawed and the timescales of release, possible mitigating nutrient feedbacks, and the role of fine-scale processes such as spatial variability in permafrost degradation. It is also uncertain how much thawed carbon will decompose to CO₂ or to CH₄ (see Section 6.4.7; and Chapter 12, Sections 12.5.5.4 and 12.4.8.1).

6.4.4 Future Ocean Acidification

A fraction of CO₂ emitted to the atmosphere dissolves in the ocean, reducing surface ocean pH and carbonate ion concentrations. The associated chemistry response to a given change in CO₂ concentration is known with *very high confidence*. Expected future changes are in line with what is measured at ocean time series stations (see Chapter 3). Multi-model projections using ocean process-based carbon cycle models discussed in AR4 demonstrate large decreases in pH and carbonate ion concentration [CO₃²⁻] during the 21st century throughout the world oceans (Orr et al., 2005). The largest decrease in surface [CO₃²⁻] occur in the warmer low and mid-latitudes, which are naturally rich in this ion (Feely et al., 2009). However, it is the low Ω_A waters in the high-latitudes and in the upwelling regions that first become undersaturated with respect to aragonite (i.e., $\Omega_A < 1$, where $\Omega_A = [\text{Ca}^{+2}][\text{CO}_3^{2-}]/K_{sp}$, where K_{sp} is the solubility product for the metastable form of CaCO₃ known as aragonite; a value of $\Omega_A < 1$ thus indicates aragonite undersaturation). This aragonite undersaturation in surface waters is reached before the end of the 21st century in the Southern Ocean as highlighted in AR4, but occurs sooner and is more intense in the Arctic (Steinacher et al., 2009). Ten percent of Arctic surface waters are projected to become undersaturated when atmospheric CO₂ reaches 428 ppm (by 2025 under all IPCC SRES scenarios). That proportion increases to 50% when atmospheric CO₂ reaches 534 ppm (Steinacher et al., 2009). By 2100 under the A2 scenario, much of the Arctic surface is projected to become undersaturated with respect to calcite (Feely et al., 2009). Surface waters would then be corrosive to all CaCO₃ minerals. These general trends are confirmed by the latest projections from the CMIP5 Earth System models (Figure 6.28 and 6.29). Between 1986–2005 and 2081–2100, decrease in global-mean surface pH is 0.065 (0.06–0.07) for RCP2.6, 0.145 (0.14–0.15) for RCP4.5, 0.203 (0.20–0.21) for RCP6.0, and 0.31 (0.30–0.32) for RCP8.5 (CMIP5 model spread).

[INSERT FIGURE 6.28 HERE]

Figure 6.28: Projected ocean acidification from 11 CMIP5 Earth System models under RCP8.5 (other RCPs scenarios have also been run with the CMIP5 models): (a) time series of surface pH shown as the mean (solid line) and range of models (filled), given as area-weighted averages over the Arctic Ocean (green), the tropical oceans (red), and the Southern Ocean (blue); (b) maps of the median model's change in surface pH from 1850 to 2100. Panel (a) also includes mean model results from RCP2.6 (dashed lines). Over most of the ocean, gridded data products of carbonate system variables (Key et al., 2004) are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following (Orr et al., 2005). Where gridded data products are unavailable (Arctic Ocean, all marginal seas, and the ocean near Indonesia), the results are shown without bias correction. The bias correction reduces the range of model projections by up to a factor of 4, e.g., in panel (a) compare the large range of model projections for the Arctic (without bias correction) to the smaller range in the Southern Ocean (with bias correction).

[INSERT FIGURE 6.29 HERE]

Figure 6.29: Projected aragonite saturation state from 11 CMIP5 Earth System models under RCP8.5 scenario: (a) time series of surface carbonate ion concentration shown as the mean (solid line) and range of models (filled), given as area-weighted averages over the Arctic Ocean (green), the tropical oceans (red), and the Southern Ocean (blue); maps of the median model's surface Ω_A in (b) 2010, (d) 2050, and (f) 2100; and zonal mean sections (latitude vs. depth) of Ω_A in 2100 over the (g) Atlantic and (h) Pacific, while the ASH is shown in 2010 (dotted line) as well as 2100 (solid line). Panel (a) also includes mean model results from RCP2.6 (dashed lines). As for Figure 6.28, gridded data products of carbonate system variables (Key et al., 2004) are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following (Orr et al., 2005). Where gridded data products are unavailable (Arctic Ocean, all marginal seas, and the ocean near Indonesia), results are shown without bias correction.

Surface CaCO_3 saturation also varies seasonally, particularly in the high latitudes, where observed saturation is higher in summer and lower in winter (Feely et al., 1988; Merico et al., 2006; Findlay et al., 2008). Future projections using ocean carbon cycle models indicate that undersaturated conditions will be reached first in winter (Orr et al., 2005). In the Southern Ocean, it is projected that wintertime undersaturation with respect to aragonite will begin when atmospheric CO_2 will reach 450 ppm, which is about 100 ppm sooner (~30 years under the IS92a scenario) than for the annual mean undersaturation (McNeil and Matear, 2008). As well, aragonite undersaturation will be reached during wintertime in parts (10%) of the Arctic when atmospheric CO_2 reaches 410 ppm (Steinacher et al., 2009).

Although projected changes in pH are generally largest at the surface, the greatest pH changes in the subtropics occur between 200–300 m where subsurface increased loads of anthropogenic CO_2 are similar to surface changes but the carbonate buffering capacity is lower (Orr, 2011). This more intense projected subsurface pH reduction is consistent with the observed subsurface changes in pH in the subtropical North Pacific (Dore et al., 2009; Byrne et al., 2010; Ishii et al., 2011). As subsurface saturation states decline, the horizon separating undersaturated waters below from supersaturated waters above is projected to move upward (shoal). By 2100 under the RCP8.5 scenario, the median projection from 11 CMIP5 models is that this interface (aragonite saturation horizon) will shoal from 200 m up to 40 m in the subarctic Pacific, from 1000 m up to the surface in the Southern Ocean, and from 2850 m to 150 m in the North Atlantic (Figure 6.29), consistent with results from previous model comparison (Orr et al., 2005; Orr, 2011). Under the SRES A2 scenario, the volume of ocean with supersaturated waters is projected to decline from 42% in the preindustrial Era to 25% in 2100 (Steinacher et al., 2009). Yet even if atmospheric CO_2 does not go over 450 ppm, most of the deep ocean volume is projected to become undersaturated with respect to both aragonite and calcite after several centuries (Caldeira and Wickett, 2005). Nonetheless, the most recent projections under all RCPs scenarios but RCP8.5 illustrate that limiting atmospheric CO_2 will greatly reduce the level of ocean acidification that will be experienced (Joos et al., 2011).

In the open ocean, future reductions in surface ocean pH and CaCO_3 (calcite and aragonite) saturation states are controlled mostly by the invasion of anthropogenic carbon. Other effects due to future climate change counteract less than 10% of the reductions in CaCO_3 saturation induced by the invasion of anthropogenic carbon (Orr et al., 2005; McNeil and Matear, 2006; Cao et al., 2007). Warming dominates other effects from climate-change by reducing CO_2 solubility and thus by enhancing $[\text{CO}_3^{2-}]$. An exception is the Arctic Ocean where reductions in pH and CaCO_3 saturation states are projected to be exacerbated by effects from increased freshwater input due to sea ice melt, more precipitation, and greater air-sea CO_2 fluxes due to less sea ice cover (Steinacher et al., 2009; Yamamoto et al., 2012). The projected effect of freshening is consistent with current observations of lower saturation states and lower pH values near river mouths and in areas under substantial fresh-water influence (Salisbury et al., 2008; Chierici and Fransson, 2009; Yamamoto-Kawai et al., 2009).

Regional ocean carbon cycle models project that some nearshore systems are also highly vulnerable to future pH decrease. In the California Current System, an eastern boundary upwelling system, observations and model results show that strong seasonal upwelling of carbon-rich waters (Feely et al., 2008) renders surface waters as vulnerable to future ocean acidification as those in the Southern Ocean (Gruber et al., 2012). In the Northwestern European Shelf Seas, large spatiotemporal variability is enhanced by local effects from river input and organic matter degradation, exacerbating acidification from anthropogenic CO₂ invasion (Artioli et al., 2012). In the Gulf of Mexico and East China Sea, coastal eutrophication, another anthropogenic perturbation, has been shown to enhance subsurface acidification as additional respired carbon accumulates at depth (Cai et al., 2011).

6.4.5 Future Ocean Oxygen Depletion

It is *very likely* that global warming will lead to declines in dissolved O₂ in the ocean interior through warming-induced reduction in O₂ solubility and increased ocean stratification. This will have implications for nutrient and carbon cycling, ocean productivity and marine habitats (Keeling et al., 2010).

Future changes in dissolved O₂ have been investigated using models of various complexity (see references in Table 6.13). The global ocean dissolved oxygen will decline significantly under future scenarios (Cocco et al., 2013). Simulated declines in mean dissolved O₂ concentration for the global ocean range from 6 to 12 μmol kg⁻¹ by the year 2100 (Table 6.13), with a projection of 3–4 μmol kg⁻¹ in one model with low climate sensitivity (Frölicher et al., 2009). This general trend is confirmed by the latest projections from the CMIP5 Earth System models, with reductions in mean dissolved O₂ concentrations from 1.5 to 4% (2.5 to 6.5 μmol kg⁻¹) in 2090s relative to 1990s for all RCPs (Figure 6.30a).

Most modelling studies (Table 6.13) explain the global decline in dissolved oxygen by enhanced surface ocean stratification leading to reductions in convective mixing and deep water formation and by a contribution of 18–50% from ocean warming-induced reduction in solubility. These two effects are in part compensated by a small increase in O₂ concentration from projected reductions in biological export production production (Bopp et al., 2001; Steinacher et al., 2010) or changes in ventilation age of the tropical thermocline (Gnanadesikan et al., 2007). The largest regional decreases in oxygen concentration (~20–100 μmol kg⁻¹) are projected for the intermediate (200–400 m) to deep waters of the North Atlantic, North Pacific and Southern Ocean for 2100 (Plattner et al., 2002; Matear and Hirst, 2003; Frölicher et al., 2009; Matear et al., 2010; Cocco et al., 2013), which is confirmed by the latest CMIP5 projections (Figure 6.30c and 6.30d).

Table 6.13: Model configuration and projections for global marine O₂ depletion by 2100 (adapted from Keeling et al. (2010))

Study	Ocean Carbon Cycle Model	Forcing	Mean [O ₂] Decrease (μmol kg ⁻¹) ^{a,b}	Solubility Contribution (%)

Notes:

(a) Assuming a total ocean mass of 1.48 x 10²¹ kg

(b) Relative to pre-industrial baseline in 1750

- (c) Model simulation ends at 2065
- (d) Radiative forcing of non-CO₂ GHGs is excluded from this simulation
- (e) For simulations with reduced ocean exchange.

It is *as likely as not* that the extent of open-ocean hypoxic (dissolved oxygen <60–80 $\mu\text{mol kg}^{-1}$) and suboxic (dissolved oxygen <5 $\mu\text{mol kg}^{-1}$) waters will increase in the coming decades. Most models show even some increase in oxygen in most O₂-poor waters and thus a slight decrease in the extent of suboxic waters under the SRES-A2 scenario (Cocco et al., 2013), as well as under RCP8.5 scenario (see the model-mean increase of sub-surface O₂ in large parts of the tropical Indian and Atlantic oceans, Figure 6.30d). This rise in oxygen in most suboxic waters has been shown to be caused in one model study by an increased supply of oxygen due to lateral diffusion (Gnanadesikan et al., 2012). Given limitations of global ocean models in simulating today's O₂ distribution (Cocco et al., 2013), as well as reproducing the measured changes in O₂ concentrations over the past 50 years (see Chapter 3, and Stramma et al., 2012), the model projections are uncertain, especially concerning the evolution of O₂ in and around oxygen minimum zones.

A number of biogeochemical ocean carbon cycle feedbacks, not yet included in most marine biogeochemical models (including CMIP5 models, see Section 6.3.2.5.6), could also impact future trends of ocean deoxygenation. For example, model experiments which include a pCO₂-sensitive C:N drawdown in primary production, as suggested by some mesocosm experiments (Riebesell et al., 2007), project future increases of up to 50% in the volume of the suboxic waters by 2100 (Oschlies et al., 2008; Tagliabue et al., 2011). In addition, future marine hypoxia could be amplified by changes in the CaCO₃ to organic matter 'rain ratio' in response to rising pCO₂ (Hofmann and Schellnhuber, 2009). Reduction in biogenic calcification due to ocean acidification would weaken the strength of CaCO₃ mineral ballasting effect, which could lead organic material to be remineralized at a shallower depth exacerbating the future expansion of shallow hypoxic waters.

The modeled estimates do not take into account processes that are specific to the coastal ocean and may amplify deoxygenation. Recent observations for the period 1976–2000 have shown that dissolved O₂ concentrations have declined at a faster rate in the coastal ocean ($-0.28 \mu\text{mol kg}^{-1} \text{yr}^{-1}$) than the open ocean ($-0.02 \mu\text{mol kg}^{-1} \text{yr}^{-1}$), and a faster rate than in the period 1951–1975 indicating a worsening of hypoxia (Gilbert et al., 2010). Hypoxia in the shallow coastal ocean (apart from continental shelves in Eastern Boundary Upwelling Systems) is largely eutrophication-driven and is controlled by the anthropogenic flux of nutrients (N and P) and organic matter from rivers. If continued industrialisation and intensification of agriculture yield larger nutrient loads in the future, eutrophication should intensify (Rabalais et al., 2010), and further increase the coastal ocean deoxygenation.

On longer time scales beyond 2100, ocean deoxygenation is projected to increase with some models simulating a tripling in the volume of suboxic waters by 2500 (Schmittner et al., 2008). Ocean deoxygenation and further expansion of suboxic waters could persist on millennial timescales, with average dissolved O₂ concentrations projected to reach minima of up to 56 $\mu\text{mol kg}^{-1}$ below pre-industrial levels in experiments with high CO₂ emissions and high climate sensitivity (Shaffer et al., 2009).

A potential expansion of hypoxic or suboxic water over large parts of the ocean is likely to impact the marine cycling of important nutrients, particularly nitrogen. The intensification of low oxygen waters has been suggested to lead to increases in water column denitrification and N₂O emissions (e.g., Codispoti, 2010; Naqvi et al., 2010). Recent works however suggest that oceanic N₂O production is dominated by nitrification with a contribution of 7% by denitrification (Freing et al., 2012), Figure 6.4c) and that ocean deoxygenation in response to anthropogenic climate change could leave N₂O production relatively unchanged (Bianchi et al., 2012).

[INSERT FIGURE 6.30 HERE]

Figure 6.30: (a) Simulated changes in dissolved O₂ (mean and model range as shading) relative to 1990s for RCP2.6, RCP4.5, RCP6.0 and RCP8.5. (b) Multi-model mean dissolved O₂ ($\mu\text{mol m}^{-3}$) in the main thermocline (200 to 600m depth average) for the 1990s, and changes in 2090s relative to 1990s for RCP2.6 (c) and RCP8.5 (d). To indicate consistency in the sign of change, regions are stippled where at least 80% of models agree on the sign of the mean change. These diagnostics are detailed in Cocco et al. (2013) in a previous model intercomparison using the SRES-A2

scenario and have been applied to CMIP5 models here. Models used: CESM1-BGC, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, MPI-ESM-LR, MPI-ESM-MR, NorESM1.

6.4.6 Future Trends in the Nitrogen Cycle and Impact on Carbon Fluxes

6.4.6.1 Projections for Formation of Reactive Nitrogen by Human Activity

Since the 1970s, food production, industrial activity and fossil fuel combustion have resulted in the creation of more reactive nitrogen (Nr) than natural terrestrial processes (Section 6.1; Box 6.2, Figure 1). Building on the general description of the set of AR4 Special Report on Emission (SRES) scenarios, Erisman et al. (2008) estimated anthropogenic N fertilizer consumption throughout the 21st century. Five driving parameters (population growth, consumption of animal protein, agricultural efficiency improvement and additional biofuel production) are used to project future nitrogen demands for four scenarios (A1, B1, A2 and B2) (Figure 6.31). Assigning these drivers to these four SRES scenarios, they estimated a production of Nr for agricultural use of 90 to 190 Tg N yr⁻¹ by 2100, a range that spans from slightly less to almost twice as much current fertilizer consumption rates (Section 6.1, Figure 6.4a, Box 6.2 Figure 2).

Despite the uncertainties and the non-inclusion of many important drivers, three of the scenarios generated by the Erisman et al. (2008) model point towards an increase in future production of reactive nitrogen. In particular, the A1 scenario which assumes a world with rapid economic growth, a global population that peaks mid-century, and rapid introduction of new and more efficient technologies ends up as the potentially largest contributor to nitrogen use, as a result of large amounts of biofuels required and the fertilizer used to produce it. This increase in nitrogen use is assumed to be largely in line with the RCP2.6 scenario, where it appears to have rather limited adverse effects like increasing N₂O emissions (van Vuuren et al., 2011).

[INSERT FIGURE 6.31 HERE]

Figure 6.31: Global nitrogen fertilizer consumption scenarios (left) and the impact of individual drivers on 2100 consumption (right). This resulting consumption is always the sum (denoted at the end points of the respective arrows) of elements increasing as well as decreasing nitrogen consumption. Other relevant estimates are presented for comparison. The A1, B1, A2 and B2 scenarios draw from the assumptions of the IPCC SRES emission scenario storylines as explained in Erisman et al. (2008).

N₂O emissions are projected to increase from increased anthropogenic Nr production. This is illustrated by the comparison of emissions from 1900 to those in 2000 and 2050, using the IAM IMAGE model that served to define the RCP2.6 pathway (Figure 6.32). The anthropogenic N₂O emission map IN 2050 shown in Figure 6.32 is established from the RCP4.5 scenario; the RCP8.5 and RCP6 scenarios have much higher emissions, and RCP2.6 much lower (van Vuuren et al., 2011). A spatially explicit inventory of soil nitrogen budgets in livestock and crop production systems using the IMAGE model (Bouwman et al., 2011) shows that between 1900 and 1950, the global soil Nr budget surplus almost doubled to 36 TgN yr⁻¹, and further increased to 138 TgN yr⁻¹ between 1950 and 2000. The IMAGE model scenario from Bouwman et al. (2011) shown in Figure 6.32 portrays a world with a further increasing global crop production (+82% for 2000–2050) and livestock production (+115%). Despite the assumed rapid increase in nitrogen use efficiency in crop (+35%) and livestock (+35%) production, global agricultural Nr surpluses are projected to continue to increase (+23%), and associated emissions of N₂O to triple compared to 1900 levels.

Regional to global scale model simulations suggest a strong effect of climate variability on inter-annual variability of land N₂O emissions (Tian et al., 2010; Zaehle et al., 2011; Xu-Ri et al., 2012). Kesik et al. (2006) found for European forests that higher temperatures and lower soil moisture will decrease future N₂O emissions under scenarios of climate change, despite local increases of emission rates by up to 20%. Xu-Ri et al. (2012) show that local climate trends result in a spatially diverse pattern of increases and decreases of N₂O emissions, which globally integrated result in a net climate response of N₂O emissions of 1 TgN yr⁻¹ per 1°C of land temperature warming. Using a further development of this model, Stocker et al. (2013) estimate increases in terrestrial N₂O from a pre-industrial terrestrial source of 6.9 TgN (N₂O) yr⁻¹ to 9.8–11.1 TgN (N₂O) yr⁻¹ (RCP 2.6) and 14.2–17.0 TgN (N₂O) yr⁻¹ (RCP 8.5) by 2100. Of these increases, 1.1–2.4 TgN (N₂O) yr⁻¹ (RCP 2.6) or 4.7–7.7 TgN (N₂O) yr⁻¹ (RCP 8.5) are due to the interacting effects of climate and CO₂ on N₂O emissions from natural and agricultural ecosystems. An independent modeling study suggested a climate change related increase of N₂O emissions between 1860 and 2100 by 3.1 TgN (N₂O) yr⁻¹ for the A2 SRES scenario (Zaehle, 2013) implying a slightly lower sensitivity of soil N₂O emissions to climate of

0.5 TgN (N₂O) yr⁻¹ per 1°C warming. While the present-day contribution of these climate-mediated effects on the radiative forcing from N₂O is likely to be small (0.016 W m⁻² K⁻¹; Zaehle and Dalmonech, 2011). Modeling results (Stocker et al., 2013) suggest that the climate and CO₂-related amplification of terrestrial N₂O emissions imply a larger feedback of 0.03–0.05 W m⁻² K⁻¹ by 2100.

[INSERT FIGURE 6.32 HERE]

Figure 6.32: N₂O emissions in 1900, 2000 and projected to 2050 (Bouwman et al., 2011). This spatially explicit soil nutrient budget and nitrogen gas emission scenario was elaborated with the IMAGE model on the basis of the International Assessment of Agricultural Knowledge, Science and Technology for Development (IAASTD) baseline scenario (McIntyre et al., 2009).

With the continuing increases in the formation of Nr from anthropogenic activities will come increased Nr emissions and distribution of Nr by waters and the atmosphere. For the atmosphere, the main driver of future global nitrogen deposition is the emission trajectories of NO_y and NH₃. For all RCP scenarios except RCP2.6, nitrogen deposition is projected to remain relatively constant globally although there is a projected increase in NH_x deposition and decrease in NO_y deposition. On a regional basis, future decreases of NH_x and NO_x are projected in North America and Northern Europe, and increases in Asia (Figure 6.33). Spatially, projected changes in total nitrogen deposition driven primarily by increases in NH_x emissions occur over large regions of the world for all RCPs, with generally the largest in RCP8.5 and the smallest in RCP2.6 (Figure 6.33) (Supplementary Material has RCP4.5 and RCP6.0). Previous IPCC scenarios (SRES A2 or IS92a) project a near doubling of atmospheric nitrogen deposition over some world biodiversity hotspots with half of these hotspots subjected to deposition rates greater than 15 kgN ha⁻¹ yr⁻¹ (critical load threshold value) over at least 10% of their total area (Dentener et al., 2005; Phoenix et al., 2006; Bleeker et al., 2011).

Large uncertainties remain in our understanding and modelling of changes in Nr emissions, atmospheric transport and deposition processes, lead to *low confidence* in the projection of future Nr deposition fluxes, particularly in regions remote from anthropogenic emissions (Dentener et al., 2006). The large spread between atmospheric GCM models associated with precipitation projections confounds extraction of a climate signal in deposition projections (Langner et al., 2005; Hedegaard et al., 2008).

6.4.6.2. Projected Changes in Sulphur Deposition

Given the tight coupling between the atmospheric nitrogen and sulphur cycles, and the impact on climate (Chapter 7, Section 7.3) this Chapter also presents scenarios for sulphur deposition. Deposition of SO_x is projected to decrease in all RCP pathways (Figure 6.33 and 6.34). By contrast, scenarios established prior to RCPs indicated decreases of sulphur deposition in North America and Europe, but increases in South America, Africa, South and East Asia (Dentener et al., 2006; Tagaris et al., 2008). In all RCPs, sulphur deposition is lower by 2100 than in 2000 in all regions, with largest decreases in North America, Europe and Asia (RCP2.6 and RCP 8.5 are seen in Figure 6.34; RCP4.5 and RCP6.0 are in the Supplementary Material) (Lamarque et al., 2011). Future hot spots of deposition are still evident in East and South East Asia, especially for RCP6.0.

Projected future increase of Nr input into terrestrial ecosystems also yields increased flux of Nr from rivers into coastal systems. As illustrated by the Global NEWS 2 model for 2050, by the base year 2000, the discharge of dissolved inorganic nitrogen (DIN) to marine coastal waters was >500 kg N km⁻² of watershed area for most watershed systems downstream of either high population or extensive agricultural activity (Mayorga et al., 2010; Seitzinger et al., 2010). Additional information and the supporting figure are found in the Supplementary Material.

[INSERT FIGURE 6.33 HERE]

Figure 6.33: Deposition of SO_x (left panel, TgS yr⁻¹), NH_x (middle panel, TgN yr⁻¹) and NO_y (right panel, TgN yr⁻¹) from 1850 to 2000 and projections of deposition to 2100 under the four RCP emission scenarios (Lamarque et al., 2011; van Vuuren et al., 2011). Also shown are the 2030 scenarios using the SRES B1/A2 energy scenario with assumed current legislation and maximum technically feasible air pollutant reduction controls (Dentener et al., 2006).

[INSERT FIGURE 6.34 HERE]

Figure 6.34: Spatial variability of nitrogen and SO_x deposition in 1990s with projections to the 2090s (shown as difference relative to the 1990s), using the RCP2.6 and RCP8.5 scenarios, kgN km⁻² yr⁻¹, adapted from Lamarque et al.

(2011). Note that no information on the statistical significance of the shown differences is available. This is of particular relevance for areas with small changes. The plots for all four of the RCP scenarios are in the Supplementary Material.

6.4.6.3 Impact of Future Changes in Reactive Nitrogen on Carbon Uptake and Storage

Anthropogenic Nr addition and natural N-cycle responses to global changes will have an important impact on the global carbon cycle. As a principal nutrient for plant growth, nitrogen can both limit future carbon uptake and stimulate it depending on changes in Nr availability. A range of global terrestrial carbon cycle models have been developed since AR4 that integrate nitrogen dynamics into the simulation of land carbon cycling (Thornton et al., 2007; Wang et al., 2007; Sokolov et al., 2008; Xu-Ri and Prentice, 2008; Churkina et al., 2009; Jain et al., 2009; Fisher et al., 2010; Gerber et al., 2010; Wang et al., 2010a; Zaehle and Friend, 2010; Esser et al., 2011). However, only two ESMs in CMIP5 (CESM1-BGC and NorESM1-ME) include a description of nitrogen-carbon interactions.

In response to climate warming, increased decomposition of soil organic matter increases nitrogen mineralisation, (*high confidence*) which can enhance Nr uptake and carbon storage by vegetation. Generally, higher C:N ratio in woody vegetation compared to C:N ratio of soil organic matter causes increased ecosystem carbon storage as increased Nr uptake shifts nitrogen from soil to vegetation (Melillo et al., 2011). In two studies (Sokolov et al., 2008; Thornton et al., 2009), this effect was strong enough to turn the carbon-climate interaction into a small negative feedback, i.e., an increased land CO₂ uptake in response to climate warming (positive γ_L values in Figure 6.20), whereas in another study that described C-N interactions (Zaehle et al., 2010b) the carbon-climate interaction was reduced but remained positive, i.e., decreased land CO₂ uptake in response to climate change (negative γ_L values in Figures 6.20, 6.21, 6.22). The two CMIP5 ESMs which include terrestrial C-N interactions (Table 6.11) also simulate a small but positive climate-carbon feedback.

Consistent with the observational evidence (Finzi et al., 2006; Palmroth et al., 2006; Norby et al., 2010), modelling studies have shown a strong effect of Nr availability in limiting the response of plant growth and land carbon storage to elevated atmospheric CO₂ (e.g., Sokolov et al., 2008; Thornton et al., 2009; Zaehle and Friend, 2010). These analyses are affected by the projected future trajectories of anthropogenic Nr deposition. The effects of Nr deposition counteract the nitrogen limitation of CO₂ fertilisation (Churkina et al., 2009; Zaehle et al., 2010a). Estimates of the total net carbon storage on land due to Nr deposition between 1860 and 2100 range between 27 and 66 PgC (Thornton et al., 2009; Zaehle et al., 2010a).

There is *high confidence* that, at the global scale, nutrient limitation will reduce the global land carbon storage projected by CMIP5 carbon-cycle only models. Only two of the current CMIP5 ESM models explicitly consider C-N interactions (CESM1-BGC and NorESM1-ME). The effect of the nitrogen limitations on terrestrial carbon sequestration in the results of the other CMIP5 models may be approximated by comparing the implicit Nr requirement given plausible ranges of terrestrial C:N stoichiometry (Wang and Houlton, 2009) to plausible increases in terrestrial Nr supply due to increased biological nitrogen fixation (Wang and Houlton, 2009) and anthropogenic Nr deposition (Figure 6.35). For the ensemble of CMIP5 projections under the RCP 8.5 scenario, this implies a lack of available nitrogen of 1.3–13.1 PgN which would reduce terrestrial C sequestration by an average of 137 PgC over the period 1860–2100, with a range of 41–273 PgC among models. This represents an ensemble mean reduction in land carbon sequestration of 55%, with a large spread across models (14–196%). Inferred reductions in ensemble-mean land carbon sink over the same period for RCPs 6.0, 4.5, and 2.6 are 109, 117, and 85 PgC, respectively. Between-model variation in these inferred reduced land carbon sinks is similar for all RCPs, with ranges of 57–162 PgC, 38–208 PgC, and 32–171 PgC for RCPs 6.0, 4.5, and 2.6, respectively. The influence of nutrient addition for agriculture and pasture management is not addressed in this analysis. Results from the two CMIP5 models which explicit C-N interactions show even lower land C sequestration than obtained by this approximation method (Figure 6.35). More models with explicit C-N interactions are needed to understand between-model variation and construct an ensemble response.

[INSERT FIGURE 6.35 HERE]

Figure 6.35: Estimated influence of nitrogen availability on total land carbon sequestration over the period 1860–2100 (based on analysis method of Wang and Houlton (2009)). Blue bars show, for each RCP scenario, the multi-model ensemble mean of land carbon sequestration, based on the carbon-only subset of CMIP5 models (CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5a-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MPI-

ESM-LR: not all models produced results for all scenarios). Red bars show, for each scenario, the mean land carbon sequestration from the same ensemble of carbon-only models after correcting for inferred constraints on carbon uptake due to limited availability of nitrogen. Black bars show \pm one standard deviation around the means. Black symbols show individual model results from the two CMIP5 models with explicit C-N interactions (CESM1-BGC and NorESM1-ME). These two models have nearly identical representations of land C-N dynamics, and differences between them here (for RCP4.5 and RCP8.5, where both models contributed results) are due to differences in coupled system climate. All simulations shown here used prescribed atmospheric CO₂ concentrations.

The positive effect on land carbon storage due to climate-increased Nr mineralization is of comparable magnitude to the land carbon storage increase associated with increased anthropogenic Nr deposition. Models disagree, however, which of the two factors is more important, with both effects dependent on the choice of scenario. Crucially, the effect of nitrogen limitation on vegetation growth and carbon storage under elevated CO₂ is the strongest effect of the natural and disturbed nitrogen cycle on terrestrial carbon dynamics (Bonan and Levis, 2010; Zaehle et al., 2010a). In consequence, the projected atmospheric CO₂ concentrations (and thus degree of climate change) in 2100 are higher in projections with models describing nitrogen limitations than in those same models without these interactions. The influence of current and future nitrogen deposition on the ocean sink for anthropogenic carbon is estimated to be rather small, with less than 5% of the ocean carbon sink in 2100 attributable to fertilization from anthropogenic Nr deposition over the oceans (Reay et al., 2008).

None of the CMIP5 models include phosphorus as a limiting nutrient for land ecosystems, although this limitation and interactions with Nr availability are observed in many systems (Elser et al., 2007). Limitation by Nr availability alone may act as a partial surrogate for combined N-P limitation (Thornton et al., 2009; Section 6.4.8.2), but are likely to underestimate the overall nutrient limitation, especially in lowland tropical forest.

6.4.7 Future Changes in CH₄ Emissions

Future atmospheric CH₄ concentrations are sensitive to changes in both emissions and OH oxidation. Atmospheric chemistry is not covered in this chapter and we assess here future changes in natural CH₄ emissions in response to climate change (e.g., O'Connor et al., 2010; Figure 6.36). Projected increases in future fire occurrence (Section 6.4.8.1) suggest that CH₄ from fires may increase (*low confidence*). Future changes in anthropogenic emissions due to anthropogenic alteration of wetlands (e.g., peatland drainage) may also be important but are not assessed here.

[INSERT FIGURE 6.36 HERE]

Figure 6.36: Schematic synthesis of the magnitude and time scales associated with possible future CH₄ emissions (adapted from O'Connor et al., 2010). Uncertainty in these future changes is large, and so this figure demonstrates the relative magnitude of possible future changes. Anthropogenic emissions starting at a present day level of 300 Tg(CH₄) yr⁻¹ (consistent with Table 6.8) and increasing or decreasing according to RCP8.5 and RCP2.6 are shown for reference. Wetland emissions are taken as 140–280 Tg(CH₄) yr⁻¹ present day values (Table 6.8) and increasing by between 0–100% (Section 6.4.7.1; Figure 6.37). Permafrost emissions may become important during the 21st century. CH₄ release from marine hydrates and subsea permafrost may also occur but uncertainty is sufficient to prevent plotting emission rates here. Large CH₄ hydrate release to the atmosphere is not expected during the 21st century. No quantitative estimates of future changes in CH₄ emissions from wildfires exist, so plotted here are continued present day emissions of 1–5 Tg(CH₄) yr⁻¹ (Table 6.8).

6.4.7.1 Future CH₄ Emissions from Global Wetlands

Wetland extent is determined by geomorphology and soil moisture, which depends on precipitation, evapotranspiration, drainage and runoff. All of these may change in the future. Increasing temperature can lead to higher rates of evapotranspiration, reducing soil moisture and therefore affect wetland extent, and temporary increasing aeration of existing wetlands with further consequences to methane emissions. Regional projections of precipitation changes are especially uncertain (see Chapter 12).

Direct effects on CH₄ emissions include: higher NPP under higher temperature and higher atmospheric CO₂ concentrations leading to more substrate for methanogenesis (White et al., 2008); higher CH₄ production rates under higher temperature; and changes in CH₄ oxidation through changed precipitation that alters water table position (Melton et al., 2013). Wetland CH₄ emissions are also affected by changes in wetland area

which may either increase (due to thawing permafrost or reduced evapotranspiration) or decrease (due to reduced precipitation or increased evaporation) regionally. In most models, elevated CO₂ has a stronger enhancement effect on CH₄ emissions than climate change. However, large uncertainties exist concerning the lack of wetland specific plant functional types in most models and the lack of understanding how wetland plants will react to CO₂ fertilization (e.g., Berendse et al., 2001; Boardman et al., 2011; Heijmans et al., 2001; Heijmans et al., 2002a, 2002b).

Since AR4, several modeling studies have attempted to quantify the sensitivity of global wetland CH₄ emissions to environmental changes (see Figure 6.37). The studies cover a wide range of simulation results but there is high agreement between model results that the combined effect of CO₂ increase and climate change by the end of the 21st century will increase wetland CH₄ emissions. Using a common experimental protocol with spatially uniform changes in precipitation, temperature and CO₂ (“WETCHIMP”; Melton et al., 2013) seven models predict that the effect of increased temperature alone (red bars in Figure 6.37) may cause an increase or decrease of wetland CH₄ emissions, while the effect of increased precipitation alone (green bars in Figure 6.37) is always an increase, although generally small. The effect of increased atmospheric CO₂ concentration (fertilization of NPP; Box 6.3; blue bars in Figure 6.37) always resulted in an increase of emissions (22 to 162%). Other studies assessed the effects of temperature and precipitation together (orange bars in Figure 6.37) and often found an increase in wetland CH₄ emissions (Eliseev et al., 2008; Gedney et al., 2004; Shindell et al., 2004; Volodin, 2008) although Ringeval et al. (2011) found a net decrease. The combined effect of climate and CO₂ resulted in an increase of wetland CH₄ emissions from 40% (Volodin (2008); fixed wetland area) to 68% (Ringeval et al., 2011); variable wetland area).

[INSERT FIGURE 6.37 HERE]

Figure 6.37: Relative changes of global CH₄ emissions from either pre-industrial (a) or present day (b) conditions and environmental changes that reflect potential conditions in 2100. The first seven models took part in the WETCHIMP intercomparison project and were run under a common protocol (Melton et al., 2013). Bars represent CH₄ emission changes associated with temperature-only changes (T), precipitation only (P), CO₂ only (CO₂) or combinations of multiple factors. Other studies as listed in the figure used different future scenarios: Eliseev et al. (2008), Gedney et al. (2004), Ringeval et al. (2011), Shindell et al. (2004), Volodin (2008), Stocker et al. (2013).

The models assessed here do not consider changes in soil hydrological properties caused by changes in organic matter content. Positive feedbacks from increased drainage due to organic carbon loss may accelerate peat decomposition rates (Ise et al., 2008). However, carbon accumulation due to elevated NPP in wetland and permafrost regions may to some extent offset CH₄ emissions (Frolking and Roulet, 2007; Turetsky et al., 2007). None of the studies or models assessed here consider CH₄ emissions from mangroves.

The models also do not agree in their simulations of present day wetland extent or CH₄ emissions, and there are not adequate datasets to evaluate them thoroughly at the grid scale (typically 0.5°) (Melton et al., 2013). Hence despite high agreement between models of a strong positive response of wetland CH₄ emission rates to increasing atmospheric CO₂ we assign *low confidence* to quantitative projections of future wetland CH₄ emissions.

Soil CH₄ oxidation of about 30 Tg(CH₄) yr⁻¹ (Table 6.8) represents the smallest of the three sinks for atmospheric methane (see Table 6.8) but is also sensitive to future environmental changes. Soil CH₄ oxidation is projected to increase by up to 23% under the SRES A1B due to rising atmospheric CH₄ concentrations, higher soil temperature and lower soil moisture (Curry, 2007, 2009).

6.4.7.2 Future CH₄ Emissions from Permafrost Areas

Permafrost thaw may lead to increased drainage and a net reduction in lakes and wetlands, a process that has already begun to be seen in lakes in the discontinuous permafrost zone (Smith et al., 2005; Jones et al., 2011) and has been projected to continue under future scenarios (Avis et al., 2011). Alternatively small lakes or ponds and wetland growth may occur in continuous permafrost areas underlain by ice-rich material subject to thermokarst (Christensen et al., 2004; Jorgenson et al., 2006; Plug and West, 2009; Jones et al., 2011).

There is high agreement between land surface models that permafrost extent is expected to reduce during the 21st century, accompanying particularly rapid warming at high latitudes (Chapter 12). However, estimates vary widely as to the pace of degradation (Lawrence and Slater, 2005; Burn and Nelson, 2006; Lawrence et

al., 2008). The LPJ-WHyMe model projected permafrost area loss of 30% (SRES B1) and 47% (SRES A2) by 2100 (Wania, 2007). Marchenko et al. (2008) calculate that by 2100, 57% of Alaska will lose permafrost within the top 2 m. For the RCP scenarios, the CMIP5 multi-model ensemble shows a wide range of projections for permafrost loss: 15–87% under RCP4.5 and 30–99% under RCP8.5 (Koven et al., 2012).

Hydrological changes may lead to tradeoffs between the CO₂ and CH₄ balance of ecosystems underlain by permafrost, with methane production rates being roughly an order of magnitude less than rates of oxic decomposition to CO₂ but CH₄ having a larger greenhouse warming potential (Frolking and Roulet, 2007). The extent of permafrost thaw simulated by climate models has been used to estimate possible subsequent carbon release (Burke et al., 2012; Harden et al., 2012; Section 6.4.3.4) but few studies explicitly partition this into CO₂ or CH₄ release to the atmosphere. Schneider von Deimling et al. (2012) estimate cumulative CH₄ emissions by 2100 between 131 and 533 Tg(CH₄) across the 4 RCPs. CMIP5 projections of permafrost thaw do not consider changes in pond or lake formation. Thawing of unsaturated Yedoma carbon deposits (which contain large, but uncertain amounts of organic carbon in permafrost in northeast Siberia; Schirrmeister et al., 2011) was postulated to produce significant CH₄ emissions (Khvorostyanov et al., 2008), however more recent estimates with Yedoma carbon lability constrained by incubation observations (Dutta et al., 2006) argue for smaller emissions at 2100 (Koven et al., 2011).

6.4.7.3 Future CH₄ Hydrate Emissions

Substantial quantities of methane are believed to be stored within submarine hydrate deposits at continental margins (see also Section 6.1, FAQ 6.2). There is concern that warming of overlying waters may melt these deposits, releasing CH₄ into the ocean and atmosphere systems.

Considering a potential warming of bottom waters by 1, 3 and 5 K during the next 100 years, Reagan and Moridis (2007) found that hydrates residing in a typical deep ocean setting (4°C and 1000 m depth) would be stable and in shallow low-latitude settings (6°C and 560 m) any sea-floor CH₄ fluxes would be oxidized within the sediments. Only in cold-shallow Arctic settings (0.4°C and 320 m) would CH₄ fluxes exceed rates of benthic sediment oxidation. Simulations of heat penetration through the sediment by Fyke and Weaver (2006) suggest that changes in the gas hydrate stability zone will be small on century timescales except in high-latitude regions of shallow ocean shelves. In the longer term, Archer et al. (2009a) estimated that between 35 and 940 PgC could be released over several thousand years in the future following a 3 K seafloor warming.

Using multiple climate models (Lamarque, 2008), predicted an upper-estimate of the global sea-floor flux of between 560 and 2140 Tg(CH₄) yr⁻¹, mostly in the high-latitudes. Hunter et al. (2013) also found 21st century hydrate dissociation in shallow Arctic waters and comparable in magnitude to Biastoch et al. (2011), although maximum CH₄ sea floor fluxes were smaller than Lamarque (2008), with emissions from 330 to 450 Tg(CH₄) yr⁻¹ for RCP 4.5 to RCP8.5. Most of the sea-floor flux of CH₄ is expected to be oxidised in the water column into dissolved CO₂. Mau et al. (2007) suggest only 1% might be released to the atmosphere but this fraction depends on the depth of water and ocean conditions. Elliott et al. (2011) demonstrated significant impacts of such sea-floor release on marine hypoxia and acidity, although atmospheric CH₄ release was small.

Observations of CH₄ release along the Svalbard margin seafloor (Westbrook et al., 2009) suggest observed regional warming of 1°C during the last 30 years is driving hydrate disassociation, an idea supported by modelling (Reagan and Moridis, 2009). However, these studies do not consider subsea-permafrost hydrates suggested recently to be regionally significant sources of atmospheric CH₄ (Shakhova et al., 2010). There was no positive excursion in the methane concentration recorded in ice cores from the largest known submarine landslide, the Storegga slide of Norway 8,200 years ago. Large methane hydrate release due to marine landslides is *unlikely* as any given landslide could only release a tiny fraction of the global inventory (Archer, 2007).

There is *low confidence* in modelling abilities to simulate transient changes in hydrate inventories, but large CH₄ release to the atmosphere during this century is *unlikely*.

6.4.8 Other Drivers of Future Carbon Cycle Changes

6.4.8.1 Changes in Fire under Climate Change / Scenarios of Anthropogenic Fire Changes

Regional studies for boreal regions suggest an increase in future fire risk (e.g., Amiro et al., 2009; Balshi et al., 2009; Flannigan et al., 2009a; Spracklen et al., 2009; Tymstra et al., 2007; Westerling et al., 2011; Wotton et al., 2010) with implications for carbon and nutrient storage (Certini, 2005). Kurz et al. (2008b) and Metsaranta et al. (2010) indicated that increased fire activity has the potential to turn the Canadian forest from a sink to a source of atmospheric CO₂. Models predict spatially variable responses in fire activity, including strong increases and decreases, due to regional variations in the climate–fire relationship, and anthropogenic interference (Scholze et al., 2006; Flannigan et al., 2009b; Krawchuk et al., 2009; Pechony and Shindell, 2010; Kloster et al., 2012). Wetter conditions can reduce fire activity, but increased biomass availability can increase fire emissions (Scholze et al., 2006; Terrier et al., 2013). Using a land-surface model and future climate projections from two GCMs, Kloster et al. (2012) projected fire carbon emissions in 2075–2099 that exceed present day emissions by 17–62% (0.3–1.0 PgC yr⁻¹) depending on scenario.

Future fire activity will also depend on anthropogenic factors especially related to land use change. For the Amazon it is estimated that at present 58% of the area is too humid to allow deforestation fires but climate change might reduce this area to 37% by 2050 (Le Page et al., 2010). Golding and Betts (2008) estimated that future Amazon forest vulnerability to fire may depend non-linearly on combined climate change and deforestation.

6.4.8.2 Other Biogeochemical Cycles and Processes Impacting Future Carbon Fluxes

Phosphorous. On centennial time scales, the Phosphorous (P) limitation of terrestrial carbon uptake could become more severe than the nitrogen limitation because of limited phosphorus sources. Model simulations have shown a shift after 2100 from nitrogen to phosphorus limitation at high latitudes (Goll et al., 2012).

Elevated surface ozone Plants are known to suffer damage due to exposure to levels of ozone (O₃) above about 40 ppb (Ashmore, 2005). Model simulations of plant O₃ damage on the carbon cycle have found a reduction in terrestrial carbon storage between 2005 and 2100 ranging from 4 to 140 PgC (Felzer et al., 2005) and up to 260 PgC (Sitch et al., 2007).

Iron deposition to oceans. Changes in iron deposition may have affected ocean carbon uptake in the past (Section 6.2.1.1), but future projections of iron deposition from desert dust over the ocean are uncertain, even about the sign of changes (Tegen et al., 2004; Mahowald et al., 2009). Tagliabue et al. (2008) found relatively little impact of varying aeolian iron input on ocean CO₂ fluxes, but Mahowald et al. (2011) show projected changes in ocean productivity as large as those due to CO₂ increases and climate change.

Changes in the diffuse fraction of solar radiation at the surface Mercado et al. (2009) estimated that variations in the diffuse fraction, associated largely with the 'global dimming' period (Stanhill and Cohen, 2001), enhanced the land carbon sink by approximately 25% between 1960 and 1999. Under heavily polluted or dark cloudy skies, plant productivity may decline as the diffuse effect is insufficient to offset decreased surface irradiance (UNEP, 2011). Under future scenarios involving reductions in aerosol emissions (Figure 6.33, 6.34), the diffuse-radiation enhancement of carbon uptake will decline.

6.4.9 The Long Term Carbon Cycle and Commitments

Long term changes in vegetation structure and induced carbon storage potentially show larger changes beyond 2100 than during the 21st century as the long timescale response of tree growth and ecosystem migrations means that by 2100 only a part of the eventual committed change will be realised (Jones et al., 2009). Holocene changes in tree-line lagged changes in climate by centuries (MacDonald et al., 2008). Long-term 'commitments' to ecosystems migration also carry long-term committed effects to changes in terrestrial carbon storage (Jones et al., 2010; Liddicoat et al., 2013) and permafrost (O'Connor et al., 2010; Sections 6.4.3.3, 6.4.7).

Warming of high latitudes is common to most climate models (Chapter 12) and this may enable increased productivity and northward expansion of boreal forest ecosystems into present tundra regions depending on nutrient availability (Kellomäki et al., 2008; Kurz et al., 2008a; MacDonald et al., 2008). CMIP5 simulations by two ESMs with dynamic vegetation for extended RCP scenarios to 2300 (Meinshausen et al., 2011) allow analysis of this longer term response of the carbon cycle. Increases in tree cover and terrestrial carbon storage north of 60°N are simulated (Figure 6.38).

Increases in fire disturbance or insect damage may drive loss of forest in temperate regions (Kurz et al., 2008c), but this process is poorly represented or not accounted at all in models. Recent evidence from models (Huntingford et al., 2013) and studies on climate variability (Cox et al., 2013) suggests that large scale loss of tropical forest as previously projected in some models (Cox et al., 2004; Scholze et al., 2006) is unlikely, but depends strongly on the predicted future changes in regional temperature (Galbraith et al., 2010) and precipitation (Good et al., 2011; 2013), although both models here simulate reduced tree cover and carbon storage for the RCP8.5 scenario. Earth System models also poorly simulate resilience of ecosystems to climate changes and usually do not account for possible existence of alternative ecosystem states such as tropical forest or savannah (Hirota et al., 2011).

Regional specific changes in ecosystem composition and carbon storage are uncertain but it is *very likely* that ecosystems will continue to change for decades to centuries following stabilisation of greenhouse gases and climate change.

[INSERT FIGURE 6.38 HERE]

Figure 6.38: Maps of changes in woody cover fraction, %, (left) and terrestrial carbon storage, kg C m⁻², (vegetation carbon, middle; soil carbon, right) between years 2100 and 2300 averaged for two models, HadGEM2-ES and MPI-ESM, which simulate vegetation dynamics for three RCP extension scenarios 2.6 (top), 4.5 (middle), and 8.5 (bottom). Note the RCP6.0 extension was not a CMIP5 required simulation. Model results were interpolated on 1° x 1° grid; white colour indicates areas where models disagree in sign of changes. Anthropogenic land use in these extension scenarios is kept constant at 2100 levels, so these results show the response of natural ecosystems to the climate change.

6.5 Potential Effects of Carbon Dioxide Removal (CDR) Methods and Solar Radiation Management on the Carbon Cycle

6.5.1 Introduction to CDR Methods

To slow or perhaps reverse projected increases in atmospheric CO₂ (Section 6.4), several methods have been proposed to augment the removal of atmospheric CO₂ and enhance the storage of carbon in land, ocean and geological reservoirs. These methods are categorized as ‘Carbon Dioxide Removal (CDR)’ methods (see Glossary). Another category of methods involves the intentional manipulation of planetary solar absorption to counter climate change, and is called the ‘Solar Radiation Management (SRM)’ (discussed in Chapter 7, Section 7.7; see Glossary). In this Section, CDR methods are discussed from the point of view of the carbon cycle processes (6.5.2) and their impacts and side effects on carbon cycle and climate (6.5.3). A brief discussion on the indirect carbon cycle effects of SRM methods is given in 6.5.4. Most of the currently proposed CDR methods are summarized in Table 6.14 and some are illustrated schematically in Chapter 7 (7.7; FAQ 7.3 Figure 1). Since some CDR methods would operate on large spatial scales they are also called ‘Geoengineering’ proposals (Keith, 2001). Removal of CH₄ and N₂O has also been proposed to reduce climate change (Stolaroff et al., 2012). While the science of geoengineering methods is assessed in this section (CDR) and Chapter 7 (SRM), the benefits and risks of SRM are planned to be assessed in Chapter 19 of AR5 WGII report. Further, Chapter 6 of AR5 WGIII report plans to assess the cost and socio-economical implications of some CDR and SRM methods for climate stabilization pathways.

Table 6.14: Examples of CDR methods and their implications for carbon cycle and climate. The list is non-exhaustive. A ‘Rebound’ effect and a thermal inertia of climate system are associated with all CDR methods.

Carbon Cycle Process to be Modified Intentionally	CDR Method Name	Nature of CDR Removal Process	Storage Location	Storage Form	Some Carbon Cycle and Climate Implications

Enhanced Biological Production and Storage on Land	Afforestation / reforestation ^a Improved forest management ^b Sequestration of wood in buildings ^c Biomass burial ^d No till agriculture ^e Biochar ^f Conservation agriculture ^g Fertilisation of land plants ^h Creation of wetlands ⁱ Biomass Energy with Carbon Capture and Storage (BECCS) ^j	Biological	^{a, b, h} Land (biomass, soils) ^d Land/ocean floor ^e ^{f, g} Land (soils) ⁱ Land (wetland soils) ^j Ocean / geological formations	^{a, b, c, d, e, f, g, h, i} Organic ^j Inorganic	^{a, b, c, d, e, f, g, h, i, j} Alters surface albedo and evapotranspiration ^{a, b, c, e, f, g} ^{h, i} Lack of permanence ^d Potentially permanent if buried on the ocean floor ^j Permanent if stored in geological reservoir
Enhanced Biological Production and Storage in Ocean	Ocean iron fertilisation ^k Algae farming and burial ^l Blue carbon (mangrove, kelp farming) ^m Modifying ocean upwelling to bring nutrients from deep ocean to surface ocean ⁿ	Biological	Ocean	^{k, n} Inorganic ^{l, m} Organic	^k May lead to expanded regions with low oxygen concentration, increased N ₂ O production, deep ocean acidification and disruptions to marine ecosystems and regional carbon cycle ⁿ Disruptions to regional carbon cycle
Accelerated Weathering	Enhanced weathering over land ^o Enhanced weathering over ocean ^p	Chemical	^o Soils and oceans ^p Ocean	^{o, p} Inorganic	^o Permanent removal; likely to change pH of soils, rivers, and ocean ^p Permanent removal; likely to change pH of ocean
Others	Direct-air capture with storage	Chemical	Ocean/geological formations	Inorganic	Permanent removal if stored in geological reservoirs

Notes:

Superscripts in column 2 refer to the corresponding superscripts in columns 4, 5 and 6 of the same row.

Large scale industrial methods such as carbon capture and storage (CCS), biofuel energy production (without CCS) and reducing emissions from deforestation and degradation (REDD) cannot be called CDR methods since they *reduce fossil fuel use or land use change CO₂ emissions* to the atmosphere but they do not involve a net removal of CO₂ that is already in the atmosphere. However, direct air capture of CO₂ using industrial methods (Table 6.14; and Chapter 7 FAQ 7.3 Figure 1) will remove CO₂ from the atmosphere and is thus considered as a CDR method. The distinction between CDR and mitigation (see Glossary) is not clear and there could be some overlap between the two.

Insofar as the CDR-removed CO₂ is sequestered in a permanent reservoir, CDR methods could potentially reduce direct consequences of high CO₂ levels, including ocean acidification (see Section 6.4.4) (Matthews et al., 2009). However, the effects of CDR methods that propose to manipulate carbon cycle processes are slow (see Box 6.1) and hence the consequent climate effects would be slow. The climate system has a less than 5-years relaxation (e-folding) time scale for an assumed instantaneous reduction in radiative forcing to

preindustrial levels (Held et al., 2010). While the climate effect of SRM could be rapid (Shepherd et al., 2009) given this time scale, at present, there is no known CDR method, including industrial direct air capture that can feasibly reduce atmospheric CO₂ to pre-industrial levels within a similar time scale. Therefore, CDR methods do not present an option for rapidly preventing climate change when compared to SRM. However, if implemented on large scales and for long enough, typically during at least a century, these methods could potentially make a contribution to slow-down the increase or even decrease atmospheric CO₂ (Matthews, 2010).

Important carbon cycle science considerations for evaluating CDR methods include the associated carbon storage capacity, the permanence of carbon storage and potential adverse side effects (Shepherd et al., 2009). Geological reservoirs could store several thousand PgC and the ocean may be able to store a few thousand PgC of anthropogenic carbon in the long-term (Metz et al., 2005; House et al., 2006; Orr, 2009) (see Box 6.1 and Archer et al., 2009b). The terrestrial biosphere may have a typical potential to store carbon equivalent to the cumulative historical land use loss of 180 ± 80 PgC (Table 6.1; Section 6.5.2.1).

In this assessment, we use “permanence” to refer to time scales larger than tens of thousands of years. CDR methods associated with either permanent or non-permanent carbon sequestration (see Table 6.14) have very different climate implications (Kirschbaum, 2003). Permanent sequestration methods have the potential to reduce the radiative forcing of CO₂ over time. By contrast, non-permanent sequestration methods will release back the temporarily sequestered carbon as CO₂ to the atmosphere, after some delayed time interval (Herzog et al., 2003). As a consequence, elevated levels of atmospheric CO₂ and climate warming will only be delayed and not avoided by the implementation of non-permanent CDR methods (Figure 6.39). Nevertheless, CDR methods that could create a temporary CO₂ removal (Table 6.14) may still have value (Dornburg and Marland, 2008) by reducing the cumulative impact of higher temperature.

[INSERT FIGURE 6.39 HERE]

Figure 6.39: Idealized model simulations (Matthews, 2010) to illustrate the effects of CDR methods associated with either permanent or non-permanent carbon sequestration. There is an emission of 1000 PgC in the reference case (black line) between 1800 and 2100, corresponding approximately to RCP4.5 scenario (Section 6.4). Permanent sequestration of 380 PgC, assuming no leakage of sequestered carbon would reduce climate change (blue line, compared to black line). By contrast, a non-permanent sequestration CDR method where carbon will be sequestered and later on returned to the atmosphere in three centuries would not. In this idealized non-permanent sequestration example scenario, climate change would only be delayed but the eventual magnitude of climate change will be equivalent to the no-sequestration case (green line, compared to black). Figure adapted from Figure 5 of Matthews (2010).

Another important carbon cycle consequence of CDR methods is the ‘rebound effect’ (see Glossary). In the Industrial Era (since 1750) about half of the CO₂ emitted into the atmosphere from fossil fuel emissions has been taken up by land and ocean carbon reservoirs (see Section 6.3 and Table 6.1). As for current CO₂ emissions and the consequent CO₂ rise, which are currently *opposed* by uptake of CO₂ by natural reservoirs, any removal of CO₂ from the atmosphere by CDR will be *opposed* by release of CO₂ from natural reservoirs (Figure 6.40). Therefore, returning to pre-industrial CO₂ levels would require permanently sequestering an amount of carbon equal to total anthropogenic CO₂ emissions that have been released before the time of CDR, roughly twice as much the excess of atmospheric CO₂ above pre-industrial level at the time CDR will begin (Lenton and Vaughan, 2009; Cao and Caldeira, 2010b; Matthews, 2010).

[INSERT FIGURE 6.40 HERE]

Figure 6.40: Idealized simulations with a simple global carbon cycle model (Cao and Caldeira, 2010b) to illustrate the ‘rebound effect’. Effects of an instantaneous cessation of CO₂ emissions at year 2050 (amber line), one-time CDR removal of the excess of atmospheric CO₂ over pre-industrial levels (blue line) and removal of this excess of atmospheric CO₂ followed by continued removal of all the CO₂ that degasses from the ocean (green line) are shown. For the years 1850–2010 observed atmospheric CO₂ concentrations are prescribed and CO₂ emissions are calculated from CO₂ concentrations and modeled carbon uptake. For years 2011–2049, CO₂ emissions are prescribed following the SRES A2 scenario. Starting from year 2050, CO₂ emission is either set to zero or calculated from modeled CO₂ concentrations and CO₂ uptake. To a first approximation, a cessation of emissions would prevent further warming but would not lead to significant cooling on the century time scale. A one-time removal of excess atmospheric CO₂ would eliminate approximately only half of the warming experienced at the time of the removal because of CO₂ that outgases from the ocean (the rebound effect). To bring atmospheric CO₂ back to pre-industrial levels permanently, would require the removal of all previously emitted CO₂, i.e., an amount equivalent to approximately twice the excess atmospheric CO₂ above pre-industrial level. Figure adapted from Cao and Caldeira (2010b).

6.5.2 Carbon Cycle Processes Involved in CDR Methods

The CDR methods listed in Table 6.14 rely primarily on human management of carbon cycle processes to remove CO₂: (1) enhanced net biological uptake and subsequent sequestration by land ecosystems, (2) enhanced biological production in ocean and subsequent sequestration in the ocean, and (3) accelerated chemical weathering reactions over land and ocean. The exceptional CDR method is industrial direct air capture of CO₂, e.g., relying on chemistry methods. CO₂ removed by CDR is expected to be stored in organic form on land and in inorganic form in ocean and geological reservoirs (Table 6.14). This management of the carbon cycle however likely has other implications on ecosystems and biogeochemical cycles. The principle of different CDR methods listed in Table 6.14 is described below and the characteristics of some CDR methods are summarized in Table 6.15.

Some of the RCP scenarios used as a basis for future projections in this Assessment Report already include some CDR methods. To achieve the RCP2.6 CO₂ peak and decline the IMAGE integrated assessment model simulates widespread implementation of BECCS technology to achieve globally negative emissions after around 2080 (see Section 6.4.3). RCP4.5 also assumes some use of BECCS to stabilise CO₂ concentration by 2100. Therefore it should be noted that potentials for CDR assessed in this section cannot be seen as additional potential for CO₂ removal from the low RCPs as this is already included in those scenarios.

[INSERT TABLE 6.15 HERE]

Table 6.15: Characteristics of some CDR methods from peer-reviewed literature. Note that a variety of economic, environmental, and other constraints could also limit their implementation and net potential.

6.5.2.1 Enhanced Carbon Sequestration by Land Ecosystems

The key driver of these CDR methods is net primary productivity on land which currently produces biomass at a rate of approximately 50–60 PgC yr⁻¹ (Nemani et al., 2003). The principle of these CDR methods is to increase net primary productivity and/or store a larger fraction of the biomass produced into ecosystem carbon pools with long turnover times, e.g., under the form of wood or refractory organic matter in soils (Table 6.14). One variant is to harvest biomass for energy production and sequester the emitted CO₂ (BECCS). BECCS technology has not been tested at industrial scale, but is commonly included in Integrated Assessment Models and future scenarios that aim to achieve low CO₂ concentrations.

Estimates of the global potential for enhanced primary productivity over land are uncertain because the potential of any specific method will be severely constrained by competing land needs (e.g., agriculture, biofuels, urbanization and conservation) and sociocultural considerations. An order of magnitude of the upper potential of afforestation/reforestation would be the restoration of all the carbon released by historical land use (180 ± 80 PgC; Table 6.1; Section 6.3.2.2). House et al. (2002) estimated that the atmospheric CO₂ concentration by 2100 would be lowered by only about 40–70 ppm in that scenario (accounting for the ‘rebound’ effect).

The capacity for enhancing the soil carbon content on agricultural and degraded lands was estimated by one study at 50–60% of the historical soil carbon released, that is 42–78 PgC (Lal, 2004a). The proposed agricultural practices are the adoption of conservation tillage with cover crops and crop residue mulch, conversion of marginal lands into restorative land uses and nutrient cycling including the use of compost and manure. Recent estimates suggest a cumulative potential of 30–60 PgC of additional storage over 25–50 years (Lal, 2004b).

Finally, biochar and biomass burial methods aim to store organic carbon into very long turnover time ecosystem carbon pools. The maximum sustainable technical potential of biochar cumulative sequestration is estimated at 130 PgC over a century by one study (Woolf et al., 2010). The residence time of carbon converted to biochar and the additional effect of biochar on soil productivity are uncertain and further research is required to assess the potential of this method (Shepherd et al., 2009).

6.5.2.2 Enhanced Carbon Sequestration in the Ocean

The principle here is to enhance the primary productivity of phytoplankton (biological pump; Section 6.1.1) so that a fraction of the extra organic carbon produced gets transported to the deep ocean. Some of the inorganic carbon in the surface ocean that is removed by the export of net primary productivity below the surface layer will be subsequently replaced by CO₂ pumped from the atmosphere, thus removing atmospheric CO₂. Ocean primary productivity is limited by nutrients (e.g., iron, nitrogen and phosphorus). Enhanced biological production in ocean CDR methods (Table 6.14) is obtained by adding nutrients that would otherwise be limiting (Martin, 1990). The expected increase in the downward flux of carbon can be partly sequestered as Dissolved Inorganic Carbon after mineralization in the intermediate and deep waters. In other ocean-based CDR methods, algae and kelp farming and burial, carbon would be stored in organic form.

The effectiveness of ocean CDR through iron addition depends on the resulting increase of productivity and the fraction of this extra-carbon exported to deep and intermediate waters, and its fate. Small scale (~10 km²) experiments (Boyd et al., 2007) have shown only limited transient effects of iron addition in removing atmospheric CO₂. An increased productivity was indeed observed, but this effect was moderated either by other limiting elements, or by compensatory respiration from increased zooplankton grazing. Most of the carbon produced by primary productivity is oxidized (remineralized into DIC) in the surface layer, so that only a small fraction is exported to the intermediate and deep ocean (Lampitt et al., 2008) although some studies indicate little remineralization in the surface layer (Jacquet et al., 2008). A recent study (Smetacek et al., 2012) finds that at least half the extra-carbon in plankton biomass generated by artificial iron addition sank far below a depth of 1,000 metres, and that a substantial portion is likely to have reached the sea floor. There are some indications that sustained natural iron fertilization may have a higher efficiency in exporting carbon from surface to intermediate and deep ocean than short term blooms induced by artificial addition of iron (Buesseler et al., 2004; Blain et al., 2007; Pollard et al., 2009). Thus, there is no consensus on the efficiency of iron fertilization from available field experiments.

Using ocean carbon models (see 6.3.2.5.6), the maximum drawdown of atmospheric CO₂ have been estimated from 15 ppm (Zeebe and Archer, 2005) to 33 ppm (Aumont and Bopp, 2006) for an idealized continuous (over 100 years) global ocean iron fertilization, which is technically unrealistic. In other idealized simulations of ocean fertilization in the global ocean or only in the Southern Ocean (Joos et al., 1991; Peng and Broecker, 1991; Watson et al., 1994; Cao and Caldeira, 2010a), atmospheric CO₂ was reduced by less than 100 ppm for ideal conditions. Jin and Gruber (2003) obtained an atmospheric drawdown of more than 60 ppm over 100 years from an idealized iron fertilization scenario over the entire Southern Ocean. The radiative benefit from lower CO₂ could be offset by a few percent to more than 100% from an increase in N₂O emissions (Jin and Gruber, 2003). All the above estimates of maximum potential CO₂ removal account for the rebound effect from oceans but not from the land (thus overestimate the atmospheric CO₂ reduction).

One ocean CDR variant is to artificially supply more nutrients to the surface ocean in upwelling areas (Lovelock and Rapley, 2007; Karl and Letelier, 2008). The amount of carbon sequestered by these enhanced upwelling methods depends critically on their location (Yool et al., 2009). Idealized simulations suggest an atmospheric CO₂ removal at a net rate of about 0.9 PgC yr⁻¹ (Oschlies et al., 2010b). This ocean-based CDR method has not been tested in the field, unlike iron addition experiments.

6.5.2.3 Accelerated Weathering

The removal of CO₂ by the weathering of silicate and carbonate minerals (Berner et al., 1983; Archer et al., 2009b) occurs on time scales from thousands to tens of thousands of years (see Box 6.1) and at a rate of ~0.3 PgC yr⁻¹ (Figure 6.1; Gaillardet et al., 1999; Hartmann et al., 2009). This rate is currently much too small to offset the rate at which fossil fuel CO₂ is being emitted (Section 6.3).

The principle of accelerated weathering CDR on land is to dissolve *artificially* silicate minerals so drawdown of atmospheric CO₂ and geochemical equilibrium restoration could proceed on a much faster (century) time scale. For instance, large amounts of silicate minerals such as olivine ((Mg,Fe)₂SiO₄) could be mined, crushed, transported to and distributed on agricultural lands, to remove atmospheric CO₂ and form carbonate minerals in soils and/or bicarbonate ions that would be transported to the ocean by rivers (Schuiling and Krijgsman, 2006). Alternatively, CO₂ removal by weathering reactions might be enhanced by exposing minerals such as basalt or olivine to elevated CO₂, with potential CO₂ removal rates exceeding 0.25 PgC yr⁻¹ (Kelemen and Matter, 2008). In the idealized case where olivine could be spread as a fine powder over all

the humid tropics, potential removal rates of up to 1 PgC yr⁻¹ have been estimated, despite limitations by the saturation concentration of silicic acid (Köhler et al., 2010). For the United Kingdom, the potential from silicate resources was estimated to be more than 100 PgC (Renforth, 2012).

Fossil fuel CO₂ released to the atmosphere leads to the addition of anthropogenic CO₂ in the ocean (6.3.2.5). This anthropogenic CO₂ will eventually dissolve ocean floor carbonate sediments to reach geochemical equilibrium on a ten thousand year time scale (Archer et al., 1997). The principle of ocean based weathering CDR methods is to accelerate this process. For instance, carbonate rocks could be crushed, reacted with CO₂ (e.g., captured at power plants) to produce bicarbonate ions that would be released to the ocean (Rau and Caldeira, 1999; Caldeira and Rau, 2000; Rau, 2008). Alternatively, carbonate minerals could be directly released into the ocean (Kheshgi, 1995; Harvey, 2008). Strong bases, derived from silicate rocks, could also be released to ocean (House et al., 2007) to increase alkalinity and drawdown of atmospheric CO₂. Carbonate minerals such as limestone could be heated to produce lime (Ca(OH)₂); this lime could be added to the ocean to increase alkalinity as well (Kheshgi, 1995). While the level of confidence is very high for the scientific understanding of weathering chemical reactions, it is low for its effects and risks at planetary scale (6.5.3.3).

6.5.2.4 CDR by Direct Industrial Capture of Atmospheric CO₂

Direct Air Capture refers to the chemical process by which a pure CO₂ stream is produced by capturing CO₂ from ambient air. The captured CO₂ could be sequestered in geological reservoirs or the deep ocean. At least three methods have been proposed to capture CO₂ from the atmosphere: (1) adsorption on solids (Gray et al., 2008; Lackner, 2009, 2010; Lackner et al., 2012); (2) absorption into highly alkaline solutions (Stolaroff et al., 2008; Mahmoudkhani and Keith, 2009); (3) absorption into moderate alkaline solution with a catalyst (Bao and Trachtenberg, 2006). The main limitation to direct air capture is the thermodynamic barrier due to the low concentration of CO₂ in ambient air.

6.5.3 Impacts of CDR Methods on Carbon Cycle and Climate

One impact common to all CDR methods is related to the thermal inertia of the climate system. Climate warming will indeed continue for at least decades after CDR is applied. Therefore, temperature (and climate change) will lag a CDR-induced decrease in atmospheric CO₂ (Boucher et al., 2012). Modelling the impacts of CDR on climate change is still in its infancy. Some of the first studies (Wu et al., 2010; Cao et al., 2011) showed that the global hydrological cycle could intensify in response to a reduction in atmospheric CO₂ concentrations.

6.5.3.1 Impacts of Enhanced Land Carbon Sequestration

In the case of land-based CDR, biomass in forests is a non-permanent ecosystem carbon pool and hence there is a risk that this carbon may return to the atmosphere e.g., by disturbances such as fire, or by future land use change. When considering afforestation/reforestation, it is also important to account for biophysical effects on climate that come together with carbon sequestration because afforestation/reforestation changes the albedo (see Glossary), evapotranspiration and the roughness of the surface (Bonan, 2008; Bernier et al., 2011). Modeling studies show that afforestation in seasonally snow covered boreal and temperate regions will decrease the land surface albedo and have a net (biophysical plus biogeochemical) warming effect, whereas afforestation in low latitudes (Tropics) is likely to enhance latent heat flux from evapotranspiration and have a net cooling effect (Bonan et al., 1992; Betts, 2000; Bala et al., 2007; Montenegro et al., 2009; Bathiany et al., 2010). Consequently, the location of land ecosystem based CDR methods needs to be considered carefully when evaluating their effects on climate (Bala et al., 2007; Arora and Montenegro, 2011; Lee et al., 2011; Pongratz et al., 2011b). In addition CDR in land ecosystems is likely to increase N₂O emissions (Li et al., 2005). Enhanced biomass production may also require more nutrients (fertilizers) which are associated with fossil fuel CO₂ emission from industrial fertilizer production and Nr impacts. Biochar-based CDR could reduce N₂O emissions but may increase CO₂ and CH₄ emissions from agricultural soils (Wang et al., 2012b). Addition of biochar could also promote a rapid loss of forest humus and soil carbon in some ecosystems during the first decades (Wardle et al., 2008).

6.5.3.2 Impacts of Enhanced Carbon Sequestration in the Ocean

In the case of ocean-based CDR using fertilization, adding macronutrients such as nitrogen and phosphate in the fertilized region could lead to a decrease in production ‘downstream’ of the fertilized region (Gnanadesikan et al., 2003; Gnanadesikan and Marinov, 2008; Watson et al., 2008). Gnanadesikan et al. (2003) simulated a decline in export production of 30 tC for every ton removed from the atmosphere. A sustained global-ocean iron fertilization for SRES A2 CO₂ emission scenario was also found to acidify the deep ocean (pH decrease of about 0.1–0.2) while mitigating surface pH change by only 0.06 (Cao and Caldeira, 2010a). Other environmental risks associated with ocean fertilization include expanded regions with low oxygen concentration (Oschlies et al., 2010a), increased N₂O emission (Jin and Gruber, 2003), increased production of dimethyl-sulphide (DMS), isoprene, CO, N₂O, CH₄ and other non-CO₂ greenhouse gases (Oschlies et al., 2010a) and possible disruptions to marine ecosystems (Denman, 2008).

In the case of enhanced ocean upwelling CDR methods there could be disturbance to the regional carbon balances, since the extra-upwelling will be balanced by extra-downwelling at another location. Along with growth-supporting nutrients, enhanced concentrations of DIC will also be brought to surface waters and partially offset the removal of CO₂ by increased biological pump. Further, in case artificially enhanced upwelling would be stopped, atmospheric CO₂ concentrations could rise rapidly because carbon removed from the atmosphere and stored in soils in the cooler climate associated with artificial upwelling could be rapidly released back (Oschlies et al., 2010b). The level of confidence on the impacts of the enhanced upwelling is low.

6.5.3.3 *Impact of Enhanced Weathering*

In the case of weathering-based CDR, the pH and carbonate mineral saturation of soils, rivers and ocean surface waters will increase where CDR is implemented. Köhler et al. (2010) simulated that the pH of the Amazon river would rise by 2.5 units if the dissolution of olivine in the entire Amazon basin was used to remove 0.5 PgC yr⁻¹ from the atmosphere. In the marine environment, elevated pH and increased alkalinity could potentially counteract the effects of ocean acidification, which is beneficial. Changes in alkalinity could also modify existing ecosystems. There is uncertainty in our understanding of the net effect on ocean CO₂ uptake but most likely there will be a partial offset of the abiotic effect by calcifying species. As for other CDR methods, the confidence level on the carbon cycle impacts of enhanced weathering is low.

6.5.4 *Impacts of Solar Radiation Management on Carbon Cycle*

Solar radiation management (SRM) methods aim to reduce incoming solar radiation at the surface (discussed in Chapter 7, 7.7 and in AR5, WG2, Chapter 19). Balancing reduced outgoing radiation by reduced incoming radiation may be able to cool global mean temperature but may lead to a less intense global hydrological cycle (Bala et al., 2008) with regionally different climate impacts (Govindasamy et al., 2003; Matthews and Caldeira, 2007; Robock et al., 2008; Irvine et al., 2010; Ricke et al., 2010). Therefore, SRM will not prevent the effects of climate change on the carbon and other biogeochemical cycles.

SRM could reduce climate warming but will not interfere with the direct biogeochemical effects of elevated CO₂ on the carbon cycle. For example, ocean acidification caused by elevated CO₂ (Section 6.4.4) and the CO₂ fertilization of productivity (Box 6.3) will not be altered by SRM (Govindasamy et al., 2002; Naik et al., 2003; Matthews and Caldeira, 2007). Similarly, SRM will not interfere with the stomatal response of plants to elevated CO₂ (the CO₂-physiological effect) that leads to a decline in evapotranspiration, causing land temperatures to warm and runoff to increase (Gedney et al., 2006; Betts et al., 2007; Matthews and Caldeira, 2007; Piao et al., 2007; Cao et al., 2010; Fyfe et al., 2013).

However, due to carbon-climate feedbacks (Section 6.4), the implementation of SRM could affect the carbon cycle. For instance, carbon uptake by land and ocean could increase in response to SRM by reducing the negative effects of climate change on carbon sinks (Matthews and Caldeira, 2007). For instance, for the SRES A2 scenario with SRM, a lower CO₂ concentration of 110 ppm by year 2100 relative to a baseline case without SRM has been simulated by Matthews and Caldeira (2007). Land carbon sinks may be enhanced by increasing the amount of diffuse relative to direct radiation (Mercado et al., 2009) if SRM causes the fraction of diffuse light to increase (e.g., injection of aerosols into the stratosphere). However, reduction of total incoming solar radiation could decrease terrestrial CO₂ sinks as well.

6.5.5 *Synthesis*

CDR methods are intentional large scale methods to remove atmospheric CO₂ either by managing the carbon cycle or by direct industrial removal of CO₂ (Table 6.14). In contrast to SRM methods, CDR methods that manage the carbon cycle are unlikely to present an option for rapidly preventing climate change. The maximum (idealized) potential for atmospheric CO₂ removal by individual CDR methods is compiled in Table 6.15. In this compilation, note that unrealistic assumptions about the scale of deployment, such as fertilizing the entire global ocean, are used, and hence large potentials are simulated. The “rebound effect” in the natural carbon cycle is likely to diminish the effectiveness of all the CDR methods (Figure 6.40). The level of confidence on the effects of both CDR and SRM methods on carbon and other biogeochemical cycles is very low.

FAQ 6.1: What Happens to Carbon Dioxide After it is Emitted into the Atmosphere?

Carbon dioxide, after it is emitted into the atmosphere, is firstly rapidly distributed between atmosphere, the upper ocean and vegetation. Subsequently, the carbon continues to be moved between the different reservoirs of the global carbon cycle, such as soils, the deeper ocean, and rocks. Some of these exchanges occur very slowly. Depending on the amount of CO₂ released, between 15% and 40% will remain in the atmosphere for up to 2000 years, after which a new balance is established between the atmosphere, the land biosphere and the ocean. Geological processes will take anywhere from tens to hundreds of thousands of years—perhaps longer—to redistribute the carbon further among the geological reservoirs. Higher atmospheric CO₂ concentrations, and associated climate impacts of present emissions, will, therefore, persist for a very long time into the future.

Carbon dioxide is a largely non-reactive gas, which is rapidly mixed throughout the entire troposphere in less than a year. Unlike reactive chemical compounds in the atmosphere which are removed and broken down by sink processes, such as methane, carbon is instead redistributed among the different reservoirs of the global carbon cycle and ultimately recycled back to the atmosphere on a multitude of time scales. FAQ 6.1, Figure 1 shows a simplified diagram of the global carbon cycle. The open arrows indicate typical timeframes for carbon atoms to be transferred through the different reservoirs.

[INSERT FAQ 6.1, FIGURE 1 HERE]

FAQ 6.1, Figure 1: Simplified schematic of the global carbon cycle showing the typical turnover time scales for carbon transfers through the major reservoirs.

Before the industrial Era, the global carbon cycle was roughly balanced. This can be inferred from ice-core measurements, which show a near constant atmospheric concentration of CO₂ over the last several thousand years prior to the industrial Era. Anthropogenic emissions of carbon dioxide into the atmosphere, however, have disturbed that equilibrium. As global CO₂ concentrations rise, the exchange processes between CO₂ and the surface ocean and vegetation are altered, as are subsequent exchanges within and among the carbon reservoirs on land, in the ocean and eventually, the Earth crust. In this way, the added carbon is redistributed by the global carbon cycle, until the exchanges of carbon between the different carbon reservoirs have reached a new, approximate balance.

Over the ocean, CO₂ molecules pass through the air-sea interface by gas exchange. In seawater, CO₂ interacts with water molecules to form carbonic acid, which reacts very quickly with the large reservoir of dissolved inorganic carbon—bicarbonate and carbonate ions—in the ocean. Currents and the formation of sinking dense waters transport the carbon between the surface and deeper layers of the ocean. The marine biota also redistribute carbon: marine organisms grow organic tissue and calcareous shells in surface waters, which, after their death, sink to deeper waters, where they are returned to the dissolved inorganic carbon reservoir by dissolution and microbial decomposition. A small fraction reaches the sea floor, and is incorporated into the sediments.

The extra carbon from anthropogenic emissions has the effect of increasing the atmospheric partial pressure of CO₂, which in turn increases the air-to-sea exchange of CO₂ molecules. In the surface ocean, the

carbonate chemistry quickly accommodates that extra CO₂. As a result, shallow surface ocean waters reach balance with the atmosphere within one or two years. Movement of the carbon from the surface into the middle depths and deeper waters takes longer — between decades and many centuries. On still longer time scales, acidification by the invading CO₂ dissolves carbonate sediments on the sea floor, which further enhances ocean uptake. However, current understanding suggests that, unless substantial ocean circulation changes occur, plankton growth remains roughly unchanged because it is limited mostly by environmental factors, such as nutrients and light, and not by the availability of inorganic carbon it does not contribute significantly to the ocean uptake of anthropogenic CO₂.

On land, vegetation absorbs CO₂ by photosynthesis and converts it into organic matter. A fraction of this carbon is immediately returned to the atmosphere as CO₂ by plant respiration. Plants use the remainder for growth. Dead plant material is incorporated into soils, eventually to be decomposed by microorganisms and then respired back into the atmosphere as CO₂. In addition, carbon in vegetation and soils is also converted back into CO₂ by fires, insects, herbivores, as well as by harvest of plants and subsequent consumption by livestock or humans. Some organic carbon is furthermore carried into the ocean by streams and rivers.

An increase in atmospheric CO₂ stimulates photosynthesis, and thus carbon uptake. In addition, elevated CO₂ concentrations help plants in dry areas to use ground water more efficiently. This in turn increases the biomass in vegetation and soils and so fosters a carbon sink on land. The magnitude of this sink, however, also depends critically on other factors, such as water and nutrient availability.

Coupled carbon-cycle climate models indicate that less carbon is taken up by the ocean and land as the climate warms constituting a positive climate feedback. Many different factors contribute to this effect: warmer seawater, for instance, has a lower CO₂ solubility, so altered chemical carbon reactions result in less oceanic uptake of excess atmospheric CO₂. On land, higher temperatures foster longer seasonal growth periods in temperate and higher latitudes, but also faster respiration of soil carbon.

The time it takes to reach a new carbon distribution balance depends on the transfer times of carbon through the different reservoirs, and takes place over a multitude of time scales. Carbon is first exchanged among the 'fast' carbon reservoirs, such as the atmosphere, surface ocean, land vegetation and soils, over time scales up to a few thousand years. Over longer time scales, very slow secondary geological processes—dissolution of carbonate sediments and sediment burial into the Earth's crust—become important.

FAQ 6.1, Figure 2 illustrates the decay of a large excess amount of CO₂ (5000 PgC, or about 10 times the cumulative CO₂ emitted so far since the beginning of the industrial Era) emitted into the atmosphere, and how it is redistributed among land and the ocean over time. During the first 200 years, the ocean and land take up similar amounts of carbon. On longer time scales, the ocean uptake dominates mainly because of its larger reservoir size (~38,000 PgC) as compared to land (~4000 PgC) and atmosphere (589 PgC prior to the Industrial Era). Because of ocean chemistry the size of the initial input is important: higher emissions imply that a larger fraction of CO₂ will remain in the atmosphere. After 2000 years, the atmosphere will still contain between 15% and 40% of those initial CO₂ emissions. A further reduction by carbonate sediment dissolution, and reactions with igneous rocks, such as silicate weathering and sediment burial, will take anything from tens to hundreds of thousands of years, or even longer.

[INSERT FAQ 6.1, FIGURE 2 HERE]

FAQ 6.1, Figure 2: Decay of a CO₂ excess amount of 5000 PgC emitted at time zero into the atmosphere, and its subsequent redistribution into land and ocean as a function of time, computed by coupled carbon-cycle climate models. The size of the colour bands indicate the carbon uptake by the respective reservoir. The first two panels show the multi-model mean from a model intercomparison project (Joos et al., 2013). The last panel shows the longer term redistribution including ocean dissolution of carbonaceous sediments as computed with an Earth System Model of Intermediate Complexity (after Archer et al., 2009b).

[START FAQ 6.2 HERE]

FAQ 6.2: Could Rapid Release of Methane and Carbon Dioxide from Thawing Permafrost or Ocean Warming Substantially Increase Warming?

Permafrost is permanently frozen ground, mainly found in the high latitudes of the Arctic. Permafrost, including the sub-sea permafrost on the shallow shelves of the Arctic Ocean, contains old organic carbon deposits. Some are relicts from the last glaciation, and hold at least twice the amount of carbon currently present in the atmosphere as carbon dioxide. Should a sizeable fraction of this carbon be released as methane and carbon dioxide, it would increase atmospheric concentrations, which would lead to higher atmospheric temperatures. That in turn would cause yet more methane and carbon dioxide to be released, creating a positive feedback, which would further amplify global warming.

The Arctic domain presently represents a net sink of carbon dioxide—sequestering around $0.4 \pm 0.4 \text{ PgCyr}^{-1}$ in growing vegetation representing about 10% of the current global land sink. It is also a modest source of methane: between 15 and 50 $\text{Tg}(\text{CH}_4) \text{ yr}^{-1}$ are emitted mostly from seasonally unfrozen wetlands corresponding to about 10% of the global wetland methane source. There is no clear evidence yet that thawing contributes significantly to the current global budgets of these two greenhouse gases. However, under sustained Arctic warming, modelling studies and expert judgments indicate with medium agreement that a potential combined release totalling up to 200 PgC as carbon dioxide equivalent could occur by the year 2100.

[INSERT FAQ 6.2, FIGURE 1 HERE]

FAQ 6.2, Figure 1: A simplified graph of current major carbon pools and flows in the Arctic domain, including permafrost on land, continental shelves and ocean (adapted from McGuire et al., 2009; and Tarnocai et al., 2009). $\text{TgC} = 10^{12} \text{ gC}$, and $\text{PgC} = 10^{15} \text{ gC}$.

Permafrost soils on land, and in ocean shelves, contain large pools of organic carbon, which must be thawed and decomposed by microbes before it can be released—mostly as carbon dioxide. Where oxygen is limited, as in waterlogged soils, some microbes also produce methane.

On land, permafrost is overlain by a surface 'active layer', which thaws during summer and forms part of the tundra ecosystem. If spring and summer temperature become warmer on average, the active layer will thicken, making more organic carbon available for microbial decomposition. However, warmer summers would also result in greater uptake of carbon dioxide by Arctic vegetation through photosynthesis. That means the net Arctic carbon balance is a delicate one between enhanced uptake and enhanced release of carbon.

Hydrological conditions during the summer thaw are also important. The melting of bodies of excess ground ice may create standing water conditions in pools and lakes, where lack of oxygen will induce methane production. The complexity of Arctic landscapes under climate warming means we have low confidence in which of these different processes might dominate on a regional scale. Heat diffusion and permafrost melting takes time—in fact, the deeper Arctic permafrost can be seen as a relict of the last glaciation, which is still slowly eroding—so any significant loss of permafrost soil carbon will happen over long time scales.

Given enough oxygen, decomposition of organic matter in soil is accompanied by the release of heat by microbes (similar to compost), which, during summer, might stimulate further permafrost thaw. Depending on carbon and ice content of the permafrost, and the hydrological regime, this mechanism could, under warming, trigger relatively fast local permafrost degradation.

Modelling studies of permafrost dynamics and greenhouse gas emissions indicate a relatively slow positive feedback, on time scales of hundreds of years. Until the year 2100, up to 200 PgC could be released as carbon dioxide, and up to five Pg as methane. Given methane's stronger greenhouse warming potential, that corresponds to a further 100 PgC of equivalent carbon dioxide released until the year 2100. These amounts are similar in magnitude to other biogeochemical feedbacks, e.g., the additional carbon dioxide released by the global warming of terrestrial soils. However, current models do not include the full complexity of Arctic processes that occur when permafrost thaws, such as the formation of lakes and ponds.

Methane hydrates are another form of frozen carbon, occurring in deep permafrost soils, ocean shelves, shelf slopes and deeper ocean bottom sediments. They consist of methane and water molecule clusters, which are only stable in a specific window of low temperatures and high pressures. On land and in the ocean, most of these hydrates originate from marine or terrestrial biogenic carbon, decomposed in the absence of oxygen and trapped in an aquatic environment under suitable temperature-pressure conditions.

Any warming of permafrost soils, ocean waters and sediments and/or changes in pressure could destabilise those hydrates, releasing their methane to the ocean. During larger, more sporadic releases, a fraction of that methane might also be outgassed to the atmosphere. There is a large pool of these hydrates: in the Arctic alone, the amount of methane stored as hydrates could be more than 10 times greater than the methane presently in the global atmosphere.

Like permafrost thawing, liberating hydrates on land is a slow process, taking decades to centuries. The deeper ocean regions and bottom sediments will take still longer—between centuries and millennia to warm enough to destabilise the hydrates within them. Furthermore, methane released in deeper waters has to reach the surface and atmosphere before it can become climatically active, but most is expected to be consumed by microorganisms before it gets there. Only the methane from hydrates in shallow shelves, such as in the Arctic Ocean north of Eastern Siberia, may actually reach the atmosphere to have a climate impact.

Several recent studies have documented locally significant methane emissions over the Arctic Siberian shelf and from Siberian lakes. How much of this methane originates from decomposing organic carbon or from destabilizing hydrates is not known. There is also no evidence available to determine whether these sources have been stimulated by recent regional warming, or whether they have always existed—it may be possible that these methane seepages have been present since the last deglaciation. In any event, these sources make a very small contribution to the global methane budget—less than 5%. This is also confirmed by atmospheric methane concentration observations, which do not show any substantial increases over the Arctic.

However modelling studies and expert judgment indicate that methane and carbon dioxide emissions will increase under Arctic warming, and that they will provide a positive climate feedback. Over centuries, this feedback will be moderate: of a magnitude similar to other climate-terrestrial ecosystem feedbacks. Over millennia and longer, however, carbon dioxide and methane releases from permafrost and shelves/shelf slopes are much more important, because of the large carbon and methane hydrate pools involved.

1 **Tables**

2

3 **Table 6.8:** Global CH₄ budget for the past three decades (in Tg(CH₄) yr⁻¹). The bottom-up estimates for the decade of 2000–2009 are used in the Executive Summary and in Figure
 4 6.2. T-D stands for Top-Down inversions and B-U for Bottom-Up approaches. Only studies covering at least five years of each decade have been used. Reported values correspond
 5 to the mean of the cited references and therefore not always equal (max-min)/2; likewise, ranges [in brackets] represent minimum and maximum values of the cited references. The
 6 sum of sources and sinks from B-U approaches does not automatically balance the atmospheric changes. For B-U studies, individual source types are also presented. For T-D
 7 inversions, the 1980s decade starts in 1984. As some atmospheric inversions did not reference their global sink, balance with the atmosphere and the sum of the sources has been
 8 assumed. One biomass burning estimate (Schultz et al., 2007) excludes biofuels (a). Stratospheric loss for B-U is the sum of the loss by OH radicals, a 10 Tg yr⁻¹ loss due to O¹D
 9 radicals (Neef et al., 2010) and a 20–35% contribution due to Cl radicals²⁴ (Allan et al., 2007).

1 Notes:

2 (a) All units for N₂O fluxes are in TgN (N₂O) yr⁻¹ as in AR4 (not based on 2006 IPCC Guidelines); lower end of range
3 in the natural ocean from Rhee et al. (2009), higher end of the range from Bianchi et al. (2012), Olivier and Janssens-
4 Maenhout (2012); natural soils in line with Stocker et al. (2013).

5 (b) Direct soil emissions and emissions from animal production; calculated following 2006 IPCC Guidelines (Syakila
6 and Kroeze, 2011); Range from AR4. Olivier and Janssens-Maenhout (2012).

7 (c) Following 2006 IPCC Guidelines (Kroeze et al., 2010; Syakila and Kroeze, 2011); Higher end of range from AR4;
8 lower end of range from 1996 IPCC Guidelines (Mosier et al., 1998). Note that a recent studies indicates that IPCC may
9 underestimate emissions from rivers (Beaulieu et al., 2011).

10 (d) Following 2006 IPCC Guidelines (Syakila and Kroeze, 2011).

11 (e) Suntharalingam et al. (2012).

12 (f) Syakila et al. (2010).

13 (g) The stratospheric sink regroups losses via photolysis and reaction with O¹D that account for 90% and 10% of the
14 sink, respectively (Minschwaner et al., 1993). The global magnitude of the stratospheric sink was adjusted in order to be
15 equal to the difference between the total sources and the observed growth rate. This value falls within literature
16 estimates (Volk et al., 1997).

17 (h) Data from Sections 6.1 and 6.3 (see Figures 6.4c). The range on the observed growth rate in this table is given by
18 the 90% confidence interval of figure 6.4c.

1 **Table 6.10:** Comparison of the magnitude of changes in carbon storage (PgC) by land and ocean over different timescales. These changes are shown as approximate numbers to
 2 allow a comparison across timescales. For more details see the indicated chapter section. An indication, where known, of what causes these changes (climate, CO₂, land use change)
 3 is also given with an indication of the sign: ‘+’ means that an increase in CO₂ or global-mean temperature is associated with an increase in carbon storage (positive β or γ), and a ‘-’
 4 means an increase in CO₂ or global-mean temperature is associated with a decrease in carbon storage (negative β or γ). The processes which operate to drive these changes can vary
 5 markedly from seasonal phenology of vegetation to long-term changes in ice sheet cover or ocean circulation. Some of these processes are ‘reversible’ in the context that they can
 6 increase and decrease cyclically, whereas some are ‘irreversible’ in the context that changes in one sense might be much longer than in the opposite direction.

Time Period	Duration	Land		Ocean		Section	
		Climate	CO ₂	Land Use	Climate		CO ₂
Seasonal Cycle	Weeks-Months	3–8 ^a +			2	1 +	6.3.2.5.1

7 Notes:

8 (a) Dominated by northern mid- to high-latitudes.

9 (b) Dominated by the tropics.

10 (c) ‘Residual terrestrial sink’, Table 6.1.

11 (d) Varies widely according to scenario. Climate effect estimated separately for RCP4.5 as –157 PgC (combined land and ocean), but not for other scenarios.

12 (e) Future scenarios may increase or decrease area of anthropogenic land use.

13 (f) Little Ice Age, 1500–1750.

14 (g) Shown here are two competing drivers of Holocene ocean carbon changes: carbonate accumulation on shelves (coral growth) and carbonate compensation to pre-Holocene
 15 changes. These are discussed in Section 6.2.2.

16 (h) Defined as positive if increasing from LGM to present, negative if decreasing.

17 (i) Idealised simulations with models to assess the response of the global carbon cycle to a sudden release of 100 PgC.

18

Direct air capture	Chemical	Geological or ocean /Inorganic	Effectively permanent for geologic, centuries for ocean	No determined limit	Keith et al. (2006), Shaffer (2010)	Not known

3 Notes:

4 * Physical potential does not account for economic or environmental constraints of CDR methods, for example the value of the physical potential for afforestation and reforestation
 5 does not consider the conflicts with land needed for agricultural production. Potentials for BECCS and biochar are highly speculative.

1 [‡] If 2.5 tC yr⁻¹ per hectare can be harvested on a sustainable basis (Kraxner et al., 2003) on ~4% (~500 million hectares, about one tenth of global agricultural land area) of global
2 land (13.4 billion hectares) for BECCS, approximately 1.25 PgC yr⁻¹ could be removed or about 125 PgC in this century. Future CO₂ concentration pathways, especially RCP2.6 and
3 RCP4.5 include some CO₂ removal by BECCS (Chapter 6 of AR5 WGIII) and hence the potentials estimated here cannot add on to existing model results (6.4).

Figures

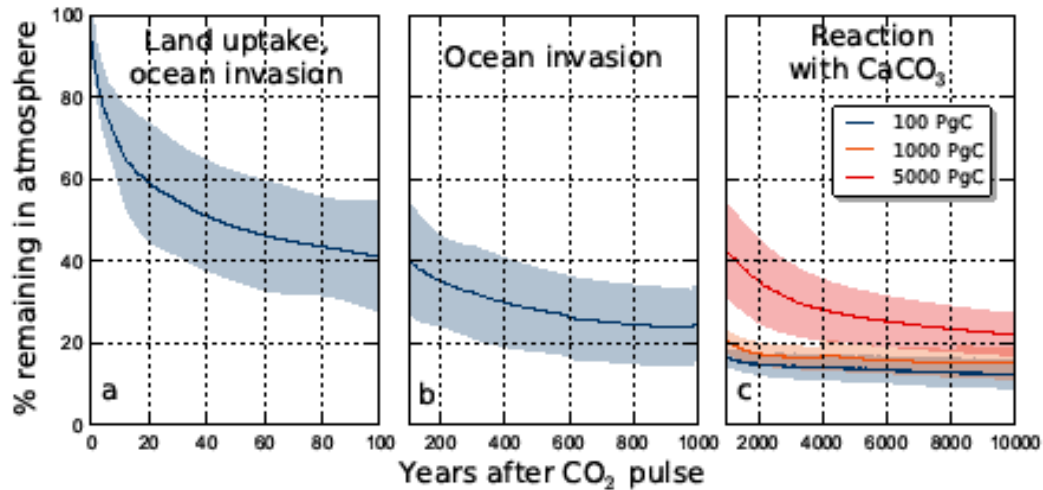

Figure 6.1: Simplified schematic of the global carbon cycle. Numbers represent reservoir mass, also called ‘carbon stocks’ in PgC ($1 \text{ PgC} = 10^{15} \text{ gC}$) and annual carbon exchange fluxes (in PgC yr^{-1}). Black numbers and arrows indicate reservoir mass and exchange fluxes estimated for the time prior to the Industrial Era, circa 1750 (see Section 6.1.1.1 for references). Fossil fuel reserves are from GEA (2006) and are consistent with numbers used by IPCC WGIII for future scenarios. The sediment storage is a sum of 150 PgC of the organic carbon in the mixed layer (Emerson and Hedges, 1988) and 1,600 PgC of the deep-sea CaCO_3 sediments available to neutralize fossil fuel CO_2 (Archer et al., 1998). Red arrows and numbers indicate annual “anthropogenic” fluxes averaged over the 2000–2009 time period. These fluxes are a perturbation of the carbon cycle during Industrial Era post 1750. These fluxes (red arrows) are: *Fossil fuel and cement emissions of CO_2* (6.3.1), *Net land use change* (6.3.2), and the *Average atmospheric increase of CO_2* in the atmosphere also called ‘ CO_2 growth rate’ (6.3). The uptake of anthropogenic CO_2 by the ocean and by terrestrial ecosystems, often called ‘carbon sinks’ are the red arrows part of *Net land flux* and *Net ocean flux*. Red numbers in the reservoirs denote cumulative changes of anthropogenic carbon over the Industrial Period 1750–2011 (column 2 in Table 6.1). By convention, a positive cumulative change means that a reservoir has gained carbon since 1750. The cumulative change of anthropogenic carbon in the terrestrial reservoir is the sum of carbon cumulatively lost through land use change and carbon accumulated since 1750 in other ecosystems (Table 6.1). Note that the mass balance of the two ocean carbon stocks *Surface ocean* and *Intermediate and deep ocean* includes a yearly accumulation of anthropogenic carbon (not shown). Uncertainties are reported as 90% confidence intervals. Emission estimates and land and ocean sinks (in red) are from Table 6.1 in Section 6.3. The change of gross terrestrial fluxes (red arrows of *Gross Photosynthesis* and *Total Respiration and Fires*) has been estimated from CMIP5 model results (Section 6.4). The change in air-sea exchange fluxes (red arrows of ocean atmosphere gas exchange) have been estimated from the difference in atmospheric partial pressure of CO_2 since 1750 (Sarmiento and Gruber, 2006). Individual gross fluxes and their changes since the beginning of the Industrial Era have typical uncertainties of more than 20%, while their differences (*Net land flux* and *Net ocean flux* in the figure) are determined from independent measurements with a much higher accuracy (see Section 6.3). Therefore, to achieve an overall balance, the values of the more uncertain gross fluxes have been adjusted so that their difference matches the *Net land flux* and *Net ocean flux* estimates. Fluxes from volcanic eruptions, rock weathering (silicates and carbonates weathering reactions resulting into a small uptake of atmospheric CO_2), export of carbon from soils to rivers, burial of carbon in freshwater lakes and reservoirs and transport of carbon by rivers to the

ocean are all assumed to be pre-industrial fluxes, that is unchanged during 1750–2011. Some recent studies (Section 6.3) indicate that this assumption is likely not verified, but global estimates of the Industrial Era perturbation of all these fluxes was not available from peer-reviewed literature. The atmospheric inventories have been calculated using a conversion factor of 2.12 PgC/ppm (Prather et al., 2012).

Box 6.1, Figure 1: A percentage of emitted CO₂ remaining in the atmosphere in response to an idealized instantaneous CO₂ pulse emitted to the atmosphere in year 0 as calculated by a range of coupled climate-carbon cycle models. (Left and middle panels, **a** and **b**) Multi-model mean (blue line) and the uncertainty interval (± 2 standard deviations, shading) simulated during 1,000 years following the instantaneous pulse of 100 PgC (Joos et al., 2013). (Right panel, **c**) A mean of models with oceanic and terrestrial carbon components and a maximum range of these models (shading) for instantaneous CO₂ pulse in year 0 of 100 PgC (blue), 1,000 PgC (orange) and 5,000 PgC (red line) on a time interval up to ten thousand years (Archer et al., 2009b). Text at the top of the panels indicates the dominant processes that remove the excess of CO₂ emitted in the atmosphere on the successive timescales. Note that higher pulse of CO₂ emissions leads to higher remaining CO₂ fraction (Section 6.3.2.4) due to reduced carbonate buffer capacity of the ocean and positive climate-carbon cycle feedback (Section 6.3.2.6.6).

Figure 6.2: Schematic of the global cycle of CH₄. Numbers represent annual fluxes in Tg(CH₄) yr⁻¹ estimated for the time period 2000–2009 and CH₄ reservoirs in Tg(CH₄): the atmosphere, and three geological reservoirs (hydrates on land and in the ocean floor, and gas reserves) (see Section 6.3.3). Black arrows denote ‘natural’ fluxes, i.e., fluxes that are not directly caused by human activities since 1750, red arrows anthropogenic fluxes, and the light brown arrow denotes a combined natural+anthropogenic flux. Note that human activities (e.g., land use) may have modified indirectly the global magnitude of the natural fluxes (6.3.3). Ranges represent minimum and maximum values from cited references as given in Table 6.8 in Section 6.3.3. Gas reserves are from GEA (2006) and are consistent with numbers used by IPCC WG III for future scenarios. Hydrate reservoir sizes are from Archer et al., 2007. The atmospheric inventories have been calculated using a conversion factor of 2.75 TgCH₄/ppb (Prather et al., 2012). The assumed preindustrial annual mean globally averaged CH₄ concentration was 722 ± 25 ppb taking the average of the Antarctic Law Dome ice core observations (MacFarling-Meure et al., 2006) and the measurements from the GRIP ice core in Greenland (Blunier et al., 1995; see also Chapter 2, Table 2.1). The atmospheric inventory in the year 2011 is based on an annual globally averaged CH₄ concentration of 1803 ± 4 ppb in the year 2011 (see Chapter 2, Table 2.1). It is the sum of the atmospheric increase between 1750 and 2011 (in red) and of the pre-industrial inventory (in black). The *average atmospheric increase* each year, also called growth rate, is based on a measured concentration increase of 2.2 ppb yr⁻¹ during the time period 2000–2009 (Dlugokencky et al., 2011).

Figure 6.3: Atmospheric concentration of CO₂, oxygen, ¹³C/¹²C stable isotope ratio in CO₂, CH₄ and N₂O recorded over the last decades at representative stations in the northern (solid lines) and the southern (dashed lines) hemisphere. **(a)** CO₂ from Mauna Loa (MLO) northern hemisphere and South Pole southern hemisphere (SPO) atmospheric stations (Keeling et al., 2005), **(b)** O₂ from Alert northern hemisphere (ALT) and Cape Grim southern hemisphere (CGO) stations (<http://scrippso2.ucsd.edu/> right axes, expressed relative to a reference standard value), **(c)** ¹³C/¹²C: Mauna Loa, South Pole (Keeling et al., 2005), **(d)** CH₄ from Mauna Loa and South Pole stations (Dlugokencky et al., 2012), **(e)** N₂O from Mace-Head northern hemisphere (MHD) and Cape Grim stations (Prinn et al., 2000).

Figure 6.4: Schematic of the global nitrogen cycle. The **upper panel (a)** shows the natural and anthropogenic processes that create reactive nitrogen and the corresponding rates of denitrification that convert reactive nitrogen back to N_2 . The **middle panel (b)** shows the flows of the reactive nitrogen species NO_y and NH_x . The **bottom panel (c)** The stratospheric sink of N_2O is the sum of losses via photolysis and reaction with O^1D (Table 6.9). The global magnitude of this sink is adjusted here in order to be equal to the difference between the total sources and the observed growth rate. This value falls within literature estimates (Volk et al., 1997). The atmospheric inventories have been calculated using a conversion factor of 4.79 TgN (N_2O) / ppb (Prather et al., 2012).

Box 6.2, Figure 1: Anthropogenic reactive nitrogen (Nr) creation rates (in TgN yr⁻¹) from fossil fuel burning (orange line), cultivation-induced biological nitrogen fixation (blue line), Haber-Bosch process (green line), and total creation (red line). Source: Galloway et al. (2003), Galloway et al. (2008). Note that updates are given in Table 6.9. The only one with significant changes in the more recent literature is cultivation-induced BNF which Herridge et al. (2008) estimated to be 60 Tg N yr⁻¹. The data are only reported since 1850, as no published estimate is available since 1750.

Box 6.2, Figure 2: Illustration of the nitrogen cascade showing the sequential effects that a single atom of nitrogen in its various molecular forms can have in various reservoirs after it has been converted from nonreactive N_2 to a reactive form by energy and food production (orange arrows). Once created the reactive nitrogen has the potential to continue to contribute to impacts until it is converted back to N_2 . The small black circle indicates that there is the potential for denitrification to occur within that reservoir. Abbreviations: NH_3 , ammonia; NH_x , ammonia plus ammonium; NO_3^- , nitrate; NO_x , nitrogen oxides; NO_y , NO_x and other combinations of nitrogen and oxygen (except N_2O); N_2O , nitrous oxide (adopted with permission from the GEO Yearbook 2003, United Nations Environmental Programme (UNEP), 2004 which was based on Galloway et al., 2003).

Figure 6.5: Mechanisms contributing to carbon dioxide concentrations changes from LGM to late Holocene (top) and from early/mid Holocene (7 ka) to late Holocene (bottom). Filled black circles represent individual model-based estimates for individual ocean, land, geological or human mechanisms. Solid color bars represent expert judgment (to the nearest 5 ppm) rather than a formal statistical average. References for the different model results used for explaining CO₂ changes from LGM to late Holocene are as per (Kohfeld and Ridgwell, 2009) with excluded model projections in grey. References for the different model results used for explaining CO₂ changes during the Holocene are: Joos et al. (2004), Brovkin et al. (2008), Kleinen et al. (2010), Broecker et al. (1999), Ridgwell et al. (2003), Brovkin et al. (2002), Schurgers et al. (2006), Yu (2011), (Kleinen et al., 2012), Ruddiman (2003), Ruddiman (2007), Strassmann et al. (2008), Olofsson and Hickler (2008), Pongratz et al. (2009), Kaplan et al. (2011), Lemmen (2009), Stocker et al. (2011), Roth and Joos (2012). Confidence levels for each mechanism are indicated in the left column — H for high confidence, M for medium confidence and L for low confidence.

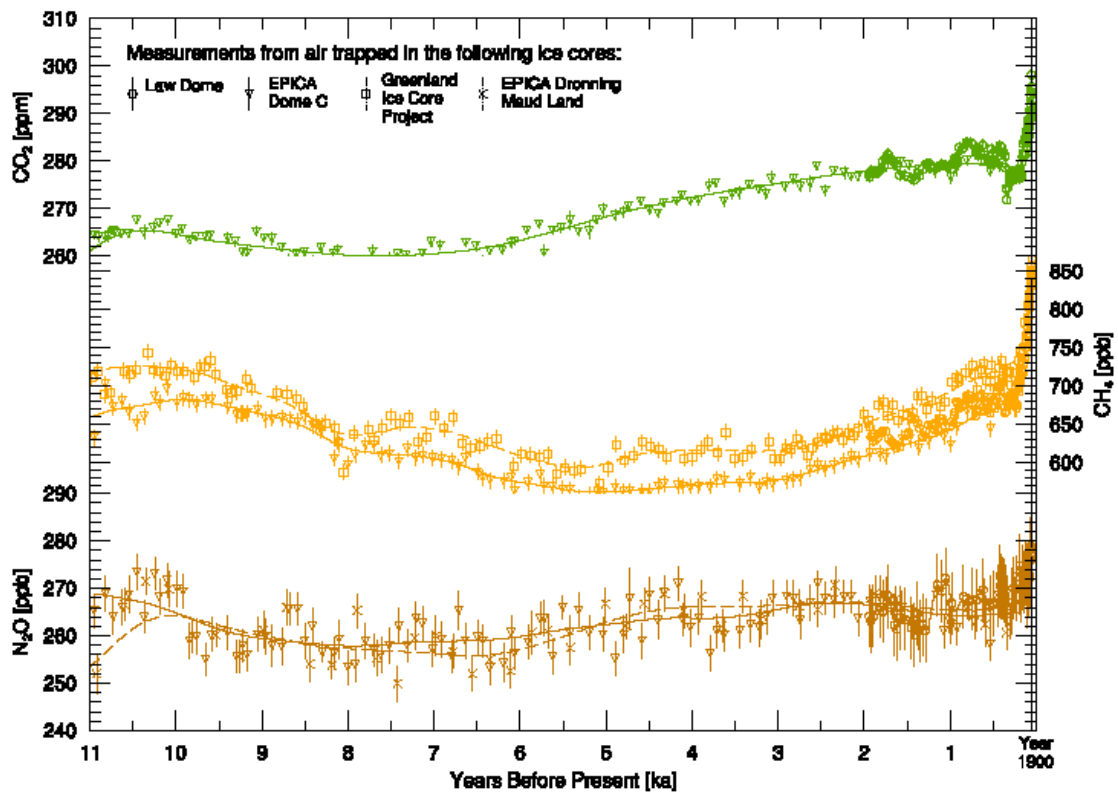

Figure 6.6: Variations of CO₂, CH₄, and N₂O concentrations during the Holocene. The data are for Antarctic ice cores: EPICA Dome C (Flückiger et al., 2002; Monnin et al., 2004), triangles; EPICA Dronning Maud Land (Schilt et al., 2010b), crosses; Law Dome (MacFarling-Meure et al., 2006), circles; and for Greenland ice core GRIP (Blunier et al., 1995), squares. Lines correspond to spline fits.

Figure 6.7: Variations of CO₂, CH₄, and N₂O during 900–1900 from ice cores. The data are for Antarctic ice cores: Law Dome (Etheridge et al., 1996; MacFarling-Meure et al., 2006), circles; West Antarctic Ice Sheet (Mitchell et al., 2011; Ahn et al., 2012), triangles; Dronning Maud Land (Siegenthaler et al., 2005a), squares. Lines are spline fits to individual measurements.

Figure 6.8: Annual anthropogenic CO₂ emissions and their partitioning among the atmosphere, land and ocean (PgC yr⁻¹) from 1750 to 2011. (Top) Fossil fuel and cement CO₂ emissions by category, estimated by the Carbon Dioxide Information Analysis Center (CDIAC) based on UN energy statistics for fossil fuel combustion and US Geological Survey for cement production (Boden et al., 2011). (Bottom) Fossil fuel and cement CO₂ emissions as above. CO₂ emissions from net land use change, mainly deforestation, are based on land cover change data and estimated for 1750–1850 from the average of four models (Pongratz et al., 2009; Shevliakova et al., 2009; van Minnen et al., 2009; Zaehle et al., 2011) before 1850 and from Houghton et al. (2012) after 1850 (see Table 6.2). The atmospheric CO₂ growth rate (term in light blue “atmosphere from measurements” in the figure) prior to 1959 is based on a spline fit to ice core observations (Neftel et al., 1982; Friedli et al., 1986; Etheridge et al., 1996) and a synthesis of atmospheric measurements from 1959 (Ballantyne et al., 2012). The fit to ice core observations does not capture the large interannual variability in atmospheric CO₂ and is represented with a dashed line. The ocean CO₂ sink prior to 1960 (term in dark blue “ocean from indirect observations and models” in the figure) is from Khatiwala et al. (2009) and from a combination of models and observations from 1960 from (Le Quéré et al., 2013). The residual terrestrial sink (term in green in the figure) is computed from the residual of the other terms. The emissions and their partitioning only include the fluxes that have changed since 1750, and not the natural CO₂ fluxes (e.g., atmospheric CO₂ uptake from weathering, outgassing of CO₂ from lakes and rivers, and outgassing of CO₂ by the ocean from carbon delivered by rivers; see Figure 6.1) between the atmosphere, land and ocean reservoirs that existed before that time and still exist today. The uncertainties in the various terms are discussed in the text and reported in Table 6.1 for decadal mean values.

Figure 6.9: Interannual surface CO₂ flux anomalies from inversions of the TRANSCOM project for the period 1981–2010 (Peylin et al., 2013). The ensemble of inversion results contains up to 17 atmospheric inversion models. The orange bars in the bottom panel indicate the number of available inversion models for each time period. The ensemble mean is bounded by the 1 sigma inter-model spread in ocean-atmosphere (blue) and land-atmosphere (green) CO₂ fluxes (PgC yr⁻¹) grouped into large latitude bands, and the global. For each flux and each region, the CO₂ flux anomalies were obtained by subtracting the long-term mean flux from each inversion and removing the seasonal signal. Grey shaded regions indicate El Niño episodes, and the black bars indicate the cooling period following the Mt. Pinatubo eruption, during which the growth rate of CO₂ remained low. A positive flux means a larger than normal source of CO₂ to the atmosphere (or a smaller CO₂ sink).

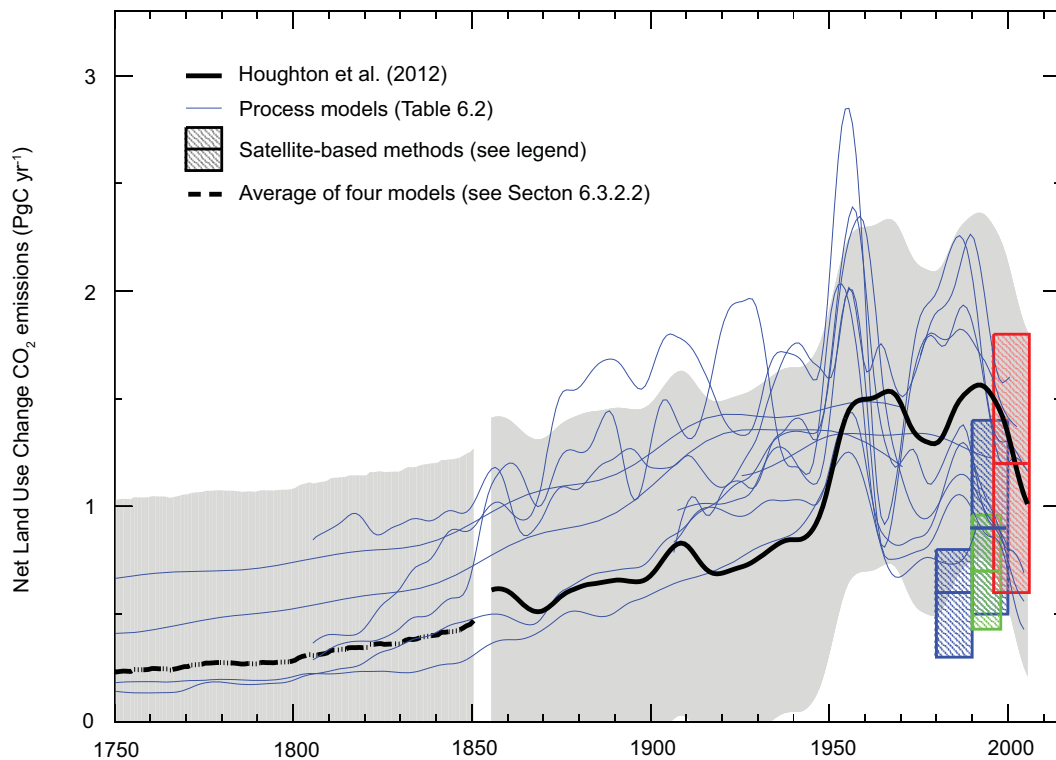

Figure 6.10: Net land use change CO₂ emissions (PgC yr⁻¹). All methods are based on land cover change data (see Table 6.2) and are smoothed with a 10 year filter to remove interannual variability. The bookkeeping estimate of Houghton et al. (2012) (thick black over 1850–2011) and the average of four process models (dash black) over 1750–1850 (see 6.3.2.2) are used in Table 6.1. The process model results for net land use change CO₂ emissions from Table 6.2 are shown in blue. Satellite-based methods are available for the tropics only, from (red) van der Werf et al. (2010), (blue) DeFries et al. (2002), and (green) Achard et al. (2004). Note that the definitions of land use change fluxes vary between models (Table 6.2).

Figure 6.11: Atmospheric CO₂, CH₄, and N₂O concentrations history over the industrial era (right hand side panels) and from the year 0 to the year 1750 (left hand side panels), determined from air enclosed in ice cores and firm air (color symbols) and from direct atmospheric measurements (blue lines, measurements from the Cape Grim observatory) (MacFarling-Meure et al., 2006).

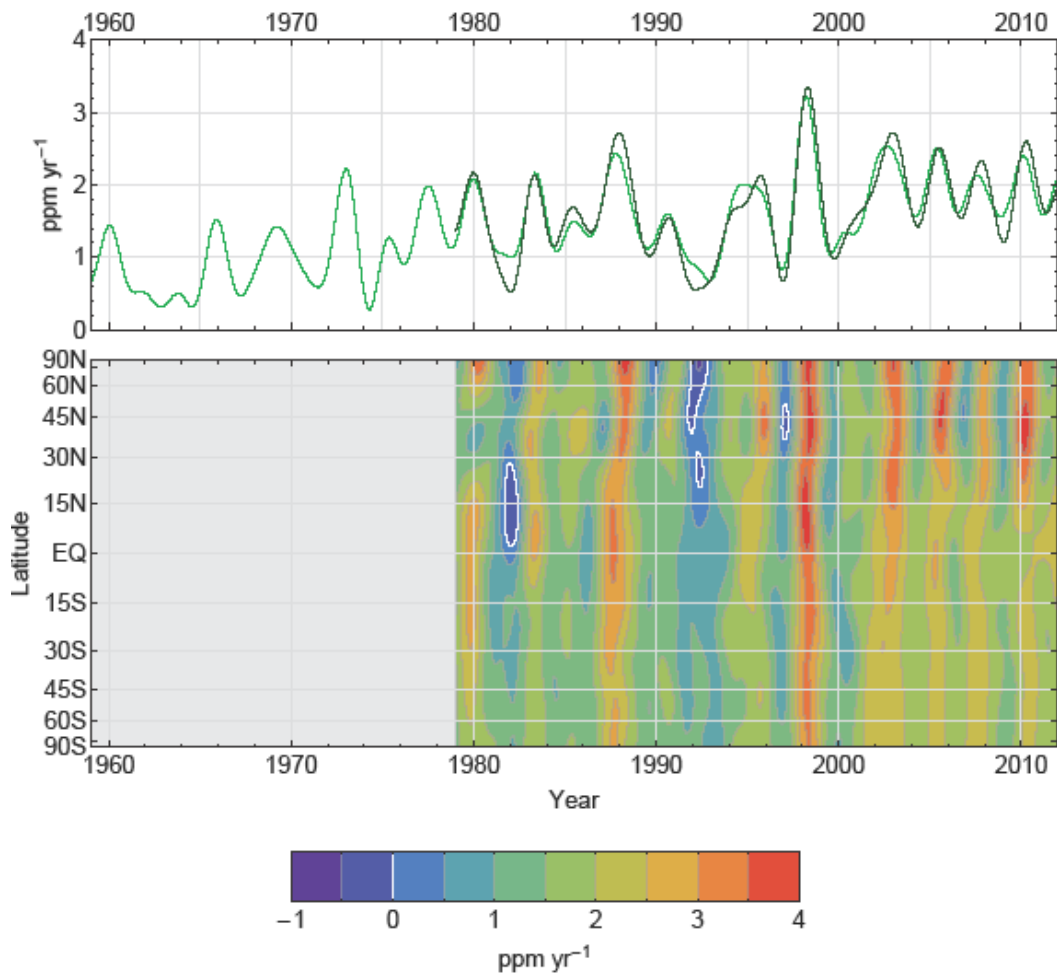

Figure 6.12: (Top) Global average atmospheric CO₂ growth rate, computed from the observations of the SIO network (light green line, Keeling et al., (2005), updated) and from the marine boundary layer air reference measurements of the NOAA-GMD network (dark green line; Conway et al., 1994; Dlugokencky and Tans, 2013). (Bottom) Atmospheric growth rate of CO₂ as a function of latitude determined from the NOAA-ESRL network, representative of stations located in the marine boundary layer at each given latitude (Masarie and Tans, 1995; Dlugokencky and Tans, 2013). Sufficient observations are available only since 1979.

Figure 6.13: Blue points: Annually averaged CO₂ concentration difference between the station Mauna Loa in the northern hemisphere and the station South Pole in the southern hemisphere (vertical axis; Keeling et al., 2005, updated) versus the difference in fossil fuel combustion CO₂ emissions between the hemispheres (Boden et al., 2011). Dark red dashed line: regression line fitted to the data points.

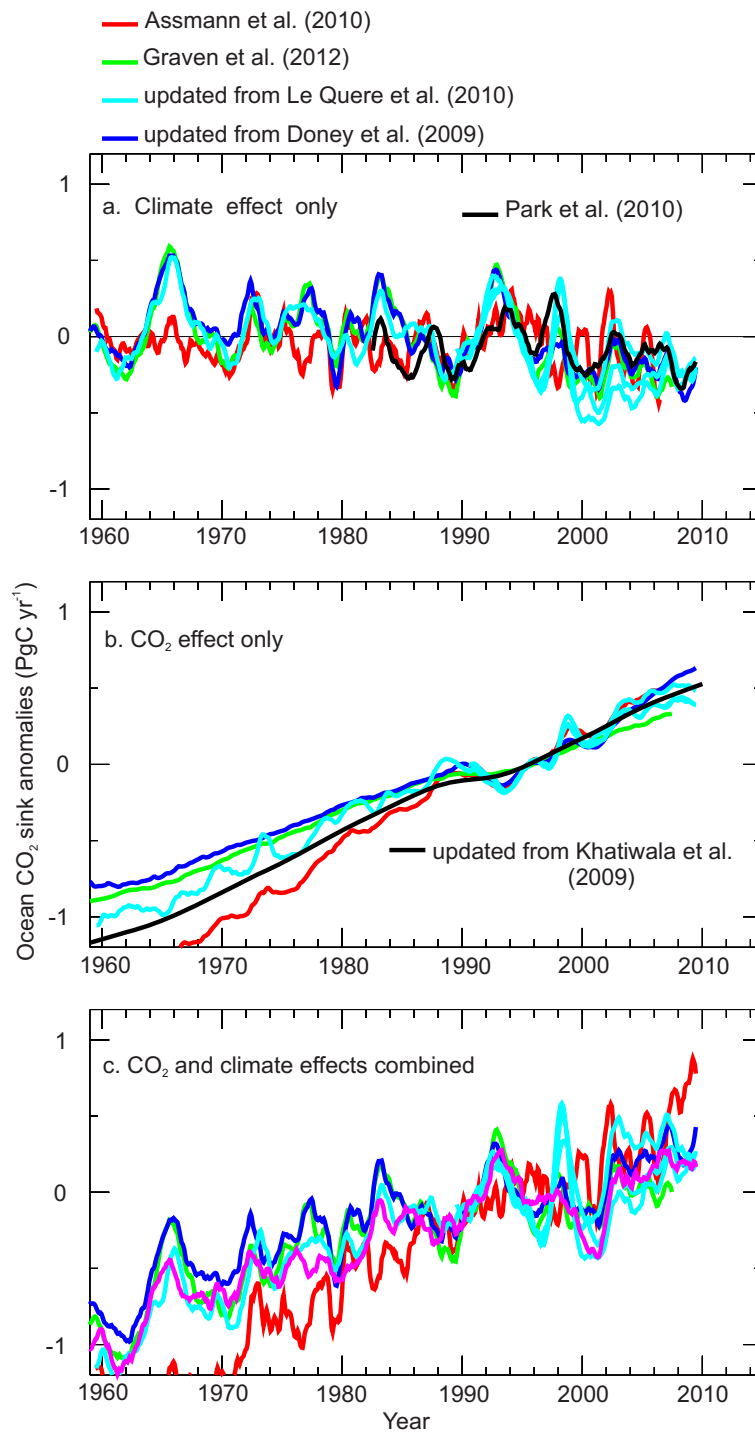

Figure 6.14: Anomalies in the ocean CO₂ ocean-to-atmosphere flux in response to: (a) changes in climate, (b) increasing atmospheric CO₂, and (c) the combined effects of increasing CO₂ and changes in climate (PgC yr⁻¹). All estimates are shown as anomalies with respect to the 1990–2000 averages. Estimates are updates from ocean models (in colours) and from indirect methods based on observations (Khatiwala et al., 2009; Park et al., 2010). A negative ocean-to-atmosphere flux represents a sink of CO₂, as in Table 6.1.

Figure 6.15: (Top) Bar plots showing decadal average CO₂ fluxes for 11 land regions (1) as estimated by 10 different atmospheric CO₂ inversions for the 1990s (yellow) and 2000s (red) (Peylin et al., 2013; data source: <http://transcom.lscce.ipsl.fr/>), and (2) as simulated by 10 dynamic vegetation models (DGVMs) for the 1990s (green) and 2000s (light green) (Piao et al., 2013; data source: <http://www-lscedods.cea.fr/invsat/RECCAP/>). The divisions of land regions are shown in the map. (Bottom) Bar plots showing decadal average CO₂ fluxes for 11 ocean regions (1) as estimated by 10 different atmospheric CO₂ inversions for the 1990s (yellow) and 2000s (red) (data source: <http://transcom.lscce.ipsl.fr/>), (2) inversion of contemporary interior ocean carbon measurements using 10 ocean transport models (dark blue) (Gruber et al., 2009), and (3) surface ocean pCO₂ measurements based air-sea exchange climatology (Takahashi et al., 2009). The divisions of 11 ocean regions are shown in the map.

Figure 6.16: Time series for the residual terrestrial CO₂ land-to-atmosphere flux (PgC yr⁻¹). The black line and gray shading represent the estimated value and its uncertainty from Table 6.1, which is calculated from the difference between emissions from fossil fuel and land use change plus emissions from net land use change, minus the atmospheric growth rate and the ocean sink. The process models from Table 6.7 are shown in thin green, and their average in thick green. A negative land-to-atmosphere flux represents a sink of CO₂. The definition of the land-to-atmosphere flux simulated by the models is close to but not identical to the terrestrial CO₂ sink from Table 6.1 (see Table 6.7).

Figure 6.17: The response of interannual land CO₂ flux anomaly to per 1°C interannual temperature anomaly and per 100 mm interannual precipitation anomaly during 1980–2009. Black circle show climate sensitivity of land CO₂ sink estimated from the residual land sink (see Figure 6.15 and Table 6.1), which is the sum of fossil fuel and cement emissions and land use change emissions minus the sum of observed atmospheric CO₂ growth rate and modeled ocean sink (Le Quéré et al., 2009; Friedlingstein and Prentice, 2010). Colored circles show land CO₂ sink estimated by 10 process-based terrestrial carbon cycle models (CLM4C, CLM4CN, HYLAND, LPJ, LPJ-GUESS, OCN, ORCHIDEE, SDGVM, TRIFFID and VEGAS). Error bars show standard error of the sensitivity estimates. Dashed error bars indicate the estimated sensitivity by the regression approach are statistically insignificant ($P > 0.05$). Grey area denoted the area bounded by the estimated climate sensitivity of the residual land sink \pm the standard error of the estimated climate sensitivity of the residual land sink. The sensitivity of land CO₂ sink interannual variations to interannual variations of temperature (or precipitation) is estimated as the regression coefficient of temperature (or precipitation) in a multiple regression of detrended anomaly of land CO₂ sink against detrended anomaly of annual mean temperature and annual precipitation.

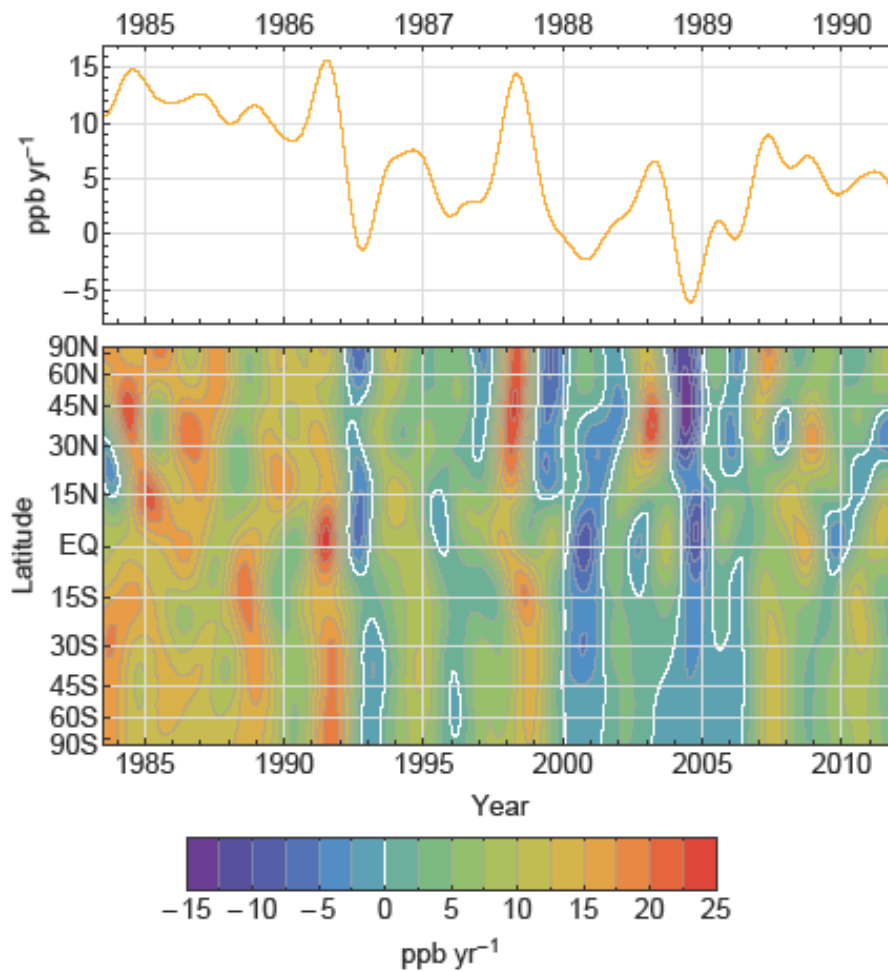

Figure 6.18: Upper panel: Globally averaged growth rate of atmospheric CH₄ in ppb yr⁻¹ determined from the NOAA/ESRL network, representative for the marine boundary layer. Lower panel: Atmospheric growth rate of CH₄ as a function of latitude (Masarie and Tans, 1995; Dlugokencky and Tans, 2013).

Figure 6.19: Upper panel: Globally averaged growth rate of atmospheric N₂O in ppb yr⁻¹ representative for the marine boundary layer. Lower panel: Atmospheric growth rate of N₂O as a function of latitude. Sufficient observations are only available since the year 2002. Observations from the NOAA/ESRL network (Masarie and Tans, 1995; Dlugokencky and Tans, 2013).

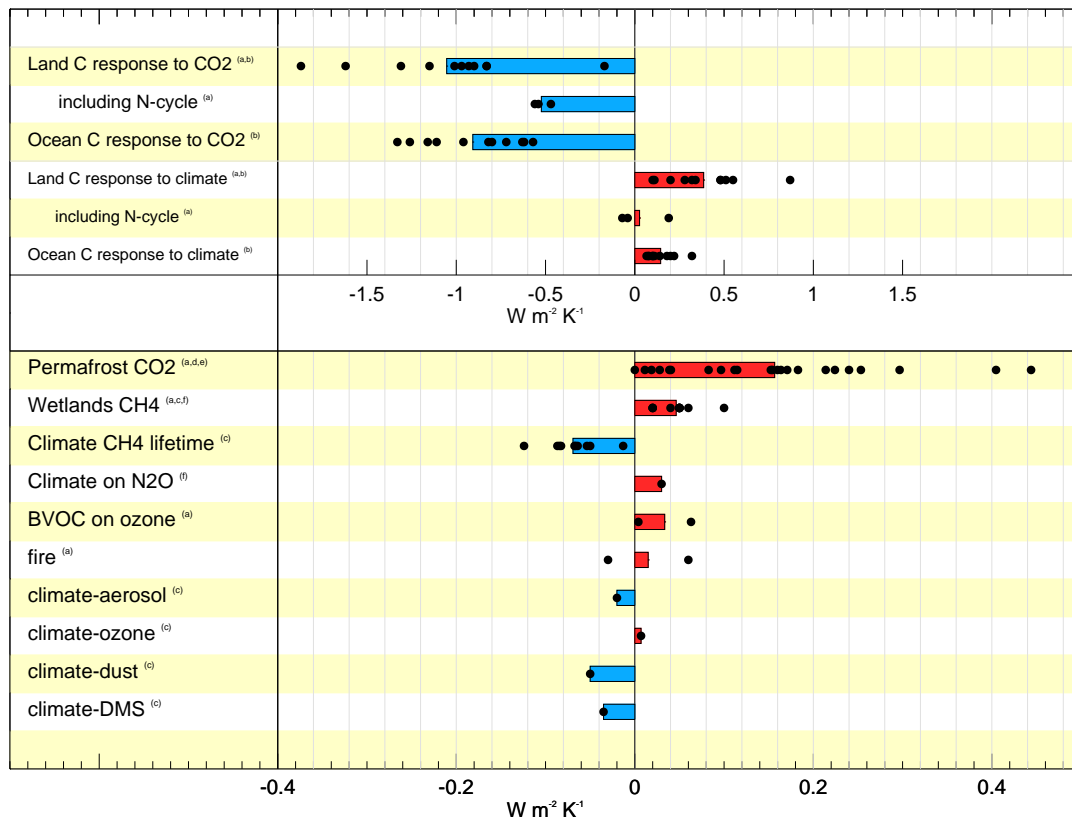

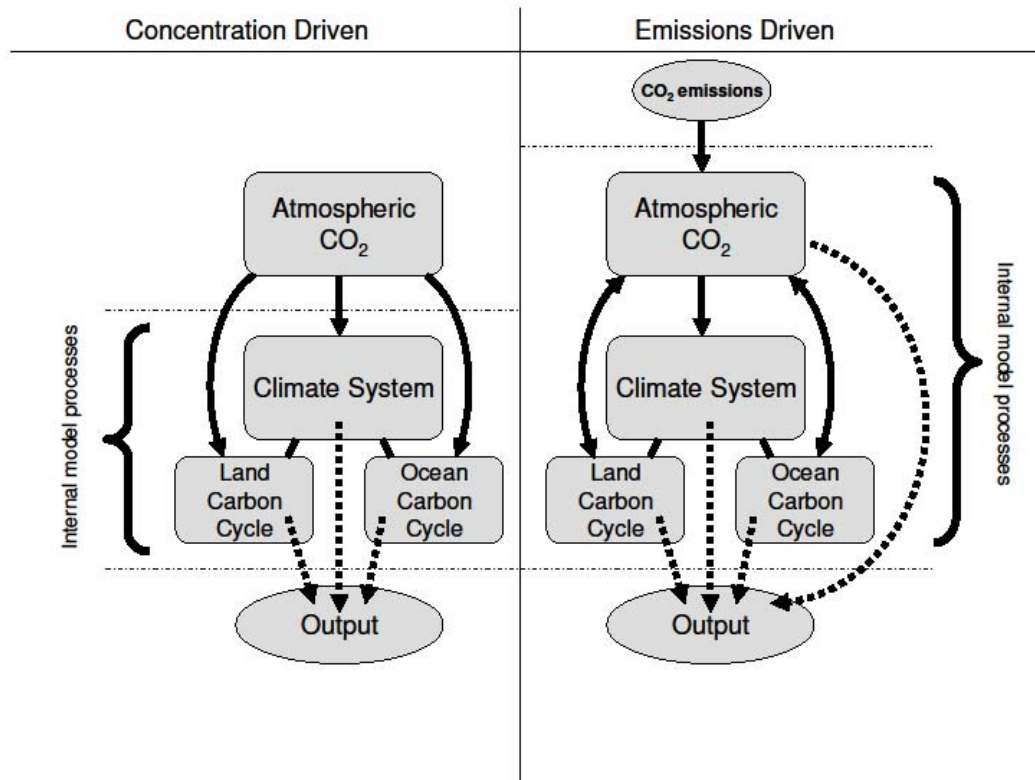

Figure 6.20: A synthesis of the magnitude of biogeochemical feedbacks on climate. Gregory et al. (2009) proposed a framework for expressing non-climate feedbacks in common units ($W m^{-2} K^{-1}$) with physical feedbacks, and Arneth et al. (2010) extended this beyond carbon cycle feedbacks to other terrestrial biogeochemical feedbacks. The figure shows the results compiled by Arneth et al. (2010), with ocean carbon feedbacks from the C4MIP coupled climate-carbon models used for AR4 also added. Some further biogeochemical feedbacks are also shown but this list is not exhaustive. Black dots represent single estimates, and coloured bars denote the simple mean of the dots with no weighting or assessment being made to likelihood of any single estimate. There is *low confidence* in the magnitude of the feedbacks in the lower portion of the figure, especially for those with few, or only one, dot. The role of nitrogen limitation on terrestrial carbon sinks is also shown — this is not a separate feedback, but rather a modulation to the climate-carbon and concentration-carbon feedbacks. These feedback metrics are also likely to be state or scenario dependent and so cannot always be compared like-for-like (see Section 6.4.2.2). Results have been compiled from (a) Arneth et al. (2010), (b) Friedlingstein et al. (2006), (c) HadGEM2-ES (Collins et al., 2011) simulations, (d) Burke et al. (2012), (e) von Deimling et al. (2012), (f) Stocker et al. (2013). Note the different x-axis scale for the lower portion of the figure.

Box 6.4, Figure 1: Schematic representation of carbon cycle numerical experimental design. Concentration-driven (left hand side) and emissions-driven (right hand side) simulation experiments make use of the same ESM models, but configured differently. Concentration-driven simulations prescribe atmospheric CO₂ as a pre-defined input to the climate and carbon cycle model components, but their output does not affect the CO₂. Compatible emissions can be calculated from the output of the concentration driven simulations. Emissions-driven simulations prescribe CO₂ emissions as the input and atmospheric CO₂ is an internally calculated element of the Earth system model.

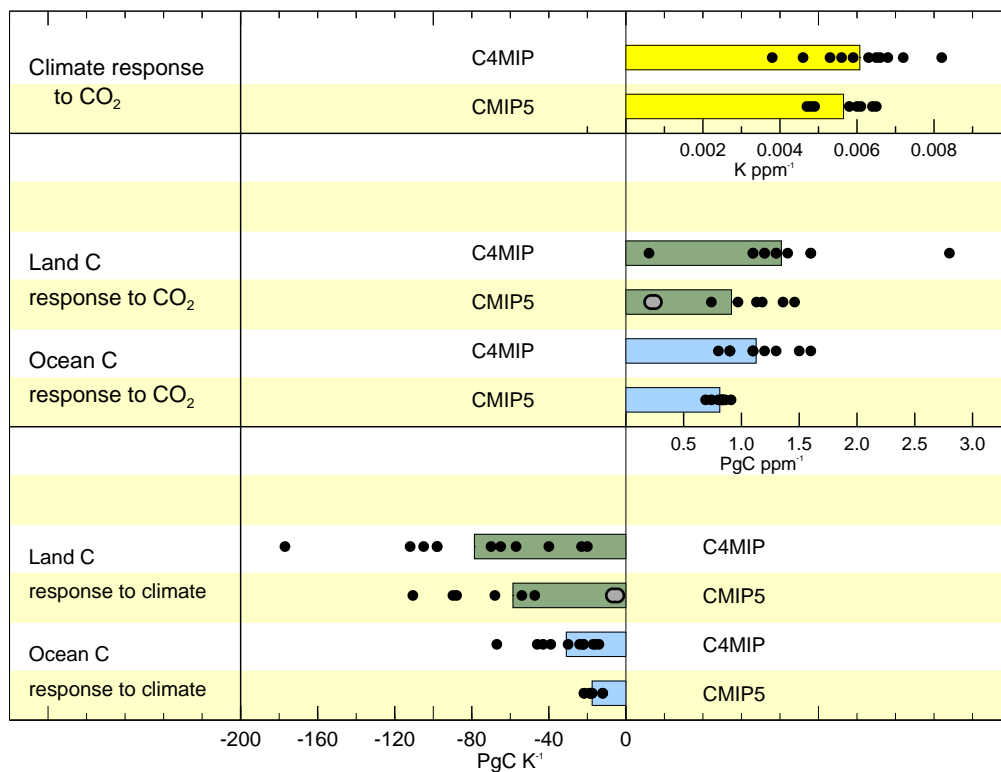

Figure 6.21: Comparison of carbon cycle feedback metrics between the C4MIP ensemble of 7 GCMs and 4 EMICs under the SRES-A2 scenario (Friedlingstein et al., 2006) and the 8 CMIP5 models (Arora et al., 2013) under the 140-year 1% CO₂ increase per year scenario. Black dots represent a single model simulation and coloured bars the mean of the multi-model results, grey dots are used for models with a coupled terrestrial nitrogen cycle. The comparison with C4MIP is for context, but these metrics are known to be variable across different scenarios and rates of change (see Section 6.4.2.2). Some of the CMIP5 models are derived from models that contributed to C4MIP and some are new to this analysis. Table 6.11 lists the main attributes of each CMIP5 model used in this analysis. The SRES A2 scenario is closer in rate of change to a 0.5% yr⁻¹ scenario and as such it should be expected that the CMIP5 γ terms are comparable, but the β terms are likely to be around 20% smaller for CMIP5 than for C4MIP due to lags in the ability of the land and ocean to respond to higher rates of CO₂ increase (Gregory et al., 2009). This dependence on scenario (Section 6.4.2.2) reduces confidence in any quantitative statements of how CMIP5 carbon cycle feedbacks differ from C4MIP. CMIP5 Models used: MPI-ESM-LR, BCC-CSM1, HadGEM2-ES, IPSL-CM5A-LR, CanESM2, NorESM-ME, CESM1-BGC, MIROC-ESM.

a. Regional carbon-concentration feedback

b. Regional carbon-climate feedback

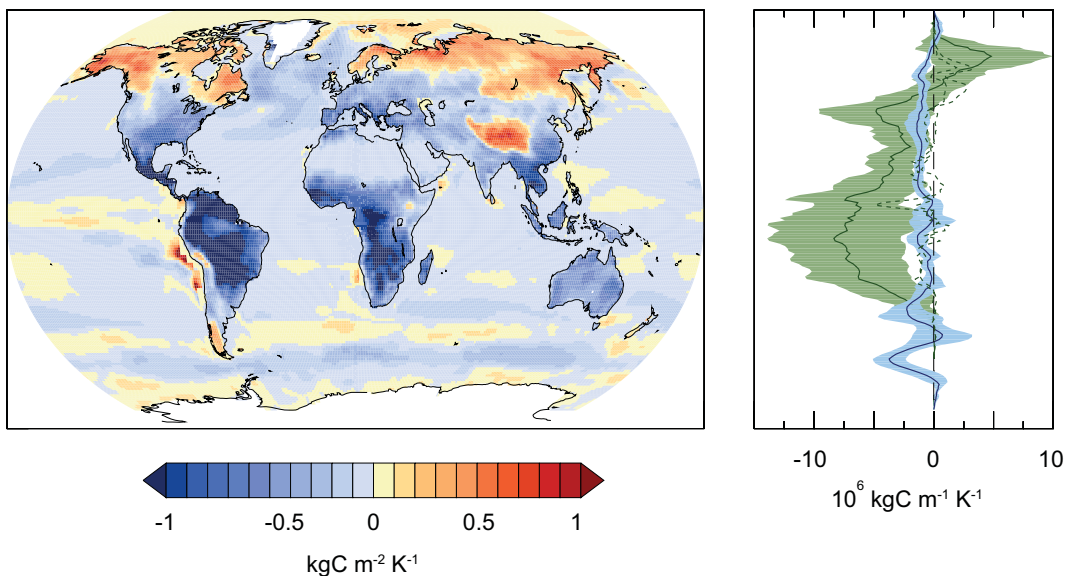

Figure 6.22: The spatial distributions of multi model-mean land and ocean β and γ for 7 CMIP5 models using the *concentration-driven* idealised 1% per year CO_2 simulations. For land and ocean, β and γ are defined from changes in terrestrial carbon storage and changes in air-sea integrated fluxes respectively, from $1\times\text{CO}_2$ to $4\times\text{CO}_2$, relative to global (not local) CO_2 and temperature change. In the zonal mean plots, the solid lines show the multi-model mean and shaded areas denote ± 1 standard deviation. Models used are: BCC-CSM1-1, CanESM2, CESM1-BGC, HadGEM2-ES, IPSL-CM5A-LR, MPI-ESM-LR, NorESM1-ME. The dashed lines show the models that include a land carbon component with an explicit representation of N-cycle processes (CESM1-BGC, NorESM1-ME).

Figure 6.23: Land use trends and CO₂ emissions according to the four different integrated assessment models (IAMs) used to define the RCP scenarios. Global changes in croplands and pasture from the historical record and the RCP scenarios (top left), and associated annual land use emissions of CO₂ (bottom left). Bars (right panel) show cumulative land use emissions for the historical period (defined here as 1850–2005) and the 4 RCP scenarios from 2006 to 2100.

Figure 6.24: Cumulative land and ocean carbon uptake simulated for the historical period 1850–2005 (top panel) and for the four RCP scenarios up to 2100 (panels b–e). Mean (thick line) and 1 standard deviation (shaded). Vertical bars on the right show the full model range as well as standard deviation. Black bars show observationally derived estimates for 2005. Models used: CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MIROC-ESM-CHEM, MIROC-ESM, MPI-ESM-LR, NorESM1-ME, INMCM4, CESM1-BGC, BCC-CSM1.1. Not every model performed every scenario simulation.

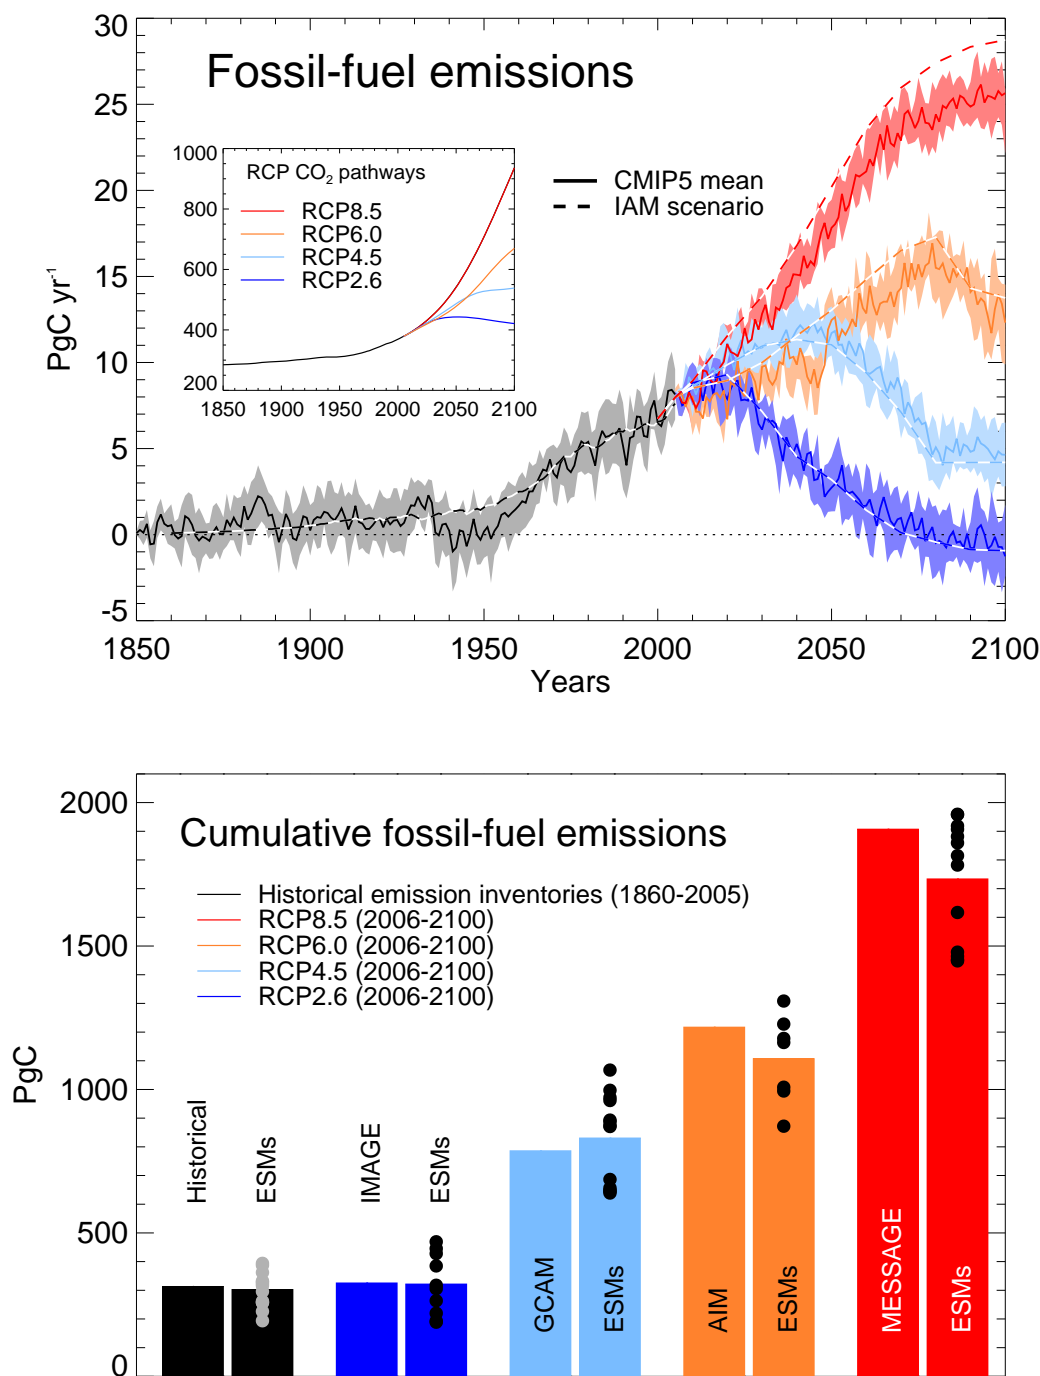

Figure 6.25: Compatible fossil fuel emissions simulated by the CMIP5 ESM models for the 4 RCP scenarios. Top: time series of compatible emission rate (PgC yr^{-1}). Dashed lines represent the historical estimates and emissions calculated by the integrated assessment models (IAM) used to define the RCP scenarios, solid lines and plumes show results from CMIP5 ESMs (model mean, with 1 standard deviation shaded). Bottom: cumulative emissions for the historical period (1860–2005) and 21st century (defined in CMIP5 as 2006–2100) for historical estimates and RCP scenarios. Dots denote individual ESM results, bars show the multi-model mean. In the CMIP5 model results, total carbon in the land-atmosphere-ocean system can be tracked and changes in this total must equal fossil fuel emissions to the system (see Box 6.4). Models used: CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MIROC-ESM-CHEM, MIROC-ESM, MPI-ESM-LR, NorESM1-ME, INMCM4, CESM1-BGC, BCC-CSM1.1. Not every model performed every scenario simulation.

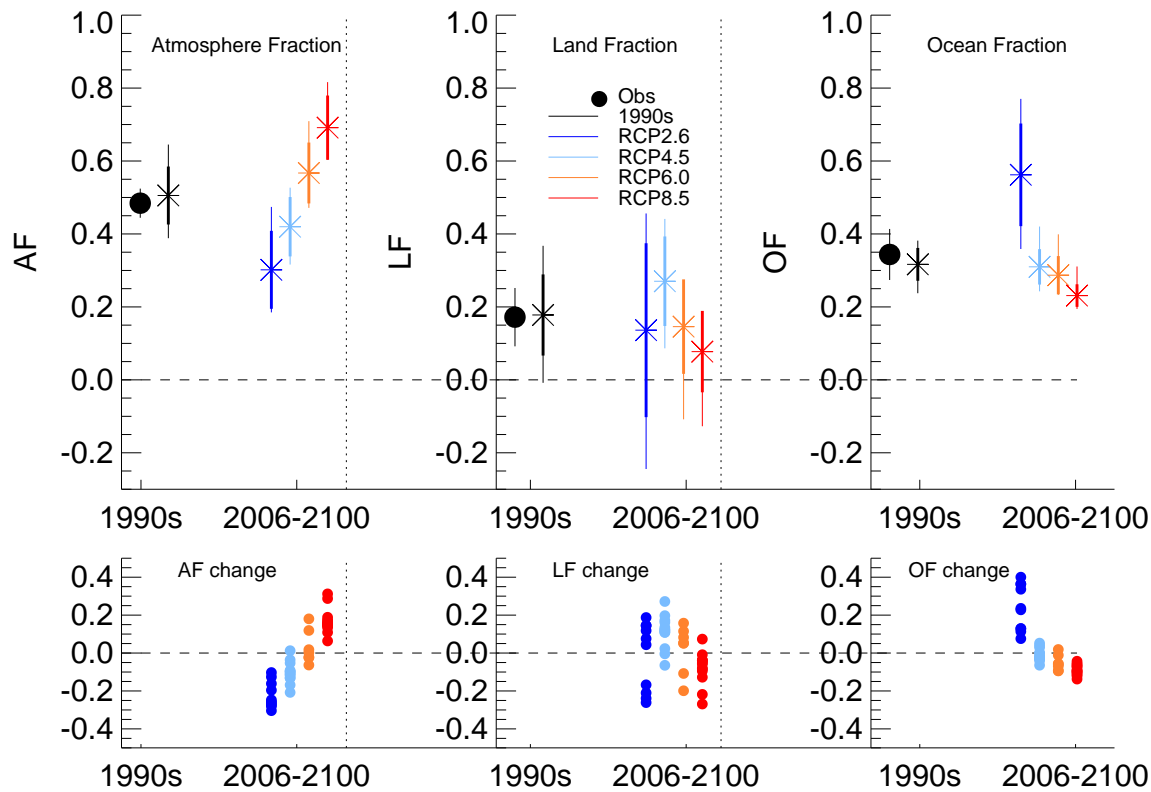

Figure 6.26: Changes in atmospheric, land and ocean fraction of fossil fuel carbon emissions. The fractions are defined as the changes in storage in each component (atmosphere, land, ocean) divided by the compatible fossil fuel emissions derived from each CMIP5 simulation for the 4 RCP scenarios. Solid circles show the observed estimate based on Table 6.1 for the 1990s. The coloured bars denote the cumulative uptake fractions for the 21st century under the different RCP scenarios for each model. Multi-model mean values are shown as star symbols and the multi-model range (min-to-max) and standard deviation are shown by thin and thick vertical lines respectively. Due to the difficulty of estimating land use emissions from the ESMs this figure uses a fossil fuel definition of airborne fraction, rather than the preferred definition of fossil and land use emissions discussed in Section 6.3.2.4. 21st century cumulative atmosphere, land and ocean fractions are shown here in preference to the more commonly shown instantaneous fractions because for RCP2.6 emissions reach and cross zero for some models and so an instantaneous definition of AF becomes singular at that point. Models used: CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MIROC-ESM-CHEM, MIROC-ESM, MPI-ESM-LR, NorESM1-ME, CESM1-BGC. Not every model performed every scenario simulation.

Figure 6.27: Compatible fossil fuel emissions for the RCP4.5 scenario (top panel) in the presence (red) and absence (blue) of the climate feedback on the carbon cycle, and the difference between them (bottom panel). Multi-model mean, 10-year smoothed values are shown, with 1 standard deviation shaded. This shows the impact of climate change on the compatible fossil fuel CO₂ emissions to achieve the RCP4.5 CO₂ concentration pathway. Models used: CanESM2, GFDL-ESM2M, HadGEM2-ES, IPSL-CM5A-LR and MIROC-ESM.

Figure 6.28: Projected ocean acidification from 11 CMIP5 Earth System models under RCP8.5 (other RCPs scenarios have also been run with the CMIP5 models): **(a)** time series of surface pH shown as the mean (solid line) and range of models (filled), given as area-weighted averages over the Arctic Ocean (green), the tropical oceans (red), and the Southern Ocean (blue); **(b)** maps of the median model's change in surface pH from 1850 to 2100. Panel **(a)** also includes mean model results from RCP2.6 (dashed lines). Over most of the ocean, gridded data products of carbonate system variables (Key et al., 2004) are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following (Orr et al., 2005). Where gridded data products are unavailable (Arctic Ocean, all marginal seas, and the ocean near Indonesia), the results are shown without bias correction. The bias correction reduces the range of model projections by up to a factor of 4, e.g., in panel **(a)** compare the large range of model projections for the Arctic (without bias correction) to the smaller range in the Southern Ocean (with bias correction).

Figure 6.29: Projected aragonite saturation state from 11 CMIP5 Earth System models under RCP8.5 scenario: (a) time series of surface carbonate ion concentration shown as the mean (solid line) and range of models (filled), given as area-weighted averages over the Arctic Ocean (green), the tropical oceans (red), and the Southern Ocean (blue); maps of the median model's surface Ω_A in (b) 2010, (d) 2050, and (f) 2100; and zonal mean sections (latitude vs. depth) of Ω_A in 2100 over the (g) Atlantic and (h) Pacific, while the ASH is shown in 2010 (dotted line) as well as 2100 (solid line). Panel (a) also includes mean model results from RCP2.6 (dashed lines). As for Figure 6.28, gridded data products of carbonate system variables (Key et al., 2004) are used to correct each model for its present-day bias by subtracting the model-data difference at each grid cell following (Orr et al., 2005). Where gridded data products are unavailable (Arctic Ocean, all marginal seas, and the ocean near Indonesia), results are shown without bias correction.

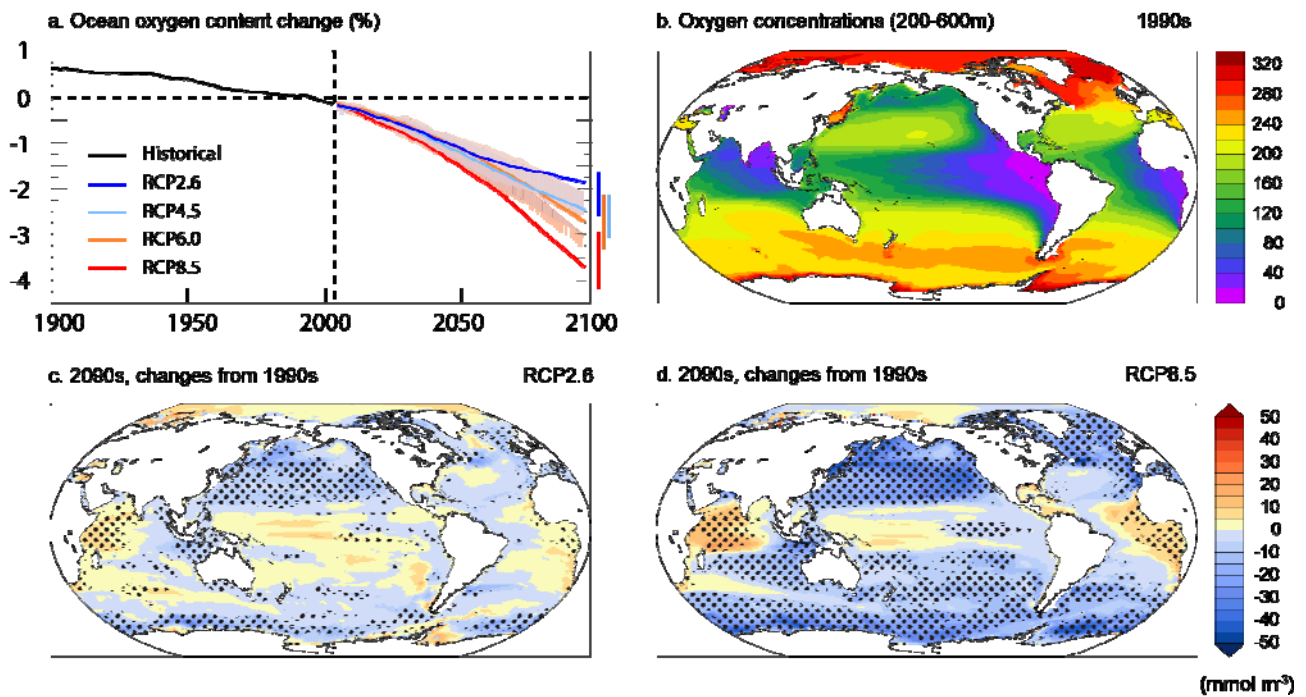

Figure 6.30: (a) Simulated changes in dissolved O_2 (mean and model range as shading) relative to 1990s for RCP2.6, RCP4.5, RCP6.0 and RCP8.5. (b) Multi-model mean dissolved O_2 ($\mu\text{mol m}^{-3}$) in the main thermocline (200 to 600m depth average) for the 1990s, and changes in 2090s relative to 1990s for RCP2.6 (c) and RCP8.5 (d). To indicate consistency in the sign of change, regions are stippled where at least 80% of models agree on the sign of the mean change. These diagnostics are detailed in Cocco et al. (2013) in a previous model intercomparison using the SRES-A2 scenario and have been applied to CMIP5 models here. Models used: CESM1-BGC, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-ES, IPSL-CM5A-LR, IPSL-CM5A-MR, MPI-ESM-LR, MPI-ESM-MR, NorESM1.

Figure 6.31: Global nitrogen fertilizer consumption scenarios (left) and the impact of individual drivers on 2100 consumption (right). This resulting consumption is always the sum (denoted at the end points of the respective arrows) of elements increasing as well as decreasing nitrogen consumption. Other relevant estimates are presented for comparison. The A1, B1, A2 and B2 scenarios draw from the assumptions of the IPCC SRES emission scenario storylines as explained in Erismann et al. (2008).

N₂O emissions (kgN km⁻² y⁻¹)

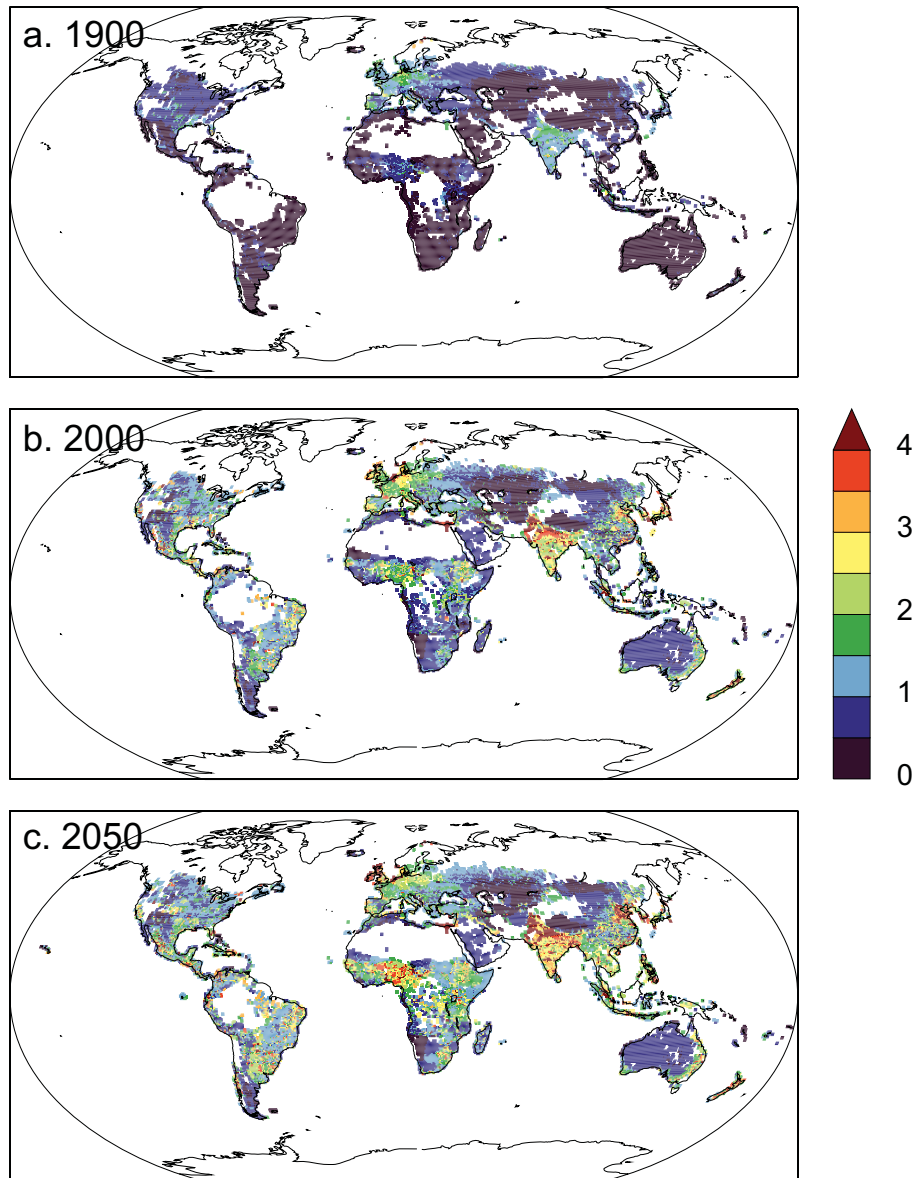

Figure 6.32: N₂O emissions in 1900, 2000 and projected to 2050 (Bouwman et al., 2011). This spatially explicit soil nutrient budget and nitrogen gas emission scenario was elaborated with the IMAGE model on the basis of the International Assessment of Agricultural Knowledge, Science and Technology for Development (IAASTD) baseline scenario (McIntyre et al., 2009).

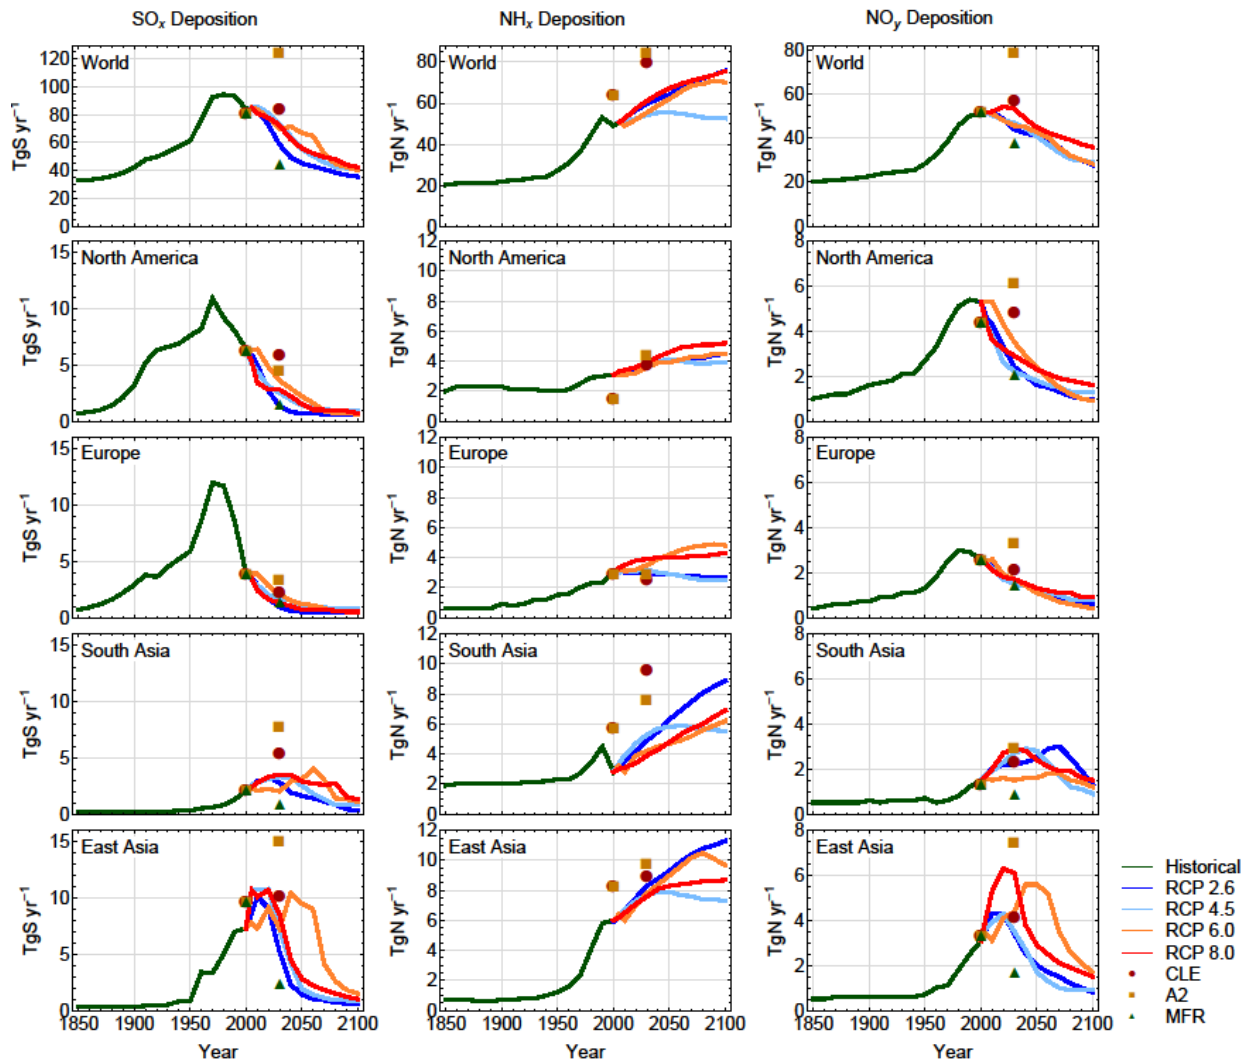

Figure 6.33: Deposition of SO_x (left panel, TgS yr⁻¹), NH_x (middle panel, TgN yr⁻¹) and NO_y (right panel, TgN yr⁻¹) from 1850 to 2000 and projections of deposition to 2100 under the four RCP emission scenarios (Lamarque et al., 2011; van Vuuren et al., 2011). Also shown are the 2030 scenarios using the SRES B1/A2 energy scenario with assumed current legislation and maximum technically feasible air pollutant reduction controls (Dentener et al., 2006).

RCP2.6

RCP2.6

Figure 6.34: Spatial variability of nitrogen and SO_x deposition in 1990s with projections to the 2090s (shown as difference relative to the 1990s), using the RCP2.6 and RCP8.5 scenarios, kgN km⁻² yr⁻¹, adapted from Lamarque et al. (2011). Note that no information on the statistical significance of the shown differences is available. This is of particular relevance for areas with small changes. The plots for all four of the RCP scenarios are in the Supplementary Material.

Figure 6.35: Estimated influence of nitrogen availability on total land carbon sequestration over the period 1860–2100 (based on analysis method of Wang and Houlton (2009)). Blue bars show, for each RCP scenario, the multi-model ensemble mean of land carbon sequestration, based on the carbon-only subset of CMIP5 models (CanESM2, GFDL-ESM2G, GFDL-ESM2M, HadGEM2-CC, HadGEM2-ES, IPSL-CM5a-LR, IPSL-CM5A-MR, IPSL-CM5B-LR, MPI-ESM-LR; not all models produced results for all scenarios). Red bars show, for each scenario, the mean land carbon sequestration from the same ensemble of carbon-only models after correcting for inferred constraints on carbon uptake due to limited availability of nitrogen. Black bars show \pm one standard deviation around the means. Black symbols show individual model results from the two CMIP5 models with explicit C-N interactions (CESM1-BGC and NorESM1-ME). These two models have nearly identical representations of land C-N dynamics, and differences between them here (for RCP4.5 and RCP8.5, where both models contributed results) are due to differences in coupled system climate. All simulations shown here used prescribed atmospheric CO₂ concentrations.

Figure 6.36: Schematic synthesis of the magnitude and time scales associated with possible future CH₄ emissions (adapted from O'Connor et al., 2010). Uncertainty in these future changes is large, and so this figure demonstrates the relative magnitude of possible future changes. Anthropogenic emissions starting at a present day level of 300 Tg(CH₄) yr⁻¹ (consistent with Table 6.8) and increasing or decreasing according to RCP8.5 and RCP2.6 are shown for reference. Wetland emissions are taken as 140–280 Tg(CH₄) yr⁻¹ present day values (Table 6.8) and increasing by between 0–100% (Section 6.4.7.1; Figure 6.37). Permafrost emissions may become important during the 21st century. CH₄ release from marine hydrates and subsea permafrost may also occur but uncertainty is sufficient to prevent plotting emission rates here. Large CH₄ hydrate release to the atmosphere is not expected during the 21st century. No quantitative estimates of future changes in CH₄ emissions from wildfires exist, so plotted here are continued present day emissions of 1–5 Tg(CH₄) yr⁻¹ (Table 6.8).

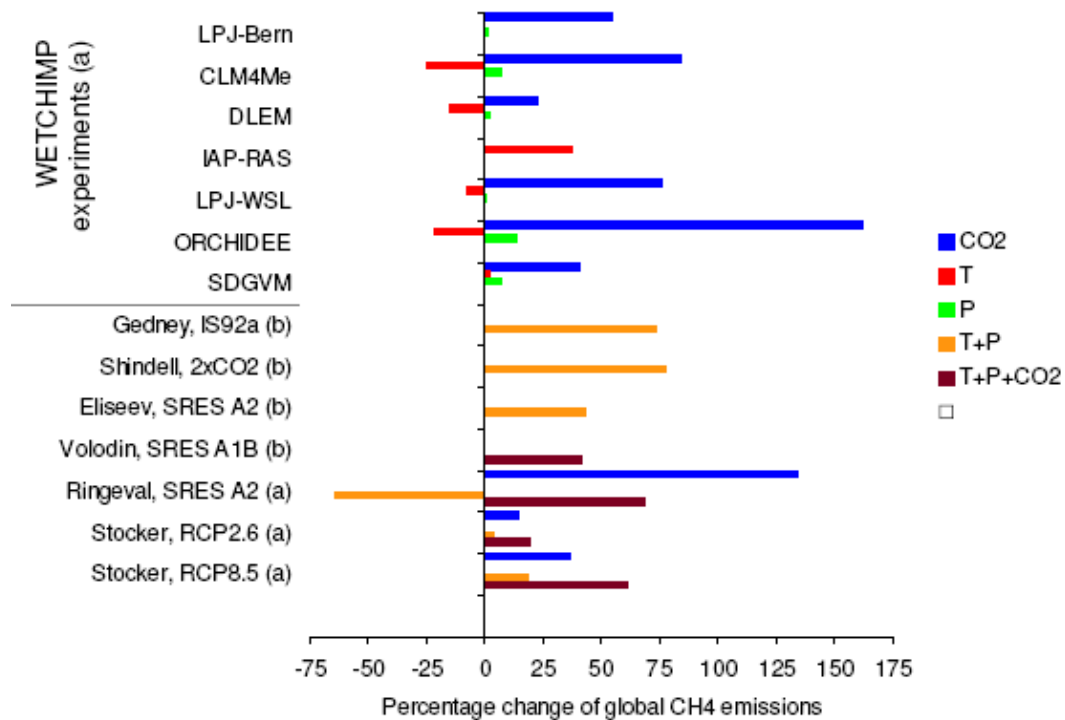

Figure 6.37: Relative changes of global CH₄ emissions from either pre-industrial (a) or present day (b) conditions and environmental changes that reflect potential conditions in 2100. The first seven models took part in the WETCHIMP intercomparison project and were run under a common protocol (Melton et al., 2013). Bars represent CH₄ emission changes associated with temperature-only changes (T), precipitation only (P), CO₂ only (CO₂) or combinations of multiple factors. Other studies as listed in the figure used different future scenarios: Eliseev et al. (2008), Gedney et al. (2004), Ringeval et al. (2011), Shindell et al. (2004), Volodin (2008), Stocker et al. (2013).

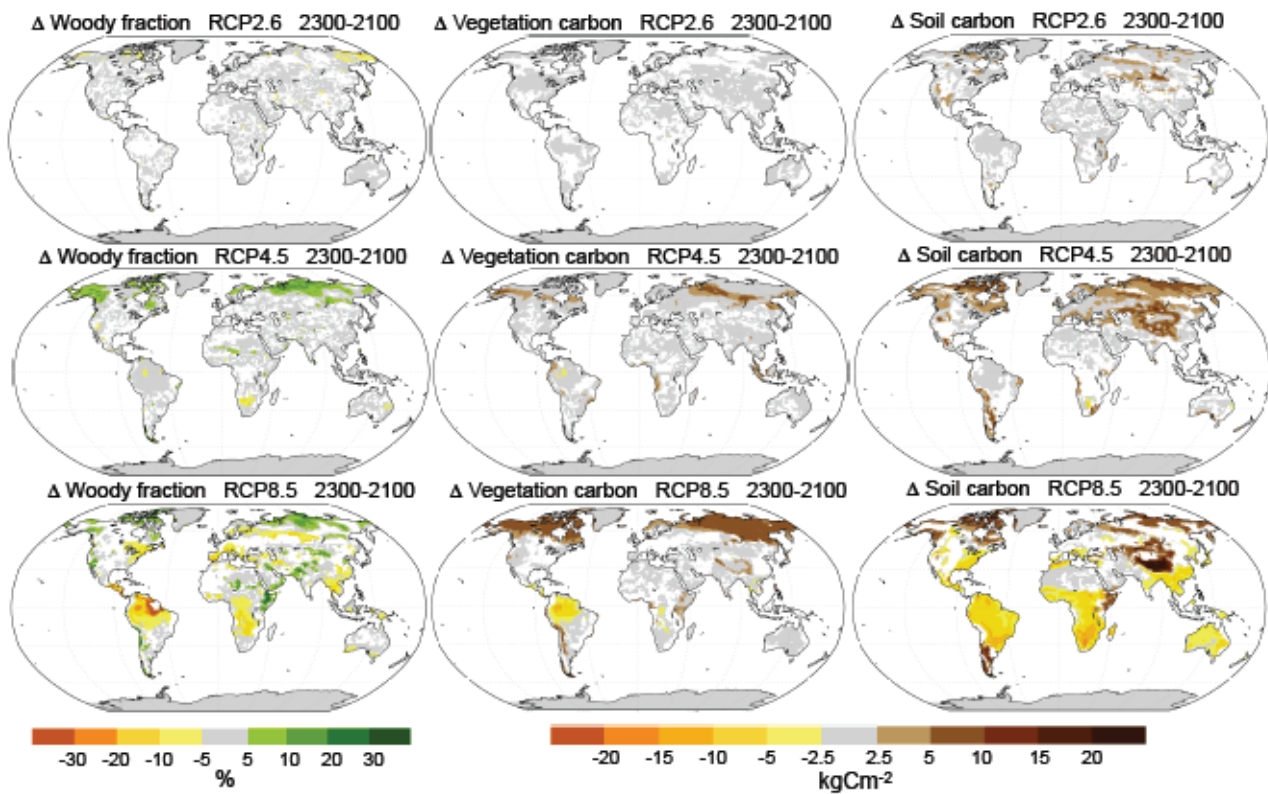

Figure 6.38: Maps of changes in woody cover fraction, %, (left) and terrestrial carbon storage, kg C m^{-2} , (vegetation carbon, middle; soil carbon, right) between years 2100 and 2300 averaged for two models, HadGEM2-ES and MPI-ESM, which simulate vegetation dynamics for three RCP extension scenarios 2.6 (top), 4.5 (middle), and 8.5 (bottom). Note the RCP6.0 extension was not a CMIP5 required simulation. Model results were interpolated on $1^\circ \times 1^\circ$ grid; white colour indicates areas where models disagree in sign of changes. Anthropogenic land use in these extension scenarios is kept constant at 2100 levels, so these results show the response of natural ecosystems to the climate change.

Figure 6.39: Idealized model simulations (Matthews, 2010) to illustrate the effects of CDR methods associated with either permanent or non-permanent carbon sequestration. There is an emission of 1000 PgC in the reference case (black line) between 1800 and 2100, corresponding approximately to RCP4.5 scenario (Section 6.4). Permanent sequestration of 380 PgC, assuming no leakage of sequestered carbon would reduce climate change (blue line, compared to black line). By contrast, a non-permanent sequestration CDR method where carbon will be sequestered and later on returned to the atmosphere in three centuries would not. In this idealized non-permanent sequestration example scenario, climate change would only be delayed but the eventual magnitude of climate change will be equivalent to the no-sequestration case (green line, compared to black). Figure adapted from Figure 5 of Matthews (2010).

Figure 6.40: Idealized simulations with a simple global carbon cycle model (Cao and Caldeira, 2010b) to illustrate the ‘rebound effect’. Effects of an instantaneous cessation of CO₂ emissions at year 2050 (amber line), one-time CDR removal of the excess of atmospheric CO₂ over pre-industrial levels (blue line) and removal of this excess of atmospheric CO₂ followed by continued removal of all the CO₂ that degasses from the ocean (green line) are shown. For the years 1850–2010 observed atmospheric CO₂ concentrations are prescribed and CO₂ emissions are calculated from CO₂ concentrations and modeled carbon uptake. For years 2011–2049, CO₂ emissions are prescribed following the SRES A2 scenario. Starting from year 2050, CO₂ emission is either set to zero or calculated from modeled CO₂ concentrations and CO₂ uptake. To a first approximation, a cessation of emissions would prevent further warming but would not lead to significant cooling on the century time scale. A one-time removal of excess atmospheric CO₂ would eliminate approximately only half of the warming experienced at the time of the removal because of CO₂ that outgases from the ocean (the rebound effect). To bring atmospheric CO₂ back to pre-industrial levels permanently, would require the removal of all previously emitted CO₂, i.e., an amount equivalent to approximately twice the excess atmospheric CO₂ above pre-industrial level. Figure adapted from Cao and Caldeira (2010b).

FAQ 6.1, Figure 1: Simplified schematic of the global carbon cycle showing the typical turnover time scales for carbon transfers through the major reservoirs.

FAQ 6.1, Figure 2: Decay of a CO₂ excess amount of 5000 PgC emitted at time zero into the atmosphere, and its subsequent redistribution into land and ocean as a function of time, computed by coupled carbon-cycle climate models. The size of the colour bands indicate the carbon uptake by the respective reservoir. The first two panels show the multi-model mean from a model intercomparison project (Joos et al., 2013). The last panel shows the longer term redistribution including ocean dissolution of carbonaceous sediments as computed with an Earth System Model of Intermediate Complexity (after Archer et al., 2009b).

FAQ 6.2, Figure 1: A simplified graph of current major carbon pools and flows in the Arctic domain, including permafrost on land, continental shelves and ocean (adapted from McGuire et al. (2009) and Tarnocai et al. (2009)). TgC = 10^{12} gC, and PgC = 10^{15} gC.

Executive Summary

Clouds and aerosols continue to contribute the largest uncertainty to estimates and interpretations of the Earth's changing energy budget. This chapter focuses on process understanding and considers observations, theory and models to assess how clouds and aerosols contribute and respond to climate change. The following conclusions are drawn.

Progress in Understanding

Many of the cloudiness and humidity changes simulated by climate models in warmer climates are now understood as responses to large-scale circulation changes that do not appear to depend strongly on subgrid-scale model processes, increasing confidence in these changes. For example, multiple lines of evidence now indicate positive feedback contributions from circulation-driven changes in both the height of high clouds and the latitudinal distribution of clouds (*medium to high confidence*¹). However, some aspects of the overall cloud response vary substantially among models, and these appear to depend strongly on subgrid-scale processes in which there is less confidence. [7.2.4, 7.2.5, 7.2.6, Figure 7.11]

Climate-relevant aerosol processes are better understood, and climate-relevant aerosol properties better observed, than at the time of AR4. However, the representation of relevant processes varies greatly in global aerosol and climate models and it remains unclear what level of sophistication is required to model their effect on climate. Globally, between 20 and 40% of aerosol optical depth (*medium confidence*) and between one quarter and two thirds of cloud condensation nucleus concentrations (*low confidence*) are of anthropogenic origin. [7.3, Figures 7.12–7.15]

Cosmic rays enhance new particle formation in the free troposphere, but the effect on the concentration of cloud condensation nuclei is too weak to have any detectable climatic influence during a solar cycle or over the last century (*medium evidence, high agreement*). No robust association between changes in cosmic rays and cloudiness has been identified. In the event that such an association exists, it is *very unlikely*² to be due to cosmic ray-induced nucleation of new aerosol particles. [7.4.6]

Recent research has clarified the importance of distinguishing forcing (instantaneous change in the radiative budget) and rapid adjustments (which modify the radiative budget indirectly through fast atmospheric and surface changes) from feedbacks (which operate through changes in climate variables that are mediated by a change in surface temperature). Furthermore one can distinguish between the traditional concept of radiative forcing (RF) and the relatively new concept of effective radiative forcing (ERF) that also include rapid adjustments. For aerosols one can further distinguish forcing processes arising from aerosol-radiation interactions (ari) and aerosol-cloud interactions (aci). [7.1, Figures 7.1–7.3]

The quantification of cloud and convective effects in models, and of aerosol-cloud interactions, continues to be a challenge. Climate models are incorporating more of the relevant processes than at the time of AR4, but confidence in the representation of these processes remains low. Cloud and aerosol properties vary at scales significantly smaller than those resolved in climate models, and cloud-scale processes respond to aerosol in nuanced ways at these scales. Until subgrid-scale parameterisations of clouds and aerosol-cloud interactions are able to address these issues, model estimates of aerosol-cloud interactions and their radiative effects will carry large uncertainties. Satellite-based estimates of aerosol-cloud

¹ In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Chapter 1, Section 1.4 and Box TS.1 for more details).

² In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99–100% probability, Very likely 90–100%, Likely 66–100%, About as likely as not 33–66%, Unlikely 0–33%, Very unlikely 0–10%, Exceptionally unlikely 0–1%. Additional terms (Extremely likely: 95–100%, More likely than not >50–100%, and Extremely unlikely 0–5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

interactions remain sensitive to the treatment of meteorological influences on clouds and assumptions on what constitutes pre-industrial conditions. [7.3, 7.4, 7.5.3, 7.5.4, 7.6.4, Figures 7.8, 7.12, 7.16]

Precipitation and evaporation are expected to increase on average in a warmer climate, but also undergo global and regional adjustments to CO₂ and other forcings that differ from their warming responses. Moreover, there is *high confidence* that, as climate warms, extreme precipitation rates on e.g., daily time scales will increase faster than the time average. Changes in average precipitation must remain consistent with changes in the net rate of cooling of the troposphere, which is affected by its temperature but also by greenhouse gases and aerosols. Consequently, while the increase in global-mean precipitation would be 1.5–3.5% °C⁻¹ due to surface temperature change alone, warming caused by CO₂ or absorbing aerosols results in a smaller sensitivity, even more so if it is partially offset by albedo increases. The complexity of land-surface and atmospheric processes limits confidence in regional projections of precipitation change, especially over land, although there is a component of a “wet-get-wetter” and “dry-get-drier” response over oceans at the large scale. Changes in local extremes on daily and sub-daily time scales are strongly influenced by lower-tropospheric water vapour concentrations, and on average will increase by roughly 5–10 % per °C of warming (*medium confidence*). Aerosol-cloud interactions can influence the character of individual storms, but evidence for a systematic aerosol effect on storm or precipitation intensity is more limited and ambiguous. [7.2.4, 7.4, 7.6, Figures 7.20, 7.21]

Water Vapour, Cloud and Aerosol Feedbacks

The net feedback from water vapour and lapse rate changes combined, as traditionally defined, is *extremely likely* positive (amplifying global climate changes). The sign of the net radiative feedback due to all cloud types is less certain, but *likely* positive. Uncertainty in the sign and magnitude of the cloud feedback is due primarily to continuing uncertainty in the impact of warming on low clouds. We estimate the water vapour plus lapse rate feedback³ to be +1.1 (+0.9 to +1.3) W m⁻² °C⁻¹ and the cloud feedback from all cloud types to be +0.6 (–0.2 to +2.0) W m⁻² °C⁻¹. These ranges are broader than those of climate models to account for additional uncertainty associated with processes that may not have been accounted for in those models. The mean values and ranges in climate models are essentially unchanged since AR4, but are now supported by stronger indirect observational evidence and better process understanding especially for water vapour. Low clouds contribute positive feedback in most models, but that behaviour is not well understood, nor effectively constrained by observations, so we are not confident that it is realistic. [7.2.4, 7.2.5, 7.2.6, Figures 7.9–7.11].

Aerosol-climate feedbacks occur mainly through changes in the source strength of natural aerosols or changes in the sink efficiency of natural and anthropogenic aerosols; a limited number of modelling studies have bracketed the feedback parameter within ±0.2 W m⁻² °C⁻¹ with *low confidence*. There is *medium confidence* for a weak dimethylsulphide-cloud condensation nuclei-cloud albedo feedback due to a weak sensitivity of cloud condensation nuclei population to changes in dimethylsulphide emissions. [7.3.5]

Quantification of climate forcings⁴ due to aerosols and clouds

The effective radiative forcing due to aerosol-radiation interactions that takes rapid adjustments into account (ERF_{ari}) is assessed to be –0.45 (–0.95 to +0.05) W m⁻². The RF from absorbing aerosol on snow and ice is assessed separately to be +0.04 (+0.02 to +0.09) W m⁻². Prior to adjustments taking place, the radiative forcing due to aerosol-radiation interactions (RF_{ari}) is assessed to be –0.35 (–0.85 to +0.15) W m⁻². The assessment for RF_{ari} is less negative than reported in AR4 because of a re-evaluation of aerosol absorption. The uncertainty estimate is wider but more robust, based on multiple lines of evidence from models, remotely sensed data, and ground-based measurements. Fossil fuel and biofuel emissions⁵ contribute to RF_{ari} via sulphate aerosol: –0.4 (–0.6 to –0.2) W m⁻², black carbon aerosol: +0.4 (+0.05 to +0.8) W m⁻², and primary and secondary organic aerosol: –0.12 (–0.4 to +0.1) W m⁻². Additional RF_{ari} contributions

³ This and all subsequent ranges given with this format are 90% uncertainty ranges unless otherwise specified.

⁴ All climate forcings (RFs and ERFs) are anthropogenic and relate to the period 1750–2010 unless otherwise specified.

⁵ This species breakdown is less certain than the total RF_{ari} and does not sum to the total exactly.

occur via biomass burning emissions⁶: +0.0 (–0.2 to +0.2) W m^{–2}, nitrate aerosol: –0.11 (–0.3 to –0.03) W m^{–2}, and mineral dust: –0.1 (–0.3 to +0.1) W m^{–2} although the latter may not be entirely of anthropogenic origin. While there is robust evidence for the existence of rapid adjustment of clouds in response to aerosol absorption, these effects are multiple and not well represented in climate models, leading to large uncertainty. Unlike in the last IPCC assessment, the RF from BC on snow and ice includes the effects on sea-ice, accounts for more physical processes, and incorporates evidence from both models and observations. This RF has a 2–4 times larger global mean surface temperature change per unit forcing than a change in carbon dioxide. [7.3.4, 7.5.2, Figures 7.17, 7.18]

The total effective radiative forcing due to aerosols (ERF_{ari+aci}, excluding the effect of absorbing aerosol on snow and ice) is assessed to be –0.9 (–1.9 to –0.1) W m^{–2} with medium confidence. The ERF_{ari+aci} estimate includes rapid adjustments, such as changes to the cloud lifetime and aerosol microphysical effects on mixed-phase, ice and convective clouds. This range was obtained from expert judgement guided by climate models that include aerosol effects on mixed-phase and convective clouds in addition to liquid clouds, satellite studies, and models that allow cloud-scale responses. This forcing can be much larger regionally but the global-mean value is consistent with several new lines of evidence suggesting less negative estimates for the effective radiative forcing due to aerosol-cloud interactions than in AR4. [7.4, 7.5.3, 7.5.4, Figure 7.19]

Persistent contrails from aviation contribute a RF of +0.01 (+0.005 to +0.03) W m^{–2} for year 2011, and the combined contrail and contrail-cirrus ERF from aviation is assessed to be +0.05 (+0.02 to +0.15) W m^{–2}. This forcing can be much larger regionally but there is now *medium confidence* that it does not produce observable regional effects on either the mean or diurnal range of surface temperature. [7.2.7]

Geoengineering Using Solar Radiation Management Methods

Theory, model studies and observations suggest that some Solar Radiation Management (SRM) methods, if practicable, could substantially offset a global temperature rise and partially offset some other impacts of global warming, but the compensation for the climate change caused by greenhouse gases would be imprecise (*high confidence*). SRM methods are unimplemented and untested. Research on SRM is in its infancy though it leverages understanding of how the climate responds to forcing more generally. The efficacy of a number of SRM strategies was assessed, and there is *medium confidence* that stratospheric aerosol SRM is scalable to counter the RF from increasing greenhouse gases at least up to approximately 4 W m^{–2}; however the required injection rate of aerosol precursors remains very uncertain. There is no consensus on whether a similarly large RF could be achieved from cloud brightening SRM due to uncertainties in understanding and representation of aerosol-cloud interactions. It does not appear that land albedo change SRM can produce a large RF. Limited literature on other SRM methods precludes their assessment. Models consistently suggest that SRM would generally reduce climate differences compared to a world with elevated greenhouse gas concentrations and no SRM; however there would also be residual regional differences in climate (e.g., temperature and rainfall) when compared to a climate without elevated greenhouse gases. [7.4.3, 7.7]

Numerous side effects, risks and shortcomings from SRM have been identified. Several lines of evidence indicate that SRM would produce a small but significant decrease in global precipitation (with larger differences on regional scales) if the global surface temperature were maintained. A number of side effects have been identified. One that is relatively well characterised is the likelihood of modest polar stratospheric ozone depletion associated with stratospheric aerosol SRM. There could also be other as yet unanticipated consequences. As long as greenhouse gas concentrations continued to increase, the SRM would require commensurate increase, exacerbating side effects. Additionally, scaling SRM to substantial levels would carry the risk that if the SRM were terminated for any reason, there is *high confidence* that surface temperatures would increase rapidly (within a decade or two) to values consistent with the greenhouse gas forcing, which would stress systems sensitive to the rate of climate change. Finally, SRM would not compensate for ocean acidification from increasing CO₂. [7.6.3, 7.7, Figures 7.22–7.24]

⁶ The RF_{ari} from biomass burning emissions is made up of a positive black carbon RF_{ari} and a negative organic carbon RF_{ari}.

7.1 Introduction

7.1.1 *Clouds and Aerosols in the Atmosphere*

The atmosphere is composed mostly of gases, but also contains liquid and solid matter in the form of particles. It is usual to distinguish these particles according to their size, chemical composition, water content and fall velocity into atmospheric aerosol particles, cloud particles and falling hydrometeors. Despite their small mass or volume fraction, particles in the atmosphere strongly influence the transfer of radiant energy and the spatial distribution of latent heating through the atmosphere, thereby influencing the weather and climate.

Cloud formation usually takes place in rising air, which expands and cools, thus permitting the activation of aerosol particles into cloud droplets and ice crystals in supersaturated air. Cloud particles are generally larger than aerosol particles and composed mostly of liquid water or ice. The evolution of a cloud is governed by the balance between a number of dynamical, radiative and microphysical processes. Cloud particles of sufficient size become falling hydrometeors, which are categorised as drizzle drops, raindrops, snow crystals, graupel and hailstones. Precipitation is an important and complex climate variable which is influenced by the distribution of moisture and cloudiness, and to a lesser extent by the concentrations and properties of aerosol particles.

Aerosol particles interact with solar radiation through absorption and scattering and, to a lesser extent with terrestrial radiation through absorption, scattering and emission. Aerosols⁷ can serve as cloud condensation nuclei (CCN) and ice nuclei (IN) upon which cloud droplets and ice crystals form. They also play a wider role in atmospheric chemistry and biogeochemical cycles in the Earth system, for instance by carrying nutrients to ocean ecosystems. They can be of natural or anthropogenic origin.

Cloud and aerosol amounts⁸ and properties are extremely variable in space and time. The short lifetime of cloud particles in subsaturated air creates relatively sharp cloud edges and fine-scale variations in cloud properties, which is less typical of aerosol layers. While the distinction between aerosols and clouds is generally appropriate and useful, it is not always unambiguous, which can cause interpretational difficulties (e.g., Charlson et al., 2007; Koren et al., 2007).

7.1.2 *Rationale for Assessing Clouds, Aerosols and Their Interactions*

The representation of cloud processes in climate models has been recognised for decades as a dominant source of uncertainty in our understanding of changes in the climate system (e.g., Arakawa, 1975; Charney et al., 1979; Cess et al., 1989; Randall et al., 2003; Arakawa, 2004; Bony et al., 2006), but has never been systematically assessed by the IPCC before. Clouds respond to climate forcing mechanisms in multiple ways and inter-model differences in cloud feedbacks constitute by far the primary source of spread of both equilibrium and transient climate responses simulated by climate models (Dufresne and Bony, 2008) despite the fact that most models agree that the feedback is positive (Randall et al., 2007; Section 7.2). Thus confidence in climate projections requires a thorough assessment of how cloud processes have been accounted for.

Aerosols of anthropogenic origin are responsible for a radiative forcing of climate change through their interaction with radiation, and also as a result of their interaction with clouds. Quantification of this forcing is fraught with uncertainties (Haywood and Boucher, 2000; Lohmann and Feichter, 2005) and aerosols dominate the uncertainty in the total anthropogenic radiative forcing (Forster et al., 2007; Haywood and Schulz, 2007; Chapter 8). Furthermore, our inability to better quantify non-greenhouse-gas radiative forcings, and primarily those that result from aerosol-cloud interactions, underlie difficulties in constraining climate sensitivity from observations even if we had a perfect knowledge of the temperature record (Andreae

⁷ For convenience the term "aerosol", which includes both the particles and the suspending gas, is often used in its plural form to mean "aerosol particles" both in this Chapter and the rest of this report.

⁸ In this chapter, we use "cloud amount" as an inexact term to refer to the quantity of clouds, both in the horizontal and vertical directions. The term "cloud cover" is used in its usual sense and refers to the horizontal cloud cover.

et al., 2005). Thus a complete understanding of past and future climate change requires a thorough assessment of aerosol-cloud-radiation interactions.

7.1.3 Forcing, Rapid Adjustments, and Feedbacks

Figure 7.1 illustrates key aspects of how clouds and aerosols contribute to climate change, and provides an overview of important terminological distinctions. *Forcings* associated with agents such as greenhouse gases and aerosols act on global mean surface temperature through the global radiative (energy) budget. *Rapid adjustments* (sometimes called rapid responses) arise when forcing agents, by altering flows of energy internal to the system, affect cloud cover or other components of the climate system and thereby alter the global budget indirectly. Because these adjustments do not operate through changes in the global mean surface temperature (ΔT), which are slowed by the massive heat capacity of the oceans, they are generally rapid and most are thought to occur within a few weeks. *Feedbacks* are associated with changes in climate variables that are mediated by a change in global-mean surface temperature; they contribute to amplify or damp global temperature changes via their impact on the radiative budget.

[INSERT FIGURE 7.1 HERE]

Figure 7.1: Overview of forcing and feedback pathways involving greenhouse gases, aerosols and clouds. Forcing agents are in the green and dark blue boxes, with forcing mechanisms indicated by the straight green and dark blue arrows. The forcing is modified by rapid adjustments whose pathways are independent of changes in the globally averaged surface temperature and are denoted by brown dashed arrows. Feedback loops, which are ultimately rooted in changes ensuing from changes in the surface temperature, are represented by curving arrows (blue denotes cloud feedbacks; green denotes aerosol feedbacks; and orange denotes other feedback loops such as those involving the lapse rate, water vapour and surface albedo). The final temperature response depends on the effective radiative forcing (ERF) that is felt by the system, i.e., after accounting for rapid adjustments, and the feedbacks.

In this report, following an emerging consensus in the literature, the traditional concept of radiative forcing (RF, defined as the instantaneous radiative forcing with stratospheric adjustment only) is deemphasized in favour of an absolute measure of the radiative effects of all responses triggered by the forcing agent that are independent of surface temperature change (see also Section 8.1). This new measure of the forcing includes rapid adjustments, and the net radiative forcing with these adjustments included is termed the *effective radiative forcing* (ERF). The climate sensitivity to ERF will differ somewhat from traditional equilibrium climate sensitivity since the latter include adjustment effects. As shown in Figure 7.1, adjustments can occur through geographic temperature variations, lapse rate changes, cloud changes and vegetation effects. Measures of ERF and rapid adjustments have existed in the literature for more than a decade, with a number of different terminologies and calculation methods adopted. These were principally aimed to help quantify the effects of aerosols on clouds (Rotstayn and Penner, 2001; Lohmann et al., 2010) and understand different forcing agent responses (Hansen et al., 2005), but it is now realised that there are rapid adjustments in response to the CO₂ forcing itself (Section 7.2.5.6).

In principle rapid adjustments are independent of ΔT , while feedbacks operate purely through ΔT . Thus, within this framework adjustments are not another type of “feedback” but rather a non-feedback phenomenon, required in the analysis by the fact that a single scalar ΔT cannot fully characterise the system. This framework brings most efficacies close to unity although they are not necessarily exactly one (Hansen et al., 2005; Bond et al., 2013). There is also no clean separation in time scale between rapid adjustments and warming. While the former mostly occur within a few days of applying a forcing (Dong et al., 2009), some adjustments such as those that occur within the stratosphere and snowpack can take several months or longer. Meanwhile the land surface warms quickly so that a small part of ΔT occurs within days to weeks of an applied forcing. This makes the two phenomena difficult to isolate in model runs. Other drawbacks are that adjustments are difficult to observe, and typically more model-dependent than RF. However, recent work is beginning to meet the challenges of quantifying the adjustments, and has noted advantages of the new framework (e.g., Vial et al., 2013; Zelinka et al., 2013).

There is no perfect method to determine ERF. Two common methods are to regress the net energy imbalance onto ΔT in a transient warming simulation (Gregory et al., 2004; Figure 7.2), or to simulate the climate response with sea-surface temperatures held fixed (Hansen et al., 2005). The former can be complicated by

natural variability or time-varying feedbacks, while the nonzero ΔT from land warming complicates the latter. Both methods are used in this Chapter.

[INSERT FIGURE 7.2 HERE]

Figure 7.2: RF and ERF estimates derived by two methods, for the example of $4 \times \text{CO}_2$ experiments in one climate model. N is the net energy imbalance at the top of atmosphere and ΔT the global-mean surface temperature change. The fixed sea-surface temperature ERF estimate is from an atmosphere-land model averaged over 30 years. The regression estimate is from 150 years of a coupled model simulation after an instantaneous quadrupling of CO_2 , with the N from individual years in this regression shown as black diamonds. The stratospherically-adjusted RF is the tropopause energy imbalance from otherwise identical radiation calculations at $1 \times$ and $4 \times \text{CO}_2$ concentrations. Figure follows Andrews et al. (2012). See also Figure 8.1.

Figure 7.3 links the former terminology of aerosol direct, semi-direct and indirect effects with the new terminology used in this Chapter and in Chapter 8. The radiative forcing from aerosol-radiation interactions (abbreviated RFari) encompasses radiative effects from anthropogenic aerosols before any adjustment takes place, and corresponds to what is usually referred to as the aerosol direct effect. Rapid adjustments induced by aerosol radiative effects on the surface energy budget, the atmospheric profile and cloudiness contribute to the effective radiative forcing from aerosol-radiation interactions (abbreviated ERFari). They include what has earlier been referred to as the semi-direct effect. The radiative forcing from aerosol-cloud interactions (abbreviated RFaci) refers to the instantaneous effect on cloud albedo due to changing concentrations of cloud condensation and ice nuclei, also known as the Twomey effect. All subsequent changes to the cloud lifetime and thermodynamics are rapid adjustments, which contribute to the effective radiative forcing from aerosol-cloud interactions (abbreviated ERFaci). RFaci is a theoretical construct that is not easy to separate from other aerosol-cloud interactions and is therefore not quantified in this Chapter.

[INSERT FIGURE 7.3 HERE]

Figure 7.3: Schematic of the new terminology used in this assessment report (AR5) for aerosol-radiation and aerosol-cloud interactions and how they relate to the terminology used in AR4. The blue arrows depict solar radiation, the grey arrows terrestrial radiation, and the brown arrow symbolises the importance of couplings between the surface and the cloud layer for rapid adjustments. See text for further details.

7.1.4 Chapter Roadmap

For the first time in the IPCC WGI assessment reports, clouds and aerosols are discussed together in a single chapter. Doing so allows us to assess, and place in context, recent developments in a large and growing area of climate change research. In addition to assessing cloud feedbacks and aerosol forcings, which were covered in previous assessment reports in a less unified manner, it becomes possible to assess understanding of the multiple interactions among aerosols, clouds and precipitation and their relevance for climate and climate change. This chapter assesses the climatic roles and feedbacks of water vapour, lapse rate and clouds (Section 7.2), discusses aerosol-radiation (Section 7.3) and aerosol-cloud (Section 7.4) interactions, and quantifies the resulting aerosol radiative forcing on climate (Section 7.5). It also introduces the physical basis for the precipitation responses to aerosols and climate changes (Section 7.6) noted later in the report, and assesses geoengineering methods based on solar radiation management (Section 7.7).

7.2 Clouds

This section summarises our understanding of clouds in the current climate from observations and process models; advances in the representation of cloud processes in climate models since AR4; assessment of cloud, water vapour and lapse rate feedbacks and adjustments; and the radiative forcing due to clouds induced by moisture released by two anthropogenic processes (air traffic and irrigation). Aerosol-cloud interactions are assessed in Section 7.4. The fidelity of climate model simulations of clouds in the current climate is assessed in Chapter 9.

7.2.1 Clouds in the Present-Day Climate System

7.2.1.1 Cloud Formation, Cloud Types, and Cloud Climatology

To form a cloud, air must cool or moisten until it is sufficiently supersaturated to activate some of the available condensation or freezing nuclei. Clouds may be composed of liquid water (possibly supercooled), ice, or both (mixed phase). The nucleated cloud particles are initially very small, but grow by vapour deposition. Other microphysical mechanisms dependent on the cloud phase (e.g., droplet collision and coalescence for liquid clouds, riming and Wegener-Bergeron-Findeisen processes for mixed-phase clouds, and crystal aggregation in ice clouds) can produce a broader spectrum of particle sizes and types; turbulent mixing produces further variations in cloud properties on scales from kilometres to less than a centimetre (Davis et al., 1999; Bodenschatz et al., 2010). If and when some of the droplets or ice particles become large enough, these will fall out of the cloud as precipitation.

Atmospheric flows often organise convection and associated clouds into coherent systems having scales from tens to thousands of kilometres, such as cyclones or frontal systems. These represent a significant modelling and theoretical challenge, since they are usually too large to represent within the limited domains of cloud-resolving models (Section 7.2.2.1), but are also not well resolved nor parameterised by most climate models; this gap however is beginning to close (Section 7.2.2.2). Finally, clouds and cloud systems are organized by larger-scale circulations into different regimes such as deep convection near the equator, subtropical marine stratocumulus, or midlatitude storm tracks guided by the tropospheric westerly jets. Figure 7.4 shows a selection of widely occurring cloud regimes schematically and as they might appear in a typical geostationary satellite image.

[INSERT FIGURE 7.4 HERE]

Figure 7.4: Diverse cloud regimes reflect diverse meteorology. (a) A visible-wavelength geostationary satellite image shows (from top to bottom) expanses and long arcs of cloud associated with extratropical cyclones, subtropical coastal stratocumulus near Baja California breaking up into shallow cumulus clouds in the central Pacific, and mesoscale convective systems outlining the Pacific intertropical convergence zone (ITCZ). (b) A schematic section along the dashed line from the orange star to the orange circle in panel (a), through a typical warm front of an extratropical cyclone. It shows (from right to left) multiple layers of upper-tropospheric ice (cirrus) and mid-tropospheric water (altostratus) cloud in the upper-tropospheric outflow from the frontal zone, an extensive region of nimbostratus associated with frontal uplift and turbulence-driven boundary layer cloud in the warm sector. (c) A schematic section along the dashed line from the red star to the red circle in panel (a), along the low-level trade wind flow from a subtropical west coast of a continent to the ITCZ. It shows (from right to left) typical low-latitude cloud mixtures, shallow stratocumulus trapped under a strong subsidence inversion above the cool waters of the oceanic upwelling zone near the coast, and shallow cumulus over warmer waters further offshore transitioning to precipitating cumulonimbus cloud systems with extensive cirrus anvils associated with rising air motions in the ITCZ.

New satellite sensors and new analysis of previous datasets have given us a clearer picture of the Earth's clouds since AR4. A notable example is the launch in 2006 of two coordinated, active sensors, the cloud profiling radar (CPR) on the CloudSat satellite (Stephens et al., 2002) and the CALIOP lidar on board the CALIPSO satellite (Winker et al., 2009). These sensors have significantly improved our ability to quantify vertical profiles of cloud occurrence and water content (see Figures 7.5 and 7.6), and complement the detection capabilities of passive multispectral sensors (e.g., Stubenrauch et al., 2010; Chan and Comiso, 2011). Satellite cloud-observing capacities are reviewed by Stubenrauch et al. (2013).

Clouds cover roughly two thirds of the globe (Figure 7.5a,c), with a more precise value depending on both the optical depth threshold used to define cloud and the spatial scale of measurement (Wielicki and Parker, 1992; Stubenrauch et al., 2013). The midlatitude oceanic storm tracks and tropical precipitation belts are particularly cloudy, while continental desert regions and the central subtropical oceans are relatively cloud-free. Clouds are composed of liquid at temperatures above 0°C, ice below about -38°C (e.g., Koop et al., 2000), and either or both phases at intermediate temperatures (Figure 7.5b). Throughout most of the troposphere, temperatures at any given altitude are usually warmer in the tropics, but clouds also extend higher there such that ice cloud amounts are no less than those at high latitudes. At any given time, most clouds are not precipitating (Figure 7.5d).

In this chapter cloud above the 440 hPa pressure level is considered “high,” that below the 680 hPa level “low,” and that in-between is considered mid-level. Most high cloud (mainly cirrus and deep cumulus outflows) occurs near the equator and over tropical continents, but can also be seen in the midlatitude storm track regions and over midlatitude continents in summer (Figure 7.6a,e); it is produced by the storms generating most of the global rainfall in regions where tropospheric air motion is upward, such that

dynamical, rainfall and high-cloud fields closely resemble one another (Figure 7.6d, h). Mid-level cloud (Figure 7.6b,f), comprising a variety of types, is prominent in the storm tracks and some occurs in the intertropical convergence zone (ITCZ). Low cloud (Figure 7.6c,g), including shallow cumulus and stratiform cloud, occurs over essentially all oceans but is most prevalent over cooler subtropical oceans and in polar regions. It is less common over land, except at night and in winter.

Overlap between cloud layers has long been an issue both for satellite (or ground-based) detection and for calculating cloud radiative effects. Active sensors show more clearly that low clouds are prevalent in nearly all types of convective systems, and are often underestimated by models (Chepfer et al., 2008; Naud et al., 2010; Haynes et al., 2011). Cloud layers at different levels overlap less often than typically assumed in general circulation models (GCM), especially over high-latitude continents and subtropical oceans (Naud et al., 2008; Mace et al., 2009), and the common assumption that the radiative effects of precipitating ice can be neglected is not necessarily warranted (Waliser et al., 2011). New observations have led to revised treatments of overlap in some models, which significantly affects cloud radiative effects (Pincus et al., 2006; Shonk et al., 2012). Active sensors have also been useful in detecting low-lying Arctic clouds over sea ice (Kay et al., 2008), improving our ability to test climate model simulations of the interaction between sea ice loss and cloud cover (Kay et al., 2011).

[INSERT FIGURE 7.5 HERE]

Figure 7.5: (a) Annual mean cloud fractional occurrence (CloudSat/CALIPSO 2B-GEOPROF-LIDAR dataset for 2006–2011; Mace et al., 2009); (b) annual zonal mean liquid water path (blue shading, microwave radiometer dataset for 1988–2005 from O’Dell et al. (2008)) and total water path (ice path shown with grey shading, from CloudSat 2C-ICE dataset for 2006–2011 from Deng et al. (2010) over oceans). The 90% uncertainty ranges, assessed to be approximately 60–140% of the mean for the liquid and total water paths, are schematically indicated by the error bars. (c-d) latitude-height sections of annual zonal mean cloud (including precipitation falling from cloud) occurrence and precipitation (attenuation-corrected radar reflectivity >0 dBZ) occurrence; the latter has been doubled to make use of a common colour scale (2B-GEOPROF-LIDAR dataset). The dashed curves show the annual-mean 0°C and –38°C isotherms.

[INSERT FIGURE 7.6 HERE]

Figure 7.6: (a-d) December-January-February mean high, middle and low cloud cover from CloudSat/CALIPSO 2B-GEOPROF R04 and 2B-GEOPROF-LIDAR P1.R04 datasets for 2006–2011 (Mace et al., 2009), 500 hPa vertical pressure velocity (colours, from ERA-Interim for 1979–2010; Dee et al., 2011), and GPCP (Global Precipitation Climatology Project) version 2.2 precipitation rate (1981–2010, grey contours at 3 mm day⁻¹ in dash and 7 mm day⁻¹ in solid); (e-h) same as (a-d), except for June-July-August. For low clouds, the CALIPSO-only GOCCP dataset for 2007–2010 (Chepfer et al., 2010) is used at locations where it indicates a larger fractional cloud cover, because the GEOPROF dataset removes some clouds with tops at altitudes below 750 m. Low cloud amounts are probably underrepresented in regions of high cloud (Chepfer et al., 2008), although not as severely as with earlier satellite instruments.

7.2.1.2 Effects of Clouds on Earth’s Radiation Budget

The effect of clouds on Earth’s present-day top-of-atmosphere (TOA) radiation budget, or cloud radiative effect (CRE), can be inferred from satellite data by comparing upwelling radiation in cloudy and non-cloudy conditions (Ramanathan et al., 1989). By enhancing the planetary albedo, cloudy conditions exert a global and annual shortwave cloud radiative effect (SWCRE) of approximately –50 W m⁻² and, by contributing to the greenhouse effect, exert a mean longwave effect (LWCRE) of approximately +30 W m⁻², with a range of 10% or less between published satellite estimates (Loeb et al., 2009). Some of the apparent LWCRE comes from the enhanced water vapour coinciding with the natural cloud fluctuations used to measure the effect, so the true cloud LWCRE is about 10% smaller (Sohn et al., 2010). The net global mean CRE of approximately –20 W m⁻² implies a net cooling effect of clouds on the current climate. Due to the large magnitudes of the SWCRE and LWCRE, clouds have the potential to cause significant climate feedback (Section 7.2.5). The sign of this feedback on climate change cannot be determined from the sign of CRE in the current climate, but depends instead on how climate-sensitive the properties are that govern the LWCRE and SWCRE.

[INSERT FIGURE 7.7 HERE]

Figure 7.7: Distribution of annual-mean top of atmosphere (a) shortwave, (b) longwave, (c) net cloud radiative effects averaged over the period 2001–2011 from the CERES-EBAF -TOA-Ed2.6r dataset (Loeb et al., 2009) and (d) precipitation rate (1981–2000 average from the GPCP version 2.2 dataset; Adler et al., 2003).

The regional patterns of annual-mean TOA CRE (Figure 7.7a-b) reflect those of the altitude-dependent cloud distributions. High clouds, which are cold compared to the clear-sky radiating temperature, dominate patterns of LWCRE, while the SWCRE is sensitive to optically thick clouds at all altitudes. SWCRE also depends on the available sunlight, so for example is sensitive to the diurnal and seasonal cycles of cloudiness. Regions of deep, thick cloud with large positive LWCRE and large negative SWCRE tend to accompany precipitation (Figure 7.7d), showing their intimate connection with the hydrological cycle. The net CRE is negative over most of the globe and most negative in regions of very extensive low-lying reflective stratus and stratocumulus cloud such as the midlatitude and eastern subtropical oceans, where SWCRE is strong but LWCRE is weak (Figure 7.7c). In these regions, the spatial distribution of net CRE on seasonal timescales is strongly correlated with measures of low-level stability or inversion strength (Klein and Hartmann, 1993; Williams et al., 2006; Wood and Bretherton, 2006; Zhang et al., 2010).

Clouds also exert a CRE at the surface and within the troposphere, thus affecting the hydrological cycle and circulation (Section 7.6), though this aspect of CRE has received less attention. The net downward flux of radiation at the surface is sensitive to the vertical and horizontal distribution of clouds. It has been estimated more accurately through radiation budget measurements and cloud profiling (Kato et al., 2011). Based on these observations, the global mean surface downward longwave flux is about 10 W m^{-2} larger than the average in climate models, probably due to insufficient model-simulated cloud cover or lower tropospheric moisture (Stephens et al., 2012). This is consistent with a global-mean precipitation rate in the real world somewhat larger than current observational estimates.

7.2.2 Cloud Process Modelling

Cloud formation processes span scales from the sub-micrometre scale of CCN, to cloud-system scales of up to thousands of kilometres. This range of scales is impossible to resolve with numerical simulations on computers, and this is not expected to change in the foreseeable future. Nonetheless progress has been made through a variety of modelling strategies, which are outlined briefly in this section, followed by a discussion in Section 7.2.3 of developments in representing clouds in global models. The implications of these discussions are synthesised in Section 7.2.3.5.

7.2.2.1 Explicit Simulations in Small Domains

High-resolution models in small domains have been widely used to simulate interactions of turbulence with various types of clouds. The grid spacing is chosen to be small enough to resolve explicitly the dominant turbulent eddies that drive cloud heterogeneity, with the effects of smaller-scale phenomena parameterized. Such models can be run in idealised settings, or with boundary conditions for specific observed cases. This strategy is typically called large-eddy simulation (LES) when boundary-layer eddies are resolved, and cloud-resolving model (CRM) when only deep cumulus motions are well resolved. It is useful not only in simulating cloud and precipitation characteristics, but also in understanding how turbulent circulations within clouds transport and process aerosols and chemical constituents. It can be applied to any type of cloud system, on any part of the Earth. Direct numerical simulation (DNS) can be used to study turbulence and cloud microphysics on scales of a few meters or less (e.g., Andrejczuk et al., 2006) but cannot span crucial meteorological scales and is not further considered here.

Cloud microphysics, precipitation and aerosol interactions are treated with varying levels of sophistication, and remain a weak point in all models regardless of resolution. For example, recent comparisons to satellite data show that liquid water clouds in CRMs generally begin to rain too early in the day (Suzuki et al., 2011). Especially for ice clouds, and for interactions between aerosols and clouds, our understanding of the basic micro-scale physics is not yet adequate, although it is improving. Moreover, microphysical effects are quite sensitive to co-variations of velocity and composition down to very small scales. High-resolution models, such as those used for LES, explicitly calculate most of these variations, and so provide much more of the information needed for microphysical calculations, whereas in a GCM they are not explicitly available. For these reasons, low-resolution (e.g., climate) models will have even more trouble representing local aerosol-cloud interactions than will high-resolution models. Parameterizations are under development that could account for the small-scale variations statistically (e.g., Larson and Golaz, 2005) but have not been used in the CMIP5 (Coupled Model Intercomparison Project Phase 5) simulations.

High-resolution models have enhanced our understanding of cloud processes in several ways. First, they can help interpret in-situ and high-resolution remote sensing observations (e.g., Stevens et al., 2005b; Blossey et al., 2007; Fridlind et al., 2007). Second, they have revealed important influences of small-scale interactions, turbulence, entrainment and precipitation on cloud dynamics that must eventually be accounted for in parameterizations (e.g., Krueger et al., 1995; Derbyshire et al., 2004; Kuang and Bretherton, 2006; Ackerman et al., 2009). Third, they can be used to predict how cloud system properties (such as cloud cover, depth, or radiative effect) may respond to climate changes (e.g., Tompkins and Craig, 1998; Bretherton et al., 2013). Fourth, they have become an important tool in testing and improving parameterizations of cloud-controlling processes such as cumulus convection, turbulent mixing, small-scale horizontal cloud variability, and aerosol-cloud interactions (Randall et al., 2003; Rio and Hourdin, 2008; Stevens and Seifert, 2008; Lock, 2009; Del Genio and Wu, 2010; Fletcher and Bretherton, 2010), as well as the interplay between convection and large-scale circulations (Kuang, 2008).

Different aspects of clouds, and cloud types, require different grid resolutions. CRMs of deep convective cloud systems with horizontal resolutions of 2 km or finer (Bryan et al., 2003) can represent some statistical properties of the cloud system, including fractional area coverage of cloud (Xu et al., 2002), vertical thermodynamic structure (Blossey et al., 2007), the distribution of updraughts and downdraughts (Khairoutdinov et al., 2009), and organisation into mesoscale convective systems (Grabowski et al., 1998). Modern high-order turbulence closure schemes may allow some statistics of boundary-layer cloud distributions, including cloud fractions and fluxes of moisture and energy, to be reasonably simulated even at horizontal resolution of 1 km or larger (Cheng and Xu, 2006; Cheng and Xu, 2008). Finer grids (down to hundreds of meters) better resolve individual storm characteristics such as vertical velocity or tracer transport. Some cloud ensemble properties remain sensitive to CRM microphysical parameterization assumptions regardless of resolution, particularly the vertical distribution and optical depth of clouds containing ice.

Because of these requirements, it is computationally demanding to run a CRM in a domain large enough to capture convective organisation or perform regional forecasts. Some studies have created smaller regions of CRM-like resolution within realistically forced regional-scale models (e.g., Zhu et al., 2010; Boutle and Abel, 2012; Zhu et al., 2012), a special case of the common “nesting” approach for regional downscaling (see Section 9.6). One application has been to orographic precipitation, both associated with extratropical cyclones (e.g., Garvert et al., 2005) and with explicitly simulated cumulus convection (e.g., Hohenegger et al., 2008); better resolution of the orography improves the simulation of precipitation initiation and wind drift of falling rain and snow between watersheds.

LES of shallow cumulus cloud fields with horizontal grid spacing of about 100 m and vertical grid spacing of about 40 m produces vertical profiles of cloud fraction, temperature, moisture and turbulent fluxes that agree well with available observations (Siebesma et al., 2003), though the simulated precipitation efficiency still shows some sensitivity to microphysical parameterizations (vanZanten et al., 2011). LES of stratocumulus-topped boundary layers reproduces the turbulence statistics and vertical thermodynamic structure well (e.g., Stevens et al., 2005b; Ackerman et al., 2009), and has been used to study the sensitivity of stratocumulus properties to aerosols (e.g., Savic-Jovicic and Stevens, 2008; Xue et al., 2008) and meteorological conditions. However, the simulated entrainment rate and cloud liquid water path are sensitive to the underlying numerical algorithms, even with vertical grid spacings as small as 5 m, due to poor resolution of the sharp capping inversion (Stevens et al., 2005a).

These grid requirements mean that low-cloud processes dominating the known uncertainty in cloud feedback cannot be explicitly simulated except in very small domains. Thus, notwithstanding all of the above benefits of explicit cloud modeling, these models cannot on their own quantify global cloud feedbacks or aerosol-cloud interactions definitively. They are important however in suggesting and testing feedback and adjustment mechanisms (see Sections 7.2.5 and 7.4)

7.2.2.2 *Global Models with Explicit Clouds*

Since AR4, increasing computer power has led to three types of developments in global atmospheric models. First, models have been run with resolution that is higher than in the past, but not sufficiently high that

cumulus clouds can be resolved explicitly. Second, models have been run with resolution high enough to resolve (or “permit”) large individual cumulus clouds over the entire globe. In a third approach, the parameterizations of global models have been replaced by embedded CRMs. The first approach is assessed in Chapter 9. The other two approaches are discussed below.

Global cloud-resolving models (GCRMs) have been run with grid spacings as small as 3.5 km (Tomita et al., 2005; Putman and Suarez, 2011). At present GCRMs can only be used for relatively short simulations of a few simulated months to a year or two on the fastest supercomputers, but in the not-too distant future they may provide climate projections. GCRMs provide a consistent way to couple convective circulations to large-scale dynamics, but must still parameterize the effects of individual clouds, microphysics, and boundary-layer circulations.

Because they avoid the use of uncertain cumulus parameterizations, GCRMs better simulate many properties of convective circulations that are very challenging for many current conventional GCMs, including the diurnal cycles of precipitation (Sato et al., 2009) and the Asian summer monsoon (Oouchi et al., 2009). Inoue et al. (2010) showed that the cloudiness simulated by a GCRM is in good agreement with observations from CloudSat and CALIPSO, but the results are sensitive to the parameterizations of turbulence and cloud microphysics (Sato et al., 2010; Iga et al., 2011; Kodama et al., 2012).

Heterogeneous multiscale methods, in which CRMs are embedded in each grid cell of a larger scale model (Grabowski and Smolarkiewicz, 1999), have also been further developed as a way to realise some of the advantages of GCRMs but at less cost. This approach has come to be known as super-parameterization, because the CRM effectively replaces some of the existing GCM parameterizations (e.g., Khairoutdinov and Randall, 2001; Tao et al., 2009). Super-parameterized models, which are sometimes called multiscale modeling frameworks, occupy a middle ground between high-resolution “process models” and “climate models” (see Figure 7.8), in terms of both advantages and cost.

Like GCRMs, super-parameterized models give more realistic simulations of the diurnal cycle of precipitation (Khairoutdinov et al., 2005; Pritchard and Somerville, 2010) and the Madden-Julian Oscillation (Benedict and Randall, 2009) than most conventional GCMs; they can also improve aspects of the Asian monsoon and the El Niño-Southern Oscillation (Stan et al., 2010; DeMott et al., 2011). Moreover, because they also begin to resolve cloud-scale circulations, both strategies provide a framework for studying aerosol-cloud interactions that conventional GCMs lack (Wang et al., 2011b). Thus both types of global model provide important insights, but since neither of them fully resolves cloud processes especially for low clouds (see Section 7.2.2.1), their results must be treated with caution just as with conventional GCMs.

[INSERT FIGURE 7.8 HERE]

Figure 7.8: Model and simulation strategy for representing the climate system and climate processes at different space and time scales. Also shown are the ranges of space and time scales usually associated with cloud processes (orange, lower left) and the climate system (blue, upper right). Classes of models are usually defined based on the range of spatial scales they represent, which in the figure is roughly spanned by the text for each model class. The temporal scales simulated by a particular type of model vary more widely. For instance, climate models are often run for a few time steps for diagnostic studies, or can simulate millennia. Hence the figure indicates the typical timescales for which a given model is used. Computational power prevents one model from covering all time and space scales. Since the AR4 the development of global cloud resolving models (GCRM), and hybrid approaches such as GCMs using the “super-parameterization” approach (sometimes called the multiscale modelling framework or MMF), have helped fill the gap between climate system and cloud process models.

7.2.3 Parameterization of Clouds in Climate Models

7.2.3.1 Challenges of Parameterization

The representation of cloud microphysical processes in climate models is particularly challenging, in part because some of the fundamental details of these microphysical processes are poorly understood (particularly for ice- and mixed-phase clouds), and because spatial heterogeneity of key atmospheric properties occurs at scales significantly smaller than a GCM grid box. Such representation however affects many aspects of a model’s overall simulated climate including the Hadley circulation, precipitation patterns,

and tropical variability. Therefore continuing weakness in these parameterizations affects not only modeled climate sensitivity, but also the fidelity with which these other variables can be simulated or projected.

Most CMIP5 climate model simulations use horizontal resolutions of 100–200 km in the atmosphere, with vertical layers varying between 100 m near the surface to more than 1000 m aloft. Within regions of this size in the real world, there is usually enormous small-scale variability in cloud properties, associated with variability in humidity, temperature and vertical motion (Figure 7.16). This variability must be accounted for to accurately simulate cloud-radiation interaction, condensation, evaporation and precipitation, and other cloud processes that crucially depend on how cloud condensate is distributed across each grid box (Cahalan et al., 1994; Pincus and Klein, 2000; Larson et al., 2001; Barker et al., 2003).

The simulation of clouds in modern climate models involves several parameterizations that must work in unison. These include parameterization of turbulence, cumulus convection, microphysical processes, radiative transfer, and the resulting cloud amount (including the vertical overlap between different grid levels), as well as subgrid-scale transport of aerosol and chemical species. The system of parameterizations must balance simplicity, realism, computational stability and efficiency. Many cloud processes are unrealistic in current GCMs, and as such their cloud response to climate change remains uncertain.

Cloud processes and/or turbulence parameterization are important not only for the GCMs used in climate projections but also for specialized chemical-aerosol-climate models (see review by Zhang, 2008), for regional climate models, and indeed for the cloud process models described in Section 7.2.2 which must still parameterise small-scale and microphysical effects. The nature of the parameterization problem however shifts as model scale decreases. The following section will briefly assess recent developments relevant to GCMs.

7.2.3.2 *Recent Advances in Representing Cloud Microphysical Processes*

7.2.3.2.1 *Liquid clouds*

Recent development efforts have been focused on the introduction of more complex representations of microphysical processes, with the dual goals of coupling them better to atmospheric aerosols and linking them more consistently to the sub-grid variability assumed by the model for other calculations. For example, most CMIP3 climate models only predicted the average cloud and rain water mass in each grid cell at a given time, diagnosing the droplet concentration using empirical relationships based on aerosol mass (e.g., Boucher and Lohmann, 1995; Menon et al., 2002), or altitude and proximity to land. Many were forced to employ an arbitrary lower bound on droplet concentration to reduce the aerosol radiative forcing (Hoose et al., 2009). Such formulations oversimplify microphysically-mediated cloud variations.

By contrast, more models participating in CMIP5 predict both mass and number mixing ratios for liquid stratiform cloud. Some determine rain and snow number concentrations and mixing ratios (e.g., Morrison and Gettelman, 2008; Salzmann et al., 2010), allowing treatment of aerosol scavenging and the radiative effect of snow. Some models explicitly treat subgrid cloud water variability for calculating microphysical process rates (e.g., Morrison and Gettelman, 2008). Cloud droplet activation schemes now account more realistically for mixing, particle composition, and particle size (Abdul-Razzak and Ghan, 2000; Ghan et al., 2011; Liu et al., 2012). Despite such advances in internal consistency, a continuing weakness in GCMs (and to a much lesser extent GCRMs and super-parameterized models) is their inability to fully represent turbulent motions to which microphysical processes are highly sensitive.

7.2.3.2.2 *Mixed-phase and ice clouds*

Ice treatments are following a similar path to those for liquid water, and face similar, but greater challenges because of the greater complexity of ice processes. Many CMIP3 models predicted the condensed water amount in just two categories—cloud and precipitation—with a temperature-dependent partitioning between liquid and ice within either category. Although supersaturation with respect to ice is commonly observed at low temperatures, only one CMIP3 GCM (ECHAM) allowed ice supersaturation (Lohmann and Kärcher, 2002).

Many climate models now include separate, physically-based equations for cloud liquid versus cloud ice, and for rain versus snow, allowing a more realistic treatment of mixed-phase processes and ice supersaturation

(Liu et al., 2007; Tompkins et al., 2007; Gettelman et al., 2010; Salzman et al., 2010; see also Section 7.4.4). These new schemes are tested in a single-column model against cases observed in field campaigns (e.g., Klein et al., 2009) or against satellite observations (e.g., Kay et al., 2012), and provide superior simulations of cloud structure than typical CMIP3 parameterizations (Kay et al., 2012). However new observations reveal complexities not correctly captured by even relatively advanced schemes (Ma et al., 2012a). New representations of the Wegener-Bergeron-Findeisen process in mixed-phase clouds (Storelvmo et al., 2008b; Lohmann and Hoose, 2009) compare the rate at which the pre-existing ice crystals deplete the water vapour with the condensation rate for liquid water driven by vertical updraught speed (Korolev, 2007); these are not yet included in CMIP5 models. Climate models are increasingly representing detailed microphysics, including mixed-phase processes, inside convective clouds (Fowler and Randall, 2002; Lohmann, 2008; Song and Zhang, 2011). Such processes can influence storm characteristics like strength and electrification, and are crucial for fully representing aerosol-cloud interactions, but are still not included in most climate models; their representation is moreover subject to all the caveats noted in Section 7.2.3.1.

7.2.3.3 *Recent Advances in Parameterizing Moist Turbulence and Convection*

Both the mean state and variability in climate models are sensitive to the parameterization of cumulus convection. Since AR4, the development of convective parameterization has been driven largely by rapidly growing use of process models, in particular LES and CRMs, to inform parameterization development (e.g., Hourdin et al., 2013).

Accounting for greater or more state-dependent entrainment of air into deep cumulus updraughts has improved simulations of the Madden-Julian Oscillation, tropical convectively-coupled waves, and mean rainfall patterns in some models (Bechtold et al., 2008; Song and Zhang, 2009; Chikira and Sugiyama, 2010; Hohenegger and Bretherton, 2011; Mapes and Neale, 2011; Del Genio et al., 2012; Kim et al., 2012) but usually at the expense of a degraded simulation of the mean state. In another model, revised criteria for convective initiation and parameterizations of cumulus momentum fluxes improved ENSO and tropical vertical temperature profiles (Neale et al., 2008; Richter and Rasch, 2008). Since AR4, more climate models have adopted cumulus parameterizations that diagnose the expected vertical velocity in cumulus updraughts (e.g., Del Genio et al., 2007; Park and Bretherton, 2009; Chikira and Sugiyama, 2010; Donner et al., 2011), in principle allowing more complete representations of aerosol activation, cloud microphysical evolution, and gravity wave generation by the convection.

Several new parameterizations couple shallow cumulus convection more closely to moist boundary layer turbulence (Siebesma et al., 2007; Neggers, 2009; Neggers et al., 2009; Couvreux et al., 2010) including cold pools generated by nearby deep convection (Grandpeix and Lafore, 2010). Many of these efforts have led to more accurate simulations of boundary-layer cloud radiative properties and vertical structure (e.g., Park and Bretherton, 2009; Köhler et al., 2011), and have ameliorated the common problem of premature deep convective initiation over land in one CMIP5 GCM (Rio et al., 2009).

7.2.3.4 *Recent Advances in Parameterizing Cloud Radiative Effects*

Some models have improved representation of subgrid-scale cloud variability, which has important effects on grid-mean radiative fluxes and precipitation fluxes, for example based on the use of probability density functions of thermodynamic variables (Sommeria and Deardorff, 1977; Watanabe et al., 2009). Stochastic approaches for radiative transfer can account for this variability in a computationally efficient way (Barker et al., 2008). New treatments of cloud overlap have been motivated by new observations (Section 7.2.1.1). Despite these advances, the CMIP5 models continue to exhibit the "too few, too bright" low-cloud problem (Nam et al., 2012), with a systematic overestimation of cloud optical depth and underestimation of cloud cover.

7.2.3.5 *Cloud Modelling Synthesis*

Global climate models used in CMIP5 have improved their representation of cloud processes relative to CMIP3, but still face challenges and uncertainties, especially regarding details of small-scale variability that are crucial for aerosol-cloud interactions (see Section 7.4). Finer-scale LES and CRM models are much better able to represent this variability and are an important research tool, but still suffer from imperfect

representations of aerosol and cloud microphysics and known biases. Most CRM and LES studies do not span the large space and time scales needed to fully determine the interactions among different cloud regimes and the resulting net planetary radiative effects. Thus our assessments in this chapter do not regard any model type on its own as definitive, but weigh the implications of process model studies in assessing the quantitative results of the global models.

7.2.4 *Water-Vapour and Lapse Rate Feedbacks*

Climate feedbacks determine the sensitivity of global surface temperature to external forcing agents. Water vapour, lapse rate and cloud feedbacks each involve moist atmospheric processes closely linked to clouds, and in combination, produce most of the simulated climate feedback and most of its inter-model spread (Section 9.7). The radiative feedback from a given constituent can be quantified as its impact (other constituents remaining equal) on the top-of-atmosphere net downward radiative flux per degree of global surface (or near-surface) temperature increase, and may be compared with the basic “black-body” response of $-3.4 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$ (Hansen et al., 1984). This definition assigns positive values to positive feedbacks, in keeping with the literature on this topic but contradictory to the conventions sometimes adopted in other climate research.

7.2.4.1 *Water-Vapour Response and Feedback*

As pointed out in previous reports (Section 8.6.3.1 in Randall et al., 2007), physical arguments and models of all types suggest global water vapour amounts increase in a warmer climate, leading to a positive feedback via its enhanced greenhouse effect. The saturated water vapour mixing ratio (WVMR) increases nearly exponentially and very rapidly with temperature, at 6–10% per $^{\circ}\text{C}$ near the surface, and even more steeply aloft (up to 17% per $^{\circ}\text{C}$) where air is colder. Mounting evidence indicates that any changes in relative humidity in warmer climates would have much less impact on specific humidity than the above increases, at least in a global and statistical sense. Hence the overall WVMR is expected to increase at a rate similar to the saturated WVMR.

Because global temperatures have been rising, the above arguments imply WVMR should be rising accordingly, and multiple observing systems indeed show this (Sections 2.5.4 and 2.5.5). A study challenging the water vapour increase (Paltridge et al., 2009) used an old reanalysis product, whose trends are contradicted by newer ones (Dessler and Davis, 2010) and by actual observations (Chapter 2). The study also reported decreasing relative humidity in data from Australian radiosondes, but more complete studies show Australia to be exceptional in this respect (Dai et al., 2011). Thus data remain consistent with the expected global feedback.

Some studies have proposed that the response of upper-level humidity to natural fluctuations in the global-mean surface temperature is informative about the feedback. However, small changes to the global mean (primarily from ENSO) involve geographically heterogeneous temperature change patterns, the responses to which may be a poor analogue for global warming (Hurley and Galewsky, 2010a). Most climate models reproduce these natural responses reasonably well (Gettelman and Fu, 2008; Dessler and Wong, 2009), providing additional evidence that they at least represent the key processes.

The “last-saturation” concept approximates the WVMR of air by its saturation value when it was last in a cloud (see Sherwood et al., 2010a for a review), which can be inferred from trajectory analysis. Studies since the AR4 using a variety of models and observations (including concentrations of water vapour isotopes) support this concept (Sherwood and Meyer, 2006; Galewsky and Hurley, 2010). The concept has clarified what determines relative humidity in the subtropical upper troposphere and placed the water-vapour feedback on firmer theoretical footing by directly linking actual and saturation WVMR values (Hurley and Galewsky, 2010b). CRMs show that convection can adopt varying degrees of self-aggregation (e.g., Muller and Held, 2012), which could modify the water vapour or other feedbacks if this were climate-sensitive, although observations do not suggest aggregation changes have a large net radiative effect (Tobin et al., 2012).

In a warmer climate, an upward shift of the tropopause and poleward shift of the jets and associated climate zones are expected (Sections 2.7.4 and 2.7.5) and simulated by most GCMs (Section 10.3.3). These changes

account, at least qualitatively, for robust regional changes in the relative humidity simulated in warmer climate by GCMs, including decreases in the subtropical troposphere and tropical uppermost troposphere, and increases near the extratropical tropopause and high latitudes (Sherwood et al., 2010b). This pattern may be amplified however by non-uniform atmospheric temperature or wind changes (Hurley and Galewsky, 2010b). It is also the apparent cause of most model-predicted changes in mid- and upper-level cloudiness patterns (Wetherald and Manabe, 1980; Sherwood et al., 2010b; see also Section 7.2.5.2). Idealised CRM simulations of warming climates also show upward shifts of the humidity patterns with little change in the mean (e.g., Kuang and Hartmann, 2007; Romps, 2011).

It remains unclear whether stratospheric water vapour contributes significantly to climate feedback. Observations have shown decadal variations in stratospheric water vapour, which may have affected the planetary radiation budget somewhat (Solomon et al., 2010) but are not clearly linked to global temperature (Section 3.4.2.4 in Trenberth et al., 2007). A strong positive feedback from stratospheric water vapour was reported in one GCM, but with parameter settings that produced an unrealistic present climate (Joshi et al., 2010).

7.2.4.2 Relationship Between Water Vapour and Lapse-Rate Feedbacks

The lapse rate (decrease of temperature with altitude) should, in the tropics, change roughly as predicted by a moist adiabat, due to the strong restoring influence of convective heating. This restoring influence has now been directly inferred from satellite data (Lebsock et al., 2010), and the near-constancy of tropical atmospheric stability and deep-convective thresholds over recent decades is also now observable in sea surface temperature (SST) and deep convective data (Johnson and Xie, 2010). The stronger warming of the atmosphere relative to the surface produces a negative feedback on global temperature because the warmed system radiates more thermal emission to space for a given increase in surface temperature than in the reference case where the lapse rate is fixed. This feedback varies somewhat among models because lapse rates in middle and high latitudes, which decrease less than in the tropics, do so differently among models (Dessler and Wong, 2009).

[INSERT FIGURE 7.9 HERE]

Figure 7.9: Clear-sky feedback parameters predicted by CMIP3 GCMs, with boxes showing interquartile range and whiskers showing extreme values. At left is shown the total radiative response including the Planck response. In the darker shaded region is shown the traditional breakdown of this into a Planck response and individual feedbacks from water vapour and lapse rate. In the lighter-shaded region at right are the equivalent three parameters calculated in an alternative, relative humidity-based framework. In this framework all three components are both weaker and more consistent among the models. Data are from Held and Shell (2012).

As shown by Cess (1975) and discussed in the AR4 (Randall et al., 2007), models with a more negative lapse-rate feedback tend to have a more positive water-vapour feedback. Cancellation between these is close enough that their sum has a 90% range in CMIP3 models of only $+0.96$ to $+1.22 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$ (based on a Gaussian fit to the data of Held and Shell (2012), see Figure 7.9) with essentially the same range in CMIP5 (Section 9.7). The physical reason for this cancellation is that as long as water vapour infrared absorption bands are nearly saturated, outgoing longwave radiation is determined by relative humidity (Ingram, 2010) which exhibits little global systematic change in any model (Section 7.2.4.1). In fact, Held and Shell (2012) and Ingram (2013a) argue that it makes more sense physically to redefine feedbacks in a different analysis framework in which relative humidity, rather than specific humidity, is the feedback variable. Analysed in that framework the inherent stabilisation by the Planck response is weaker, but the water-vapour and lapse-rate feedbacks are also very small; thus the traditional view of large and partially compensating feedbacks has, arguably, arisen from arbitrary choices made when the analysis framework was originally set out, rather than being an intrinsic feature of climate or climate models.

There is some observational evidence (Section 2.4.4) suggesting tropical lapse rates might have increased in recent decades in a way not simulated by models (Section 9.4.1.4.2). Since the combined lapse-rate and water-vapour feedback depends on relative humidity change, however, the imputed lapse-rate variations would have little influence on the total feedback or climate sensitivity even if they were a real warming response (Ingram, 2013b). In summary, there is increased evidence for a strong, positive feedback (measured in the traditional framework) from the combination of water-vapour and lapse-rate changes since AR4, with no reliable contradictory evidence.

7.2.5 *Cloud Feedbacks and Rapid Adjustments to CO₂*

The dominant source of spread among GCM climate sensitivities in AR4 was due to diverging cloud feedbacks, particularly due to low clouds, and this continues to be true (Section 9.7). All global models continue to produce a near-zero to moderately strong positive net cloud feedback. Progress has been made since the AR4 in understanding the reasons for positive feedbacks in models and providing a stronger theoretical and observational basis for some mechanisms contributing to them. There has also been progress in quantifying feedbacks—including separating the effects of different cloud types, using radiative-kernel residual methods (Soden et al., 2008) and by computing cloud effects directly (e.g., Zelinka et al., 2012b)—and in distinguishing between feedback and adjustment responses (Section 7.2.5.6).

Until very recently cloud feedbacks have been diagnosed in models by differencing cloud radiative effects in doubled CO₂ and control climates, normalised by the change in global mean surface temperature. Different diagnosis methods do not always agree, and some simple methods can make positive cloud feedbacks look negative by failing to account for the nonlinear interaction between cloud and water vapour (Soden and Held, 2006). Moreover, it is now recognised that some of the cloud changes are induced directly by the atmospheric radiative effects of CO₂ independently of surface warming, and are therefore rapid adjustments rather than feedbacks (Section 7.2.5.6). Most of the published studies available for this assessment did not separate these effects, and only the total response is assessed here unless otherwise noted. It appears that the adjustments are sufficiently small in most models that general conclusions regarding feedbacks are not significantly affected.

Cloud changes cause both longwave (greenhouse warming) and shortwave (reflective cooling) effects, which combine to give the overall cloud feedback or forcing adjustment. Cloud feedback studies point to five aspects of the cloud response to climate change which are distinguished here: changes in high-level cloud altitude, effects of hydrological cycle and storm track changes on cloud systems, changes in low-level cloud amount, microphysically-induced opacity (optical depth) changes, and changes in high-latitude clouds. Finally, recent research on the rapid cloud adjustments to CO₂ is assessed. Feedbacks involving aerosols (Section 7.3.5) are not considered here, and the discussion focuses only on mechanisms affecting the top-of-atmosphere radiation budget.

7.2.5.1 *Feedback Mechanisms Involving the Altitude of High-Level Cloud*

A dominant contributor of positive cloud feedback in models is the increase in the height of deep convective outflows tentatively attributed in AR4 to the so-called “fixed anvil-temperature” mechanism (Hartmann and Larson, 2002). According to this mechanism, the average outflow level from tropical deep convective systems is determined in steady state by the highest point at which water vapour cools the atmosphere significantly through infrared emission; this occurs at a particular water vapour partial pressure, therefore at a similar temperature (higher altitude) as climate warms. A positive feedback results because, since the cloud top temperature does not keep pace with that of the troposphere, its emission to space does not increase at the rate expected for the no-feedback system. This occurs at all latitudes and has long been noted in model simulations (Hansen et al., 1984; Cess et al., 1990). This mechanism, with a small modification to account for lapse-rate changes, predicts roughly $+0.5 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$ of positive longwave feedback in GCMs (Zelinka and Hartmann, 2010), compared to an overall cloud-height feedback of $+0.35 (+0.09 \text{ to } +0.58) \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$ (Figure 7.9). Importantly, CRMs also reproduce this increase in cloud height (Tompkins and Craig, 1998; Kuang and Hartmann, 2007; Romps, 2011; Harrop and Hartmann, 2012).

On average, natural fluctuations in tropical high cloud amount exert little net top-of-atmosphere radiative effect in the current climate due to near-compensation between their longwave and shortwave cloud radiative effects (Harrison et al., 1990; Figure 7.7). Similar compensation can be seen in the opposing variations of these two components of the high-cloud feedback across GCMs (Figure 7.10). This might suggest that the altitude feedback could be similarly compensated. However, GCMs can reproduce the observed compensation in the present climate (Sherwood et al., 1994) without producing one under global warming. In the above-noted cloud-resolving simulations, the entire cloud field (including the typical base) moved upward, in accord with a general upward shift of tropospheric fields (Singh and O’Gorman, 2012) and with drying at levels near cloud base (Minschwaner et al., 2006; Sherwood et al., 2010b). This supports the

prediction of GCMs that the altitude feedback is not compensated by an increase in high-cloud thickness or albedo.

[INSERT FIGURE 7.10 HERE]

Figure 7.10: Cloud feedback parameters as predicted by GCMs for responses to CO₂ increase including rapid adjustments. Total feedback shown at left, with centre light-shaded section showing components attributable to clouds in specific height ranges (see Section 7.2.1.1), and right dark-shaded panel those attributable to specific cloud property changes where available. Type attribution reported for CMIP3 does not conform exactly to the definition used in CFMIP but is shown for comparison, with their “mixed” category assigned to middle cloud. CFMIP data (original and CFMIP2) are from Zelinka et al. (2012a, 2012b; 2013); CMIP3 from Soden and Vecchi (2011); and CMIP5 from Tomassini et al. (2013).

The observational record offers limited further support for the altitude increase. The global tropopause is rising as expected (Section 2.7.4). Observed cloud heights change roughly as predicted with regional, seasonal and interannual changes in near-tropopause temperature structure (Xu et al., 2007; Eitzen et al., 2009; Chae and Sherwood, 2010; Zelinka and Hartmann, 2011), although these tests may not be good analogues for global warming. Davies and Molloy (2012) report an apparent recent downward mean cloud height trend but this is probably an artefact (Evan and Norris, 2012); observed cloud height trends do not appear sufficiently reliable to test this cloud-height feedback mechanism (Section 2.5.7).

In summary, the consistency of GCM responses, basic understanding, strong support from process models, and weak further support from observations give us *high confidence* in a positive feedback contribution from increases in high-cloud altitude.

7.2.5.2 Feedback Mechanisms Involving the Amount of Middle and High Cloud

As noted in Section 7.2.5.1, models simulate a range of nearly-compensating differences in shortwave and longwave high-cloud feedbacks, consistent with different changes in high-cloud amount, but also show a net positive offset consistent with higher cloud altitude (Figure 7.10). However there is a tendency in most GCMs toward reduced middle and high cloud amount in warmer climates in low- and mid-latitudes, especially in the subtropics (Trenberth and Fasullo, 2009; Zelinka and Hartmann, 2010). This loss of cloud amount adds a positive shortwave and negative longwave feedback to the model average, which causes the average net positive feedback to appear to come from the shortwave part of the spectrum. The net effect of changes in amount of all cloud types averaged over models is a positive feedback of about $+0.2 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$, but this roughly matches the contribution from low clouds (see the following section), implying a near-cancellation of longwave and shortwave effects for the mid- and high-level amount changes.

Changes in predicted cloud cover are geographically correlated with simulated subtropical drying (Meehl et al., 2007), suggesting that they are partly tied to large-scale circulation changes including the poleward shifts found in most models (Wetherald and Manabe, 1980; Sherwood et al., 2010b; Section 2.7). Bender et al. (2012) and Eastman and Warren (2013) report poleward shifts in cloud since the 1970s consistent with those reported in other observables (Section 2.5.6) and simulated by most GCMs albeit with weaker amplitude (Yin, 2005). This shift of clouds to latitudes of weaker sunlight decreases the planetary albedo and would imply a strong positive feedback if it were due to global warming (Bender et al., 2012), although it is probably partly driven by other factors (Chapter 10, Section 10.3). The true amount of positive feedback coming from poleward shifts therefore remains highly uncertain, but is underestimated by GCMs if, as suggested by observational comparisons, the shifts are underestimated (Johanson and Fu, 2009; Allen et al., 2012).

The upward mass flux in deep clouds should decrease in a warmer climate (Section 7.6.2), which might contribute to cloudiness decreases in storm tracks or the ITCZ (Chou and Neelin, 2004; Held and Soden, 2006). Tselioudis and Rossow (2006) predict this within the storm tracks based on observed present-day relationships with meteorological variables combined with model-simulated changes to those driving variables but do not infer a large feedback. Most CMIP3 GCMs produce too little storm-track cloud cover in the southern hemisphere compared to nearly-overcast conditions in reality, but clouds are also too bright. Arguments have been advanced that such biases could imply either model overestimation or underestimation of feedbacks (Trenberth and Fasullo, 2010; Brient and Bony, 2012).

The role of thin cirrus clouds for cloud feedback is not known and remains a source of possible systematic bias. Unlike high-cloud systems overall, these particular clouds exert a clear net warming effect (Jensen et al., 1994; Chen et al., 2000), making a significant cloud-cover feedback possible in principle (e.g., Rondanelli and Lindzen, 2010). While this does not seem to be important in recent GCMs (Zelinka et al., 2012a), and no specific mechanism has been suggested, the representation of cirrus in GCMs appears to be poor (Eliasson et al., 2011) and such clouds are microphysically complex (Section 7.4.4). This implies significant feedback uncertainty in addition to that already evident from model spread.

Model simulations, physical understanding and observations thus provide *medium confidence* that poleward shifts of cloud distributions will contribute to positive feedback, but by an uncertain amount. Feedbacks from thin cirrus amount cannot be ruled out and are an important source of uncertainty.

7.2.5.3 Feedback Mechanisms Involving Low Cloud

Differences in the response of low clouds to a warming are responsible for most of the spread in model-based estimates of equilibrium climate sensitivity (Randall et al., 2007). Since the AR4 this finding has withstood further scrutiny (e.g., Soden and Vecchi, 2011; Webb et al., 2013), holds in CMIP5 models (Vial et al., 2013), and has been shown to apply also to the transient climate response (e.g., Dufresne and Bony, 2008). This discrepancy in responses occurs over most oceans and cannot be clearly confined to any single region (Trenberth and Fasullo, 2010; Webb et al., 2013), but is usually associated with the representation of shallow cumulus or stratocumulus clouds (Williams and Tselioudis, 2007; Williams and Webb, 2009; Xu et al., 2010). Because the spread of responses emerges in a variety of idealised model formulations (Medeiros et al., 2008; Zhang and Bretherton, 2008; Brient and Bony, 2013), or conditioned on a particular dynamical state (Bony et al., 2004), and is similar in equilibrium or transient simulations (Yokohata et al., 2008), it appears to be attributable to how cloud, convective and boundary layer processes are parameterized in GCMs.

The modelled response of low clouds does not appear to be dominated by a single feedback mechanism, but rather the net effect of several potentially competing mechanisms as elucidated in LES and GCM sensitivity studies (e.g., Zhang and Bretherton, 2008; Blossey et al., 2013; Bretherton et al., 2013). Starting with some proposed negative feedback mechanisms, it has been argued that in a warmer climate, low clouds will be: (i) horizontally more extensive, because changes in the lapse rate of temperature also modify the lower-tropospheric stability (Miller, 1997); (ii) optically thicker, because adiabatic ascent is accompanied by a larger condensation rate (Somerville and Remer, 1984); and (iii) vertically more extensive, in response to a weakening of the tropical overturning circulation (Caldwell and Bretherton, 2009). While these mechanisms may play some role in subtropical low cloud feedbacks, none of them appears dominant. Regarding (i), dry static stability alone is a misleading predictor with respect to climate changes, as models with comparably good simulations of the current regional distribution and/or relationship to stability of low cloud can produce a broad range of cloud responses to climate perturbations (Wyant et al., 2006). Mechanism (ii), discussed briefly in the next section, appears to have a small effect. Mechanism (iii) cannot yet be ruled out but does not appear to be the dominant factor in determining subtropical cloud changes in GCMs (Bony and Dufresne, 2005; Zhang and Bretherton, 2008).

Since the AR4, several new positive feedback mechanisms have been proposed, most associated with the marine boundary layer clouds thought to be at the core of the spread in responses. These include the ideas that: warming-induced changes in the absolute humidity lapse rate change the energetics of mixing in ways that demand a reduction in cloud amount or thickness (Webb and Lock, 2012; Bretherton et al., 2013; Brient and Bony, 2013); energetic constraints prevent the surface evaporation from increasing with warming at a rate sufficient to balance expected changes in dry air entrainment thereby reducing the supply of moisture to form clouds (Rieck et al., 2012; Webb and Lock, 2012); and that increased concentrations of greenhouse gases reduce the radiative cooling that drives stratiform cloud layers and thereby the cloud amount (Caldwell and Bretherton, 2009; Stevens and Brenguier, 2009; Bretherton et al., 2013). These mechanisms, crudely operating through parameterized representations of cloud processes, could explain why climate models consistently produce positive low-cloud feedbacks. Among CFMIP GCMs, the low-cloud feedback ranges from -0.09 to $+0.63 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$ (Figure 7.10), and is largely associated with a reduction in low-cloud amount, albeit with considerable spatial variability (e.g., Webb et al., 2013). One “super-parameterized”

GCM (Section 7.2.2.2) simulates a negative low-cloud feedback (Wyant et al., 2006; Wyant et al., 2009), but that model's representation of low clouds was worse than some conventional GCMs.

The tendency of both GCMs and process models to produce these positive feedback effects suggests that the feedback contribution from changes in low clouds is positive. However, deficient representation of low clouds in GCMs, diverse model results, a lack of reliable observational constraints, and the tentative nature of the suggested mechanisms leave us with *low confidence* in the sign of the low-cloud feedback contribution.

7.2.5.4 *Feedbacks Involving Changes in Cloud Opacity*

It has long been suggested that cloud water content could increase in a warmer climate simply due to the availability of more vapour for condensation in a warmer atmosphere, yielding a negative feedback (Paltridge, 1980; Somerville and Remer, 1984), but this argument ignores the physics of crucial cloud-regulating processes like precipitation formation and turbulence. Observational evidence discounting a large effect of this kind was reported in AR4 (Randall et al., 2007).

The global-mean net feedback from cloud opacity changes in CFMIP models (Figure 7.10) is approximately zero. Optical depths tend to reduce slightly at low and middle latitudes, but increase poleward of 50°, yielding a positive longwave feedback that roughly offsets the negative shortwave feedback. These latitude-dependent opacity changes may be attributed to phase changes at high latitudes and greater poleward moisture transport (Vavrus et al., 2009), and possibly to poleward shifts of the circulation.

Studies have reported warming-related changes in cloud opacity tied to cloud phase (e.g., Senior and Mitchell, 1993; Tsushima et al., 2006). This might be expected to cause negative feedback, because at mixed-phase temperatures of –38 to 0°C, cloud ice particles have typical diameters of 10–100 µm (e.g., Figure 8 in Donovan, 2003), several-fold larger than cloud water drops, so a given mass of cloud water would have less surface area and reflect less sunlight in ice form than in liquid form. As climate warms, a shift from ice to liquid at a given location could increase cloud opacity. An offsetting factor that may explain the absence of this in CFMIP, however, is that mixed-phase clouds may form at higher altitudes, and similar local temperatures, in warmer climates (Section 7.2.5.1). The key physics is in any case not adequately represented in climate models. Thus this particular feedback mechanism is highly uncertain.

7.2.5.5 *Feedback From Arctic Cloud Interactions With Sea Ice*

Arctic clouds, despite their low altitude, have a net heating effect at the surface in the present climate because their downward emission of infrared radiation over the year outweighs their reflection of sunlight during the short summer season. Their net effect on the atmosphere is cooling, however, so their effect on the energy balance of the whole system is ambiguous and depends on the details of the vertical cloud distribution and the impact of cloud radiative interactions on ice cover (Palm et al., 2010).

Low-cloud amount over the Arctic oceans varies inversely with sea ice amount (open water producing more cloud) as now confirmed since AR4 by visual cloud reports (Eastman and Warren, 2010) and lidar and radar observations (Kay and Gettelman, 2009; Palm et al., 2010). The observed effect is weak in boreal summer, when the melting sea-ice is at a similar temperature to open water and stable boundary layers with extensive low cloud are common over both surfaces, and strongest in boreal autumn when cold air flowing over regions of open water stimulates cloud formation by boundary-layer convection (Kay and Gettelman, 2009; Vavrus et al., 2011). Kay et al. (2011) show that a GCM can represent this seasonal sensitivity of low cloud to open water, but doing so depends on the details of how boundary-layer clouds are parameterized. Vavrus et al. (2009) show that in a global warming scenario, GCMs simulate more Arctic low cloud in all seasons, but especially during autumn and the onset of winter when open water and very thin sea ice increase considerably, increasing upward moisture transport to the clouds.

A few studies in the literature suggest negative feedbacks from Arctic clouds, based on spatial correlations of observed warming and cloudiness (Liu et al., 2008) or tree-ring proxies of cloud shortwave effects over the last millenium (Gagen et al., 2011). However the spatial correlations are not reliable indicators of feedback (Section 7.2.5.7), and the tree-ring evidence (assuming it is a good proxy) applies only to the shortwave

effect of summertime cloud cover. The GCM studies would be consistent with warmer climates being cloudier, but have opposite radiative effects and positive feedback during the rest of the year. Even though a small positive feedback is suggested by models, there is overall little evidence for significant feedbacks from Arctic cloud.

7.2.5.6 *Rapid Adjustments of Clouds to a CO₂ Change*

It is possible to partition the response of top-of-atmosphere radiation in GCMs to an instantaneous doubling of CO₂ into a “rapid adjustment” in which the land surface, atmospheric circulations and clouds respond to the radiative effect of the CO₂ increase, and an ‘SST-mediated’ response that develops more slowly as the oceans warm (see Section 7.1.3). This distinction is important not only to help understand model processes, but because the presence of rapid adjustments would cause clouds to respond slightly differently to a transient climate change (in which SST changes have not caught up to CO₂ changes) or to a climate change caused by other forcings, than they would to the same warming at equilibrium driven by CO₂. There is also a rapid adjustment of the hydrological cycle and precipitation field, discussed in Section 7.6.3.

Gregory and Webb (2008) reported that in some climate models, rapid adjustment of clouds can have top-of-atmosphere radiative effects comparable to those of the ensuing SST-mediated cloud changes, though Andrews and Forster (2008) found a smaller effect. Subsequent studies using more accurate kernel-based techniques find a cloud adjustment of roughly +0.4 to +0.5 W m⁻² per doubling of CO₂, with standard deviation of about 0.3 W m⁻² across models (Vial et al., 2013; Zelinka et al., 2013). This would account for about 20% of the overall cloud response in a model with average sensitivity; and since it is not strongly correlated with model sensitivity, it contributes perhaps 20% of the intermodel response spread (Andrews et al., 2012; Webb et al., 2013), which therefore remains dominated by feedbacks. The response occurs due to a general decrease in cloud cover caused by the slight stratification driven by CO₂ warming of the troposphere, which especially for middle and low clouds has a net warming effect (Colman and McAvaney, 2011; Zelinka et al., 2013). As explained at the beginning of Section 7.2.5, feedback numbers given in this report already account for these rapid adjustments.

7.2.5.7 *Observational Constraints on Global Cloud Feedback*

A number of studies since AR4 have attempted to constrain overall cloud feedback (or climate sensitivity) from observations of natural climate variability; here we discuss those using modern cloud, radiation or other measurements (see a complementary discussion in Section 12.5 based on past temperature data and forcing proxies).

One approach is to seek observable aspects of present-day cloud behaviour that reveal cloud feedback or some component thereof. Varying parameters in a GCM sometimes produces changes in cloud feedback that correlate with the properties of cloud simulated for the present day, but this depends on the GCM (Yokohata et al., 2010; Gettelman et al., 2013), and the resulting relationships do not hold across multiple models such as those from CMIP3 (Collins et al., 2011). Among the AR4 models, net cloud feedback is strongly correlated with mid-latitude relative humidity (Volodin, 2008), with top-of-atmosphere radiation at high southern latitudes (Trenberth and Fasullo, 2010), and with humidity at certain latitudes during boreal summer (Fasullo and Trenberth, 2012); if valid each of these regression relations would imply a relatively strong positive cloud feedback in reality, but no mechanism has been proposed to explain or validate them and such apparent skill can arise fortuitously (Klocke et al., 2011). Likewise, Clement et al. (2009) found realistic decadal variations of cloud cover over the North Pacific in only one model (HadGEM1) and argued that the relatively strong cloud feedback in this model should therefore be regarded as more likely, but this finding lacks a mechanistic explanation and may depend on how model output is used (Broccoli and Klein, 2010). Chang and Coakley (2007) examined midlatitude maritime clouds and found cloud thinning with increasing temperature, consistent with a positive feedback, whereas Gordon and Norris (2010) found the opposite result following a methodology that tried to isolate thermal and advective effects. In summary, there is no evidence of a robust link between any of the noted observables and the global feedback, though some apparent connections are tantalising and are being studied further.

Several studies have attempted to derive global climate sensitivity from interannual relationships between global-mean observations of top-of-atmosphere radiation and surface temperature (see also Chapter 10,

Section 10.8.2.2). One problem with this is the different spatial character of interannual and long-term warming; another is that the methodology can be confounded by cloud variations not caused by those of surface temperature (Spencer and Braswell, 2008). A range of climate sensitivities has been inferred based on such analyses (Forster and Gregory, 2006; Lindzen and Choi, 2011). Crucially, however, among different GCMs there is no correlation between the interannual and long-term cloud-temperature relationships (Dessler, 2010; Colman and Hanson, 2012), contradicting the basic assumption of these methods. Many but not all atmosphere-ocean GCMs predict relationships that are consistent with observations (Dessler, 2010, 2013). More recently there is interest in relating the time-lagged correlations of cloud and temperature to feedback processes (Spencer and Braswell, 2010) but again these relationships appear to reveal only a model's ability to simulate ENSO or other modes of interannual variability properly, which are not obviously informative about the cloud feedback on long-term global warming (Dessler, 2011).

For a putative observational constraint on climate sensitivity to be accepted, it should have a sound physical basis and its assumptions should be tested appropriately in climate models. No method yet proposed meets both conditions. Moreover, cloud responses to warming can be sensitive to relatively subtle details in the geographic warming pattern, such as the slight hemispheric asymmetry due to the lag of southern ocean warming relative to northern latitudes (Senior and Mitchell, 2000; Yokohata et al., 2008). Cloud responses to specified uniform ocean warming without CO₂ increases are not the same as those to CO₂-induced global warming simulated with more realistic oceans (Ringer et al., 2006), partly because of rapid adjustments (Section 7.2.5.6) and because low clouds also feed back tightly to the underlying surface (Caldwell and Bretherton, 2009). Simulated cloud feedbacks also differ significantly between colder and warmer climates in some models (Crucifix, 2006; Yoshimori et al., 2009) and between volcanic and other forcings (Yokohata et al., 2005). These sensitivities highlight the challenges facing any attempt to infer long-term cloud feedbacks from simple data analyses.

7.2.6 Feedback Synthesis

Together, the water-vapour, lapse-rate and cloud feedbacks are the principal determinants of equilibrium climate sensitivity. The water-vapour and lapse-rate feedbacks, as traditionally defined, should be thought of as a single phenomenon rather than in isolation (see Section 7.2.4.2). To estimate a 90% probability range for that feedback, we double the variance of GCM results about the mean to account for the possibility of errors common to all models, to arrive at +1.1 (+0.9 to +1.3) W m⁻² °C⁻¹. Values in this range are supported by a steadily growing body of observational evidence, model tests, and physical reasoning. As a corollary, the net feedback from water vapour and lapse rate changes combined is *extremely likely* positive, allowing for the possibility of deep uncertainties or a fat-tailed error distribution. Key aspects of the responses of water vapour and clouds to climate warming now appear to be constrained by large-scale dynamical mechanisms that are not sensitive to poorly-represented small-scale processes, and as such, are more credible. This feedback is thus known to be positive with *high confidence*, and contributes only a small part of the spread in GCM climate sensitivity (Section 9.7). An alternative framework has recently been proposed in which these feedbacks, and stabilisation via thermal emission, are all significantly smaller and more consistent among models; thus the range given above may overstate the true uncertainty.

Several cloud feedback mechanisms now appear consistently in GCMs, summarised in Figure 7.11, most supported by other lines of evidence. Nearly all act in a positive direction. First, high clouds are expected to rise in altitude and thereby exert a stronger greenhouse effect in warmer climates. This altitude feedback mechanism is well understood, has theoretical and observational support, occurs consistently in GCMs and CRMs, and explains about half of the mean positive cloud feedback in GCMs. Second, middle and high-level cloud cover tends to decrease in warmer climates even within the ITCZ, although the feedback effect of this is ambiguous and it cannot yet be tested observationally. Third, observations and most models suggest storm tracks shift poleward in a warmer climate, drying the subtropics and moistening the high latitudes, which causes further positive feedback via a net shift of cloud cover to latitudes that receive less sunshine. Finally, most GCMs also predict that low cloud amount decreases, especially in the subtropics, another source of positive feedback though one that differs significantly among models and lacks a well-accepted theoretical basis. Over middle and high latitudes, GCMs suggest warming-induced transitions from ice to water clouds may cause clouds to become more opaque, but this appears to have a small systematic net radiative effect in models, possibly because it is offset by cloud altitude changes.

[INSERT FIGURE 7.11 HERE]

Figure 7.11: Robust cloud responses to greenhouse warming (those simulated by most models and possessing some kind of independent support or understanding). The tropopause and melting level are shown by the thick solid and thin grey dashed lines, respectively. Changes anticipated in a warmer climate are shown by arrows, with red colour indicating those making a robust positive feedback contribution and grey indicating those where the feedback contribution is small and/or highly uncertain. No robust mechanisms contribute negative feedback. Changes include rising high cloud tops and melting level, and increased polar cloud cover and/or optical thickness (*high confidence*); broadening of the Hadley Cell and/or poleward migration of storm tracks, and narrowing of rainfall zones such as the ITCZ (*medium confidence*); and reduced low-cloud amount and/or optical thickness (*low confidence*). Confidence assessments are based on degree of GCM consensus, strength of independent lines of evidence from observations or process models, and degree of basic understanding.

Currently, neither cloud process models (CRMs and LES) nor observations provide clear evidence to contradict or confirm feedback mechanisms involving low clouds. In some cases these models show stronger low-cloud feedbacks than GCMs, but each model type has limitations, and some studies suggest stronger positive feedbacks are more realistic (Section 7.2.5.7). Cloud process models suggest a variety of potentially opposing response mechanisms that may account for the current spread of GCM feedbacks. In summary we find no evidence to contradict either the cloud or water-vapour-lapse-rate feedback ranges shown by current GCMs, although the many uncertainties mean that true feedback could still lie outside these ranges. In particular, microphysical mechanisms affecting cloud opacity or cirrus amount may well be missing from GCMs. Missing feedbacks, if any, could act in either direction.

Based on the above synthesis of cloud behaviour, the net radiative feedback due to all cloud types is judged *likely* to be positive. This is reasoned probabilistically as follows. First, since evidence from observations and process models is mixed as to whether GCM cloud feedback is too strong or too weak overall, and since the positive feedback found in GCMs comes mostly from mechanisms now supported by other lines of evidence, the central (most likely) estimate of the total cloud feedback is taken as the mean from GCMs ($+0.6 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$). Second, since there is no accepted basis to discredit individual GCMs a priori, the probability distribution of the true feedback cannot be any narrower than the distribution of GCM results. Third, since feedback mechanisms are probably missing from GCMs and some CRMs suggest feedbacks outside the range in GCMs, the probable range of the feedback must be broader than its spread in GCMs. We estimate a probability distribution for this feedback by doubling the spread about the mean of all model values in Figure 7.10 (in effect assuming an additional uncertainty circa 1.7 times as large as that encapsulated in the GCM range, added to it in quadrature). This yields a 90% (*very likely*) range of -0.2 to $+2.0 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$, with a 17% probability of a negative feedback.

Note that the assessment of feedbacks in this chapter is independent of constraints on climate sensitivity from observed trends or palaeoclimate information discussed in Box 12.2.

7.2.7 Anthropogenic Sources of Moisture and Cloudiness

Human activity can be a source of additional cloudiness through specific processes involving a source of water vapour in the atmosphere. We discuss here the impact of aviation and irrigation on water vapour and cloudiness. The impact of water vapour sources from combustion at the Earth's surface is thought to be negligible. Changes to the hydrological cycle because of land use change are briefly discussed in Section 12.4.8.

7.2.7.1 Contrails and Contrail-Induced Cirrus

Aviation jet engines emit hot moist air, which can form line shaped persistent condensation trails (contrails) in environments that are supersaturated with respect to ice and colder than about -40°C . The contrails are composed of ice crystals that are typically smaller than those of background cirrus (Heymsfield et al., 2010; Frömming et al., 2011). Their effect on longwave radiation dominates over their shortwave effect (Stuber and Forster, 2007; Rap et al., 2010b; Burkhardt and Kärcher, 2011) but models disagree on the relative importance of the two effects. Contrails have been observed to spread into large cirrus sheets which may persist for several hours, and observational studies confirm their overall positive net RF impact (Haywood et al., 2009). Aerosol emitted within the aircraft exhaust may also affect high-level cloudiness. This last effect is classified as an aerosol-cloud interaction and is deemed too uncertain to be further assessed here (see also

Section 7.4.4). Climate model experiments (Rap et al., 2010a) confirm earlier results (Kalkstein and Balling Jr, 2004; Ponater et al., 2005) that aviation contrails do not have, at current levels of coverage, an observable effect on the mean or diurnal range of surface temperature (*medium confidence*).

Estimates of the RF from persistent (linear) contrails often correspond to different years and need to be corrected for the continuous increase in air traffic. More recent estimates tend to indicate somewhat smaller RF than assessed in the AR4 (see Table 7.SM.1 and text in Supplementary Material). We adopt a RF estimate of +0.01 (+0.005 to +0.03) W m^{-2} for persistent (linear) contrails for 2011, with a *medium confidence* attached to this estimate. An additional RF of +0.003 W m^{-2} is due to emissions of water vapour in the stratosphere by aviation as estimated by Lee et al. (2009).

Forster et al. (2007) quoted Sausen et al. (2005) to update the 2000 forcing for aviation-induced cirrus (including linear contrails) to +0.03 (+0.01 to +0.08) W m^{-2} but did not consider this to be a best estimate because of large uncertainties. Schumann and Graf (2013) constrained their model with observations of the diurnal cycle of contrails and cirrus in a region with high air traffic relative to a region with little air traffic, and estimated a RF of +0.05 (+0.04 to +0.08) W m^{-2} for contrails and contrail-induced cirrus in 2006, but their model has a large shortwave contribution, and larger estimates are possible. An alternative approach was taken by Burkhardt and Kärcher (2011), who estimated a global RF for 2002 of +0.03 W m^{-2} from contrails and contrail cirrus within a climate model (Burkhardt and Kärcher, 2009), after compensating for reduced background cirrus cloudiness in the main traffic areas. Based on these two studies we assess the combined contrail and contrail-induced cirrus ERF for the year 2011 to be +0.05 (+0.02 to +0.15) W m^{-2} to take into uncertainties on spreading rate, optical depth, ice particle shape and radiative transfer and the ongoing increase in air traffic (see also Supplementary Material). A *low confidence* is attached to this estimate.

7.2.7.2 Irrigation-Induced Cloudiness

Boucher et al. (2004) estimated a global ERF due to water vapour from irrigation in the range of +0.03 to +0.10 W m^{-2} but the net climate effect was dominated by the evaporative cooling at the surface and by atmospheric thermal responses to low-level humidification. Regional surface cooling was confirmed by a number of more recent regional and global studies (Kueppers et al., 2007; Lobell et al., 2009). The resulting increase in water vapour may induce a small enhancement in precipitation downwind of the major irrigation areas (Puma and Cook, 2010), as well as some regional circulation patterns (Kueppers et al., 2007). Sacks et al. (2009) reported a 0.001 increase in cloud fraction over land (0.002 over irrigated land). This suggests an ERF no more negative than -0.1 W m^{-2} with very *low confidence*.

7.3 Aerosols

The section assesses the role of aerosols in the climate system, focusing on aerosol processes and properties, as well as other factors, that influence aerosol-radiation and aerosol-cloud interactions. Processes directly relevant to aerosol-cloud interactions are discussed in Section 7.4, and estimates of aerosol radiative and effective radiative forcings are assessed in Section 7.5. The time evolution of aerosols and their forcing are discussed in Chapters 2 and 8, with Chapter 8 also covering changes in natural volcanic aerosols.

7.3.1 Aerosols in the Present-Day Climate System

7.3.1.1 Aerosol Formation and Aerosol Types

Atmospheric aerosols, whether natural or anthropogenic, originate from two different pathways: emissions of primary particulate matter and formation of secondary particulate matter from gaseous precursors (Figure 7.12). The main constituents of the atmospheric aerosol are inorganic species (such as sulphate, nitrate, ammonium, sea salt), organic species (also termed organic aerosol or OA), black carbon (BC, a distinct type of carbonaceous material formed from the incomplete combustion of fossil and biomass based fuels under certain conditions), mineral species (mostly desert dust) and primary biological aerosol particles (PBAP). Mineral dust, sea salt, BC and PBAP are introduced into the atmosphere as primary particles, whereas non-sea-salt sulphate, nitrate and ammonium are predominantly from secondary aerosol formation processes. The OA has both significant primary and secondary sources. In the present-day atmosphere, the majority of BC,

sulphate, nitrate and ammonium come from anthropogenic sources, whereas sea salt, most mineral dust and PBAP are predominantly of natural origin. Primary and secondary organic aerosols (POA and SOA) are influenced by both natural and anthropogenic sources. Emission rates of aerosols and aerosol precursors are summarized in Table 7.1. The characteristics and role of the main aerosol species are listed in Table 7.2.

[INSERT FIGURE 7.12 HERE]

Figure 7.12: Overview of atmospheric aerosol and environmental variables and processes influencing aerosol-radiation and aerosol-cloud interactions. Gas-phase variables and processes are highlighted in red while particulate-phase variables and processes appear in green. Although this figure shows a linear chain of processes from aerosols to forcings (ERF_{air} and ERF_{aci}), it is increasingly recognised that aerosols and clouds form a coupled system with two-way interactions (see Figure 7.16).

[INSERT TABLE 7.1 HERE]

Table 7.1: (a) Global and regional anthropogenic emissions of aerosols and aerosol precursors. The average, minimum and maximum values are from a range of available inventories (Cao et al., 2006; European Commission et al., 2009; Sofiev et al., 2009; Lu et al., 2010; Granier et al., 2011 and references therein; Lu et al., 2011; Knorr et al., 2012). It should be noted that the min-max range is not a measure of uncertainties which are often difficult to quantify. Units are Tg yr⁻¹ and TgS yr⁻¹ for SO₂. NMVOCs stand for non-methane volatile organic compounds. **(b)** Global natural emissions of aerosols and aerosol precursors. Dust and sea-spray estimates span the range in the historical CMIP5 simulations. The ranges for monoterpenes and isoprene are from Arneth et al. (2008). There are other BVOCs such as sesquiterpenes, alcohols and aldehydes which are not listed here. Marine POA and terrestrial PBAP emission ranges are from Gantt et al. (2011) and Burrows et al. (2009), respectively. Note that emission fluxes from mineral dust, sea spray and terrestrial PBAP are highly sensitive to the cut-off radius. The conversion rate of BVOCs to SOA is also indicated using the range from Spracklen et al. (2011) and a lower bound from Kanakidou et al. (2005). Units are Tg yr⁻¹ except for BVOCs (monoterpenes and isoprene) in TgC yr⁻¹ and dimethylsulphide (DMS) in TgS yr⁻¹.

[INSERT TABLE 7.2 HERE]

Table 7.2: Key aerosol properties of the main aerosol species in the troposphere. Terrestrial primary biological aerosol particles (PBAP), brown carbon and marine primary organic aerosols (POA) are particular types of organic aerosols (OA) but are treated here as separate components because of their specific properties. The estimated lifetimes in the troposphere are based on the AeroCom models, except for terrestrial PBAP which are treated by analogy to other coarse mode aerosol types.

7.3.1.2 Aerosol Observations and Climatology

New and improved observational aerosol datasets have emerged since AR4. A number of field experiments have taken place such as the Intercontinental Chemical Transport Experiment (INTEX, Bergstrom et al., 2010; Logan et al., 2010), African Monsoon Multidisciplinary Analysis (Jeong et al., 2008; AMMA, Hansell et al., 2010), Integrated Campaign for Aerosols, gases and Radiation Budget (ICARB, Moorthy et al., 2008 and references therein), Megacity Impact on Regional and Global Environments field experiment (MILAGRO, Paredes-Miranda et al., 2009), Geostationary Earth Radiation Budget Inter-comparisons of Longwave and Shortwave (GERBILS, Christopher et al., 2009), Arctic Research of the Composition of the Troposphere from Aircraft and Satellites (ARCTAS, Lyapustin et al., 2010), the Amazonian Aerosol Characterization Experiment 2008 (AMAZE-08, Martin et al., 2010b), the Integrated project on Aerosol Cloud Climate and Air Quality interactions (EUCAARI, Kulmala et al., 2011) and Atmospheric Brown Clouds (ABC, Nakajima et al., 2007), which have improved our understanding of regional aerosol properties.

Long-term aerosol mass concentrations are also measured more systematically at the surface by global and regional networks (see Section 2.2.3), and there are institutional efforts to improve the coordination and quality assurance of the measurements (e.g., GAW, 2011). A survey of the main aerosol types can be constructed from such measurements (e.g., Jimenez et al., 2009; Zhang et al., 2012b; Figure 7.13). Such analyses show a wide spatial variability in aerosol mass concentration, dominant aerosol type, and aerosol composition. Mineral dust dominates the aerosol mass over some continental regions with relatively higher concentrations especially in urban South Asia and China, accounting for about 35% of the total aerosol mass with diameter smaller than 10 µm. In the urban U.S. and South America, organic carbon (OC) contributes the largest mass fraction to the atmospheric aerosol (i.e., 20% or more), while in other areas of the world the OC fraction ranks second or third with a mean of about 16%. Sulphate normally accounts for about 10–30% by mass, except for the areas in rural Africa, urban Oceania and South America where it is less than about

10%. The mass fractions of nitrate and ammonium are only around 6% and 4% on average, respectively. In most areas, elemental carbon (EC, which refers to a particular way of measuring BC) represents less than 5% of the aerosol mass, although this percentage may be larger (about 12%) in South America, urban Africa, urban Europe, South, South-East and East Asia and urban Oceania due to the larger impact of combustion sources. Sea salt can be dominant at oceanic remote sites with 50–70% of aerosol mass.

[INSERT FIGURE 7.13 HERE]

Figure 7.13: Bar chart plots summarizing the mass concentration ($\mu\text{g m}^{-3}$) of seven major aerosol components for particles with diameter smaller than 10 μm , from various rural and urban sites (dots on the central world map) in six continental areas of the world with at least an entire year of data, and two marine sites. The density of the sites is a qualitative measure of the spatial representativeness of the values for each area. The North Atlantic and Indian Oceans panels correspond to measurements from single sites (Mace Head and Amsterdam Island, respectively) that are not necessarily representative. The relative abundances of different aerosol compounds are considered to reflect the relative importance of emissions of these compounds or their precursors, either anthropogenic or natural, in the different areas. For consistency the mass of OA has been converted to that of organic carbon (OC), according to a conversion factor (typically 1.4–1.6), as provided in each study. For each area, the panels represent the median, the 25th to 75th percentiles (box), and the 10th to 90th percentiles (whiskers) for each aerosol component. These include: 1) **urban United States** (Chow et al., 1993; Kim et al., 2000; Ito et al., 2004; Malm and Schichtel, 2004; Sawant et al., 2004; Liu et al., 2005); **rural United States** (Chow et al., 1993; Malm et al., 1994; Malm and Schichtel, 2004; Liu et al., 2005); 2) **marine northern Atlantic Ocean** (Rinaldi et al., 2009; Ovadnevaite et al., 2011); 3) **urban Europe** (Lenschow et al., 2001; Querol et al., 2001; Roosli et al., 2001; Rodriguez et al., 2002; Putaud et al., 2004; Querol et al., 2004; Rodriguez et al., 2004; Hueglin et al., 2005; Lonati et al., 2005; Querol et al., 2006; Viana et al., 2006; Viana et al., 2007; Perez et al., 2008; Querol et al., 2008; Yin and Harrison, 2008; Lodhi et al., 2009); **rural Europe** (Gullu et al., 2000; Querol et al., 2001; Rodriguez et al., 2002; Putaud et al., 2004; Puxbaum et al., 2004; Querol et al., 2004; Rodriguez et al., 2004; Hueglin et al., 2005; Kocak et al., 2007; Salvador et al., 2007; Yttri, 2007; Viana et al., 2008; Yin and Harrison, 2008; Querol et al., 2009; Theodosi et al., 2010); 4) **high Asia**, with altitude larger than 1680 m (Shresth et al., 2000; Zhang et al., 2001; Carrico et al., 2003; Rastogi and Sarin, 2005; Ming et al., 2007a; Rengarajan et al., 2007; Qu et al., 2008; Zhang et al., 2008; Decesari et al., 2010; Ram et al., 2010; Zhang et al., 2012b); **urban South Asia** (Rastogi and Sarin, 2005; Kumar et al., 2007; Lodhi et al., 2009; Chakraborty and Gupta, 2010; Khare and Baruah, 2010; Raman et al., 2010; Safai et al., 2010; Stone et al., 2010; Sahu et al., 2011); **urban China** (Cheng et al., 2000; Yao et al., 2002; Zhang et al., 2002; Wang et al., 2003; Ye et al., 2003; Xiao and Liu, 2004; Wang et al., 2005b; Hagler et al., 2006; Oanh et al., 2006; Wang et al., 2006; Zhang et al., 2011; Zhang et al., 2012b); **rural China** (Hu et al., 2002; Zhang et al., 2002; Hagler et al., 2006; Zhang et al., 2012b); **South-East and East Asia** (Lee and Kang, 2001; Oanh et al., 2006; Kim et al., 2007; Han et al., 2008; Khan et al., 2010); 5) **South America** (Artaxo et al., 1998; Morales et al., 1998; Artaxo et al., 2002; Celis et al., 2004; Bourotte et al., 2007; Fuzzi et al., 2007; Mariani and Mello, 2007; de Souza et al., 2010; Martin et al., 2010a; Gioda et al., 2011); 6) **urban Africa** (Favez et al., 2008; Mkoma, 2008; Mkoma et al., 2009a); **rural Africa** (Maenhaut et al., 1996; Nyanganyura et al., 2007; Mkoma, 2008; Mkoma et al., 2009b; Mkoma et al., 2009a; Weinstein et al., 2010); 7) **marine Indian Ocean** (Sciare et al., 2009; Rinaldi et al., 2011); 8) **urban Oceania** (Chan et al., 1997; Maenhaut et al., 2000; Wang and Shooter, 2001; Wang et al., 2005a; Radhi et al., 2010).

Aerosol optical depth (AOD), which is related to the column-integrated aerosol amount, is measured by the Aerosol Robotic Network (AERONET, Holben et al., 1998), other ground-based networks (e.g., Bokoye et al., 2001; Che et al., 2009), and a number of satellite-based sensors. Instruments designed for aerosol retrievals such as MODIS (Remer et al., 2005; Levy et al., 2010; Kleidman et al., 2012), MISR (Kahn et al., 2005; Kahn et al., 2007) and POLDER/PARASOL (Tanré et al., 2011) are used preferentially to less specialised instruments such as AVHRR (e.g., Zhao et al., 2008a; Mishchenko et al., 2012), TOMS (Torres et al., 2002) and ATSR/AATSR (Thomas et al., 2010) although the latter are useful for building aerosol climatologies because of their long measurement records (see Section 2.2.3). While each AOD retrieval by satellite sensors shows some skill against more accurate sunphotometer measurements such as those of AERONET, there are still large differences among satellite products in regional and seasonal patterns because of differences and uncertainties in calibration, sampling, cloud screening, treatment of the surface reflectivity and aerosol microphysical properties (e.g., Li et al., 2009; Kokhanovsky et al., 2010). The global but incomplete sampling of satellite measurements can be combined with information from global aerosol models through data assimilation techniques (e.g., Benedetti et al., 2009; Figure 7.14a). Due to the heterogeneity in their sources, their short lifetime and the dependence of sinks on the meteorology, aerosol distributions show large variations on daily, seasonal and interannual scales.

[INSERT FIGURE 7.14 HERE]

Figure 7.14: a) Spatial distribution of the 550 nm aerosol optical depth (AOD, unitless) from the ECMWF Integrated Forecast System model with assimilation of MODIS aerosol optical depth (Benedetti et al., 2009; Morcrette et al.,

2009) averaged over the period 2003–2010; b) to e) latitudinal vertical cross-sections of the 532 nm aerosol extinction coefficient (km^{-1}) for four longitudinal bands (180°W to 120°W, 120°W to 60°W, 20°W to 40°E, and 60°E to 120°E, respectively) from the CALIOP instrument for the year 2010 (nighttime all-sky data, version 3; Winker et al., 2013).

The CALIPSO spaceborne lidar (Winker et al., 2009) complements existing ground-based lidars. It now provides a climatology of the aerosol extinction coefficient (Figure 7.14b–e), highlighting that over most regions the majority of the optically-active aerosol resides in the lowest 1–2 km. Yu et al. (2010) and Koffi et al. (2012) found that global aerosol models tend to have a positive bias in the aerosol extinction scale height in some (but not all) regions, due to an overestimate of aerosol concentrations above 6 km. There is less information available on the vertical profile of aerosol number and mass concentrations, although a number of field experiments involving research and commercial aircraft have measured aerosol concentrations (e.g., Heintzenberg et al., 2011). In particular vertical profiles of BC mixing ratios have been measured during the ARFI aircraft/high altitude balloon campaigns (Satheesh et al., 2008), ARCTAS (Jacob et al., 2010), ARCPAC (Warneke et al., 2010), A-FORCE (Oshima et al., 2012) and HIPPO1 (Schwarz et al., 2010) campaigns. Comparison between models and observations have shown that aerosol models tend to underestimate BC mass concentrations in some outflow regions, especially in Asia, but overestimate concentrations in remote regions, especially at altitudes (Koch et al., 2009b; Figure 7.15), which make estimates of their R_{Fari} uncertain (see Section 7.5.2) given the large dependence of R_{Fari} on the vertical distribution of BC (Ban-Weiss et al., 2012). Absorption AOD can be retrieved from sun photometer measurements (Dubovik et al., 2002) or a combination of ground-based transmittance and satellite reflectance measurements (Lee et al., 2007) in situations where AOD is larger than about 0.4. Koch et al. (2009b) and Bond et al. (2013) used AERONET-based retrievals of absorption AOD to show that most AeroCom models underestimate absorption in many regions, but there remain representativeness issues when comparing point observations to a model climatology.

[INSERT FIGURE 7.15 HERE]

Figure 7.15: Comparison of vertical profiles of BC mass mixing ratios (ng kg^{-1}) as measured by airborne SP2 instruments during the HIPPO1 (Schwarz et al., 2010) and A-FORCE (Oshima et al., 2012) campaigns and simulated by a range of AeroCom II models (Schulz et al., 2009). The black solid lines are averages of a number of vertical profiles in each latitude zone with the horizontal lines representing the standard deviation of the measurements at particular height ranges. Each HIPPO1 profile is the average of about 20 vertical profiles over the mid-Pacific in a two week period in January 2009. The A-FORCE profile is the average of 120 vertical profiles measured over the East China Sea and Yellow Sea downstream of the Asian continent in March–April 2009. The model values (colour lines) are monthly averages corresponding to the measurement location and month, using meteorology and emissions corresponding to the year 2006.

7.3.2 Aerosol Sources and Processes

7.3.2.1 Aerosol Sources

Sea spray is produced at the sea surface by bubble bursting induced mostly, but not exclusively, by breaking waves. The effective emission flux of sea spray particles to the atmosphere depends on the surface wind speed, sea state and atmospheric stability, and to a lesser extent on the temperature and composition of the sea water. Our understanding of sea spray emissions has increased substantially since AR4; however, process-based estimates of the total mass and size distribution of emitted sea spray particles continue to have large uncertainties (de Leeuw et al., 2011; Table 7.1). Sea spray particles are composed of sea salt and marine primary organic matter, the latter being found preferentially in particles smaller than 200 nm in diameter (Leck and Bigg, 2008; Russell et al., 2010). The emission rate of marine POA depends on biological activity in ocean waters (Facchini et al., 2008) and its global emission rate has been estimated to be in the range 2–20 Tg yr^{-1} (Gantt et al., 2011). Uncertainty in the source and composition of sea spray translates into a significant uncertainty in the aerosol number concentration in the marine atmosphere that, unlike aerosol optical depth and mass concentrations, can only be constrained by in-situ observations (Heintzenberg et al., 2000; Jaeglé et al., 2011).

Mineral dust particles are produced mainly by disintegration of aggregates following creeping and saltation of larger soil particles over desert and other arid surfaces (e.g., Zhao et al., 2006; Kok, 2011). The magnitude of dust emissions to the atmosphere depends on the surface wind speed and many soil-related factors such as its texture, moisture and vegetation cover. The range of estimates for the global dust emissions spans a factor

of about five (Huneeus et al., 2011; Table 7.1). Anthropogenic sources, including road dust and mineral dust due to human land use change, remain ill quantified although some recent satellite observations suggest the fraction of mineral dust due to the latter source could be 20 to 25% of the total (Ginoux et al., 2012b; Ginoux et al., 2012a).

The sources of biomass burning aerosols at the global scale are usually inferred from satellite retrieval of burned areas and/or active fires, but inventories continue to suffer from the lack of sensitivity of satellite data to small fires (Randerson et al., 2012) and uncertainties in emission factors. Terrestrial sources of PBAP include bacteria, pollen, fungal spores, lichen, viruses and fragments of animals and plants (Després et al., 2012). Most of these particles are emitted in the coarse mode (Pöschl et al., 2010) and the contribution to the accumulation mode is thought to be small. There are only a few estimates of the global flux of PBAP and these are poorly constrained (Burrows et al., 2009; Heald and Spracklen, 2009; see Table 7.1).

The main natural aerosol precursors are dimethylsulphide (DMS) emitted by the oceans and biogenic volatile organic compounds (BVOC) emitted mainly by the terrestrial biosphere. BVOC emissions depend on the amount and type of vegetation, temperature, radiation, the ambient CO₂ concentration and soil humidity (Grote and Niinemets, 2008; Pacifico et al., 2009; Peñuelas and Staudt, 2010). While speciated BVOC emission inventories have been derived for some continental regions, global emission inventories or schemes are available only for isoprene, monoterpenes and a few other compounds (Müller et al., 2008; Guenther et al., 2012). The total global BVOC emissions have large uncertainties, despite the apparent convergence in different model-based estimates (Arneth et al., 2008).

The ratio of secondary to primary organic aerosol is larger than previously thought, but has remained somewhat ambiguous due to atmospheric transformation processes affecting both these components (Robinson et al., 2007; Jimenez et al., 2009; Pye and Seinfeld, 2010). Globally, most of the atmospheric SOA is expected to originate from biogenic sources, even though anthropogenic sources could be equally important at northern midlatitudes (de Gouw and Jimenez, 2009; Lin et al., 2012). Recent studies suggest that the SOA formation from BVOCs may be enhanced substantially by anthropogenic pollution due to i) high concentrations of nitrogen oxides (NO_x) enhancing BVOC oxidation, and ii) high anthropogenic POA concentrations that facilitate transformation of oxidized volatile organic compounds (VOCs) to the particle phase (Carlton et al., 2010; Heald et al., 2011; Hoyle et al., 2011). The uncertainty range of atmospheric SOA formation is still large and estimated to be approximately 20–380 Tg yr⁻¹ (Hallquist et al., 2009; Farina et al., 2010; Heald et al., 2010; Spracklen et al., 2011; Table 7.1).

Anthropogenic sources of aerosol particles (BC, POA) and aerosol precursors (sulphur dioxide, ammonia, NO_x and NMVOCs, hereafter also referred to as VOCs for simplicity) can be inferred from a priori emission inventories (Table 7.1). They are generally better constrained than natural sources, exceptions being anthropogenic sources of BC, which could be underestimated (Bond et al., 2013), and anthropogenic emissions of some VOCs, fly-ash and dust which are still poorly known. Since AR4, remote sensing by satellites has been increasingly used to constrain natural and anthropogenic aerosol and aerosol precursor emissions (e.g., Dubovik et al., 2008; Jaeglé et al., 2011; Huneeus et al., 2012).

7.3.2.2 *Aerosol Processes*

New particle formation is the process by which low-volatility vapors nucleate into stable molecular clusters, which under certain condensable vapor regimes, can grow rapidly to produce nanometre-sized aerosol particles. Since AR4, substantial progress in our understanding of atmospheric nucleation and new particle formation has been made (e.g., Zhang et al., 2012a). Multiple lines of evidence indicate that while sulphuric acid is the main driver of nucleation (Kerminen et al., 2010; Sipilä et al., 2010), the nucleation rate is affected by ammonia and amines (Kurten et al., 2008; Smith et al., 2010; Kirkby et al., 2011; Yu et al., 2012) as well as low-volatility organic vapors (Metzger et al., 2010; Paasonen et al., 2010; Wang et al., 2010a). Nucleation pathways involving only uncharged molecules are expected to dominate over nucleation induced by ionization of atmospheric molecules in continental boundary layers, but the situation might be different in the free atmosphere (Kazil et al., 2010; Hirsikko et al., 2011).

Condensation is the main process transferring low-volatility vapors to aerosol particles, and also usually the dominant process for growth to larger sizes. The growth of the smallest particles depends crucially on the

condensation of organic vapors (Donahue et al., 2011b; Riipinen et al., 2011; Yu, 2011) and is therefore tied strongly with atmospheric SOA formation discussed in Section 7.3.3.1. The treatment of condensation of semi-volatile compounds, such as ammonia, nitric acid and most organic vapors, remains a challenge in climate modeling. In addition, small aerosol particles collide with one another and stick (coagulate), one of the processes contributing to aerosol internal mixing. Coagulation is an important sink for sub-micrometer size particles, typically under high concentrations near sources and at lower concentrations in locations where the aerosol lifetime is long and amount of condensable vapors are low. It is the main sink for the smallest aerosol particles (Pierce and Adams, 2007).

Since AR4, observations of atmospheric nucleation and subsequent growth of nucleated particles to larger sizes have been increasingly reported in different atmospheric environments (Kulmala and Kerminen, 2008; Manninen et al., 2010; O'Dowd et al., 2010). Nucleation and growth enhance atmospheric CCN concentrations (Spracklen et al., 2008; Merikanto et al., 2009; Pierce and Adams, 2009a; Yu and Luo, 2009) and potentially affect aerosol-cloud interactions (Wang and Penner, 2009; Kazil et al., 2010; Makkonen et al., 2012a). However, CCN concentrations may be fairly insensitive to changes in nucleation rate because the growth of nucleated particles to larger sizes is limited by coagulation (see Sections 7.3.3.3 and 7.4.6.2).

Aerosols also evolve due to cloud processing, followed by the aerosol release upon evaporation of cloud particles, affecting the number concentration, composition, size and mixing state of atmospheric aerosol particles. This occurs via aqueous-phase chemistry taking place inside clouds, via altering aerosol precursor chemistry around and below clouds, and via different aerosol-hydrometeor interactions. These processes are discussed further in Section 7.4.1.2.

The understanding and modelling of aerosol sinks has seen less progress since AR4 in comparison to other aerosol processes. Improved dry deposition models, which depend on the particle size as well as the characteristics of the Earth's surface, have been developed and are increasingly being used in global aerosol models (Kerckweg et al., 2006; Feng, 2008; Petroff and Zhang, 2010). Sedimentation throughout the atmosphere and its role in dry deposition at the surface are important for the largest particles in the coarse mode. The uncertainty in the estimate of wet deposition by nucleation and impaction scavenging is controlled by the uncertainties in the prediction of the amount, frequency and areal extent of precipitation, as well as the size and chemical composition of aerosol particles. For insoluble primary particles like BC and dust, nucleation scavenging also depends strongly on their degree of mixing with soluble compounds. Parameterization of aerosol wet deposition remains a key source of uncertainty in aerosol models, which affects the vertical and horizontal distributions of aerosols (Prospero et al., 2010; Vignati et al., 2010; Lee et al., 2011), with further impact on model estimates of aerosol forcings.

7.3.3 Progress and Gaps in Understanding Climate Relevant Aerosol Properties

The climate effects of atmospheric aerosol particles depend on their atmospheric distribution, along with their hygroscopicity, optical properties and ability to act as CCN and IN. Key quantities for aerosol optical and cloud forming properties are the particle number size distribution, chemical composition, mixing state and morphology. These properties are determined by a complex interplay between their sources, atmospheric transformation processes and their removal from the atmosphere (Section 7.3.2, Figures 7.12 and 7.16). Since AR4, measurement of some of the key aerosol properties has been greatly improved in laboratory and field experiments using advanced instrumentation, which allows for instance the analysis of individual particles. These experimental studies have in turn stimulated improvement in the model representations of the aerosol physical, chemical and optical properties (Ghan and Schwartz, 2007). We focus our assessment on some of the key issues where there has been progress since AR4.

7.3.3.1 Chemical Composition and Mixing State

Research on the climate impacts of aerosols has moved beyond the simple cases of externally-mixed sulphate, BC emitted from fossil-fuel combustion, and biomass burning aerosols. Although the role of inorganic aerosols as an important anthropogenic contributor to aerosol-radiation and aerosol-cloud interactions has not been questioned, BC has received increasing attention because of its high absorption as has SOA because of its ubiquitous nature and ability to mix with other aerosol types.

The physical properties of BC (strongly light-absorbing, refractory with a vaporization temperature near 4000 K, aggregate in morphology, insoluble in most organic solvents) allow a strict definition in principle (Bond et al., 2013). Direct measurement of individual BC-containing particles is possible with laser-induced incandescence (also called SP2, Gao et al., 2007; Schwarz et al., 2008a; Moteki and Kondo, 2010), which has enabled accurate measurements of the size of BC cores, as well as total BC mass concentrations. Condensation of gas-phase compounds on BC and coagulation with other particles alter the mixing state of BC (e.g., Li et al., 2003; Pósfai et al., 2003; Adachi et al., 2010), which can produce internally mixed BC in polluted urban air on a timescale of about 12 hours (Moteki et al., 2007; McMeeking et al., 2010). The resulting BC-containing particles can become hygroscopic, which can lead to reduced lifetime and atmospheric loading (Stier et al., 2006).

Formation processes of OA still remain highly uncertain, which is a major weakness in the present understanding and model representation of atmospheric aerosols (Kanakidou et al., 2005; Hallquist et al., 2009; Ziemann and Atkinson, 2012). Measurements by aerosol mass spectrometers have provided some insights into sources and atmospheric processing of OA (Zhang et al., 2005b; Lanz et al., 2007; Ulbrich et al., 2009). Observations at continental mid-latitudes including urban and rural/remote air suggest that the majority of SOA is probably oxygenated OA (Zhang et al., 2005a; Zhang et al., 2007a). Experiments within and downstream of urban air indicate that under most circumstances SOA substantially contributes to the total OA mass (de Gouw et al., 2005; Volkamer et al., 2006; Zhang et al., 2007a).

There is a large range in the complexity with which OA is represented in global aerosol models. Some complex, yet still parameterized, chemical schemes have been developed recently that account for multigenerational oxidation (Robinson et al., 2007; Jimenez et al., 2009; Donahue et al., 2011a). Since AR4, some regional and global model have used a new scheme based on lumping VOCs into volatility bins (Robinson et al., 2007), which is an improved representation of the two-product absorptive partitioning scheme (Kroll and Seinfeld, 2008) for the formation and aging of SOA. This new framework includes organic compounds of different volatility, produced from parent VOCs by multi-generation oxidation processes and partitioned between the aerosol and gas phases (Farina et al., 2010; Tsimpidi et al., 2010; Yu, 2011), which improves the agreement between observed and modeled SOA in urban areas (Hodzic et al., 2010; Shrivastava et al., 2011). Field observations and laboratory studies suggest that OA is also formed efficiently in aerosol and cloud and liquid water contributing a substantial fraction of the organic aerosol mass (Sorooshian et al., 2007; Miyazaki et al., 2009; Lim et al., 2010; Ervens et al., 2011a). Chemical reactions in the aerosol phase (e.g., oligomerization) also make OA less volatile and more hygroscopic, influencing aerosol-radiation and aerosol-cloud interactions (Jimenez et al., 2009). As a consequence OA concentrations are probably underestimated in many global aerosol models that do not include these chemical processes (Hallquist et al., 2009).

Some of the OA is light absorbing and can be referred to as brown carbon (BrC, Kirchstetter et al., 2004; Andreae and Gelencser, 2006). A fraction of the SOA formed in cloud and aerosol water is light-absorbing in the visible (e.g., Shapiro et al., 2009), while SOA produced from gas-phase oxidation of VOCs absorbs ultraviolet radiation (e.g., Nakayama et al., 2010).

Multiple observations show co-existence of external and internal mixtures relatively soon after emission (e.g., Hara et al., 2003; Schwarz et al., 2008b; Twohy and Anderson, 2008). In biomass burning aerosol, organic compounds and BC are frequently internally mixed with ammonium, nitrate, and sulphate (Deboudt et al., 2010; Pratt and Prather, 2010). Over urban locations, as much as 90% of the particles are internally mixed with secondary inorganic species (Bi et al., 2011). Likewise mineral dust and biomass burning aerosols can become internally mixed when these aerosol types age together (Hand et al., 2010). The aerosol mixing state can alter particle size distribution and hygroscopicity and hence the aerosol optical properties and ability to act as CCN (Wex et al., 2010). Global aerosol models can now approximate the aerosol mixing state using size-resolving bin or modal schemes (e.g., Stier et al., 2005; Kim et al., 2008; Mann et al., 2010).

7.3.3.2 *Size Distribution and Optical Properties*

Aerosol size distribution is a key parameter determining both the aerosol optical and CCN properties. Since the AR4, much effort has been put on measuring and simulating the aerosol number rather than volume size distribution. For instance, number size distributions in the submicron range (30–500 nm) were measured at

24 sites in Europe for two years (Asmi et al., 2011), although systematic measurements are still limited in other regions. Although validation studies show agreement between column-averaged volume size distribution from sunphotometer measurements and direct in situ (surface as well as aircraft-based) measurements at some locations (Gerasopoulos et al., 2007; Radhi et al., 2010; Haywood et al., 2011), these inversion products have not been systematically validated. Satellite measurements produce valuable but more limited information on aerosol size.

The aerosol scattering, absorption and extinction coefficients depend on the aerosol size distribution, aerosol refractive index and mixing state. The humidification of internally-mixed aerosols further influences their light scattering and absorption properties, through changes in particle shape, size, and refractive index (Freney et al., 2010). Aerosol absorption is a key climate-relevant aerosol property and earlier in-situ methods to measure it suffered from significant uncertainties (Moosmüller et al., 2009), partly due to the lack of proper reference material for instrument calibration and development (Baumgardner et al., 2012). Recent measurements using photo-acoustic methods and laser-induced incandescence methods are more accurate but remain sparse. The mass absorption cross sections for freshly generated BC were measured to be $7.5 \pm 1.2 \text{ m}^2 \text{ g}^{-1}$ at 550 nm (Bond et al., 2013). Laboratory measurements conducted under well controlled conditions show that thick coating of soluble material over BC cores enhance the mass absorption cross section by a factor of 1.8 to 2 (Cross et al., 2010; Shiraiwa et al., 2010). It is more difficult to measure the enhancement factor in mass absorption cross sections for ambient BC, partly due to the necessity of removing coatings of BC. Knox et al. (2009) observed enhancement by a factor 1.2 to 1.6 near source regions. A much lower enhancement factor was observed by Cappa et al. (2012) by a new measurement technique, in contradiction to the laboratory experiments and theoretical calculations. These results may not be representative and would require confirmation by independent measurement methods.

As discussed in Section 7.3.1.2, the global-mean AOD is not well constrained from satellite-based measurements and remains a significant source of uncertainty when estimating aerosol-radiation interactions (Su et al., 2013). This is also true of the anthropogenic fraction of AOD which is more difficult to constrain from observations. AeroCom phase II models simulate an anthropogenic AOD at 550 nm of 0.03 ± 0.01 (with the range corresponding to one standard deviation) relative to 1850, which represents $24 \pm 6\%$ of the total AOD (Myhre et al., 2013). This is less than suggested by some satellite-based studies, i.e., 0.03 over the ocean only in Kaufman et al. (2005), and about 0.06 as a global average in Loeb and Su (2010) and Bellouin et al. (2013), but more than in the CMIP5 models (see Figure 9.29). Overall there is *medium confidence* that between 20 and 40% of the global-mean AOD is of anthropogenic origin. There is agreement that the anthropogenic aerosol is smaller in size and more absorbing than the natural aerosol (Myhre, 2009; Loeb and Su, 2010), but there is disagreement on the anthropogenic absorption AOD and its contribution to the total absorption AOD, i.e., 0.0015 ± 0.0007 (one standard deviation) relative to 1850 in Myhre et al. (2013) but about 0.004 and half of the total absorption AOD in Bellouin et al. (2013).

7.3.3.3 Cloud Condensation Nuclei (CCN)

A subset of aerosol particles acts as CCN (see Table 7.2). The ability of an aerosol particle to take up water and subsequently activate, thereby acting as a CCN at a given supersaturation, is determined by its size and composition. Common CCN in the atmosphere are composed of sea salt, sulphates and sulphuric acid, nitrate and nitric acid and some organics. The uptake of water vapour by hygroscopic aerosols strongly affects their R_{Fari}.

CCN activity of inorganic aerosols is relatively well understood, and lately most attention has been paid to the CCN activity of mixed organic/inorganic aerosols (e.g., King et al., 2010; Prisle et al., 2010). Uncertainties in our current understanding of CCN properties are due primarily to SOA (Good et al., 2010), mainly because OA is still poorly characterized (Jimenez et al., 2009). The important effect of the formation of SOA is that internally mixed SOA contributes to the mass of aerosol particles, and therefore to their sizes. The size of the CCN has been found to be more important than their chemical composition at two continental locations as larger particles are more readily activated than smaller particles because they require a lower critical supersaturation (Dusek et al., 2006; Ervens et al., 2007). However, the chemical composition may be important in other locations such as the marine environment, where primary organic particles (hydrogels) have been shown to be exceptionally good CCN (Orellana et al., 2011; Ovadnevaite et al., 2011). For SOA it is not clear how important surface tension effects and bulk-to-surface

partitioning of surfactants are, and if the water activity coefficient changes significantly as a function of the solute concentration (Prisle et al., 2008; Good et al., 2010).

The bulk hygroscopicity parameter κ has been introduced as a concise measure of how effectively an aerosol particle acts as a CCN (Rissler et al., 2004; Petters and Kreidenweis, 2007; Rissler et al., 2010). It can be measured experimentally and is increasingly being used as a way to characterize aerosol properties. Pringle et al. (2010) used surface and aircraft measurements to evaluate the κ distributions simulated by a global aerosol model, and found generally good agreement. When the aerosol is dominated by organics, discrepancies between values of κ obtained directly from both CCN activity measurements and sub-saturated particle water uptake measurements have been observed in some instances (e.g., Prenni et al., 2007; Irwin et al., 2010; Roberts et al., 2010), whereas in other studies closure has been obtained (e.g., Duplissy et al., 2008; Kammermann et al., 2010; Rose et al., 2011). Adsorption theory (Kumar et al., 2011) replaces κ -theory for CCN activation for insoluble particles (e.g., mineral dust) while alternative theories are still required for explanation of marine POA that seem to have peculiar gel-like properties (Ovadnevaite et al., 2011).

Available modelling studies (Pierce and Adams, 2009a; Wang and Penner, 2009; Schmidt et al., 2012a) disagree on the anthropogenic fraction of CCN (taken here at 0.2% supersaturation). Based on these studies we assess this fraction to be between 1/4 and 2/3 in the global mean with *low confidence*, and highlight large interhemispheric and regional variation. Models that neglect or underestimate volcanic and natural organic aerosols would overestimate this fraction.

7.3.3.4 Ice Nuclei (IN)

Aerosols that act as IN are solid substances at atmospheric temperatures and supersaturations. Mineral dust, volcanic ash and primary bioaerosols such as bacteria, fungal spores and pollen, are typically known as good IN (Vali, 1985; Hoose and Möhler, 2012). Conflicting evidence has been presented for the ability of BC, organic, organic semi-solid/glassy organic and biomass burning particles to act as IN (Hoose and Möhler, 2012; Murray et al., 2012). The importance of biological particles acting as IN is unclear. A new study finds evidence of a large fraction of submicron particles in the middle-to-upper troposphere to be composed of biological particles (DeLeon-Rodriguez et al., 2013); however global modelling studies suggest that their concentrations are not sufficient to play an important role for ice formation (Hoose et al., 2010a; Sesartic et al., 2012). Since BC has anthropogenic sources, its increase since pre-industrial times may have caused changes to the lifetime of mixed-phase clouds (Section 7.4.4) and thus to radiative forcing (Lohmann, 2002b; Section 7.5).

Four heterogeneous ice-nucleation modes are distinguished in the literature: immersion freezing (initiated from within a cloud droplet), condensation freezing (freezing during droplet formation), contact freezing (due to collision with an IN), and deposition nucleation which refers to the direct deposition of vapour onto IN. Lidar observations reveal that liquid cloud droplets are present before ice crystals form via heterogeneous freezing mechanisms (Ansmann et al., 2008; de Boer et al., 2011) indicating that deposition nucleation does not seem to be important for mixed-phase clouds. IN can either be bare or mixed with other substances. As bare particles age in the atmosphere, they acquire liquid surface coatings by condensing soluble species and water vapour or by coagulating with soluble particles, which may transform IN from deposition or contact nuclei into possible immersion nuclei. A change from contact to immersion freezing implies activation at colder temperatures, with consequences for the lifetime and radiative effect of mixed-phase clouds (Sections 7.4.4 and 7.5.3).

The atmospheric concentrations of IN are very uncertain because of the above-mentioned uncertainties in freezing mechanisms and the difficulty of measuring IN in the upper troposphere. The anthropogenic fraction cannot be estimated at this point because of a lack of knowledge about the anthropogenic fractions of BC and mineral dust acting as IN and the contributions of PBAP, OC and other aerosols acting as IN.

7.3.4 Aerosol-Radiation Interactions (ARI)

7.3.4.1 Aerosol-Radiation Interactions

The radiative effect due to aerosol-radiation interactions (RE_{ari}), formerly known as direct radiative effect, is the change in radiative flux caused by the combined scattering and absorption of radiation by anthropogenic and natural aerosols. The RE_{ari} results from well-understood physics and is close to being an observable quantity, yet our knowledge of aerosol and environmental characteristics needed to quantify the RE_{ari} at the global scale remains incomplete (Anderson et al., 2005; Satheesh and Moorthy, 2005; Jaeglé et al., 2011). The RE_{ari} requires knowledge of the spectrally-varying aerosol extinction coefficient, single scattering albedo, and phase function, which can in principle be estimated from the aerosol size distribution, shape, chemical composition, and mixing state (Figure 7.12). Radiative properties of the surface, atmospheric trace gases, and clouds also influence the RE_{ari}. In the solar spectrum under cloud-free conditions the RE_{ari} is typically negative at the top-of-atmosphere, but it weakens and can become positive with increasing aerosol absorption, decreasing upscatter fraction, or increasing albedo of the underlying surface. RE_{ari} is weaker in cloudy conditions, except when the cloud layer is thin or when absorbing aerosols are located above or between clouds (e.g. Chand et al., 2009). The RE_{ari} at the surface is negative and can be much stronger than the RE_{ari} at the top-of-atmosphere over regions where aerosols are absorbing (Li et al., 2010). In the longwave part of the spectrum, top-of-atmosphere RE_{ari} is generally positive and mainly exerted by coarse-mode aerosols, such as sea spray and desert dust (Reddy et al., 2005), and by stratospheric aerosols (McCormick et al., 1995).

There have been many measurement-based estimates of shortwave RE_{ari} (e.g., Yu et al., 2006; Bergamo et al., 2008; Di Biagio et al., 2010; Bauer et al., 2011) although some studies involve some degree of modelling. In contrast estimates of longwave RE_{ari} remain limited (e.g., Bharmal et al., 2009). Observed and calculated shortwave radiative fluxes agree within measurement uncertainty when aerosol properties are known (e.g., Osborne et al., 2011). Global observational estimates of the RE_{ari} rely on satellite remote sensing of aerosol properties and/or measurements of the Earth's radiative budget (Chen et al., 2011; Kahn, 2012). Estimates of shortwave top-of-atmosphere RE_{ari} annually averaged over cloud-free oceans range from -4 to -6 W m⁻², mainly contributed by sea spray (Bellouin et al., 2005; Loeb and Manalo-Smith, 2005; Yu et al., 2006; Myhre et al., 2007). However, RE_{ari} can reach tens of W m⁻² locally. Estimates over land are more difficult as the surface is less well characterised (Chen et al., 2009; Jethva et al., 2009) despite recent progress in aerosol inversion algorithms (e.g., Dubovik et al., 2011). Attempts to estimate the RE_{ari} in cloudy sky remain elusive (e.g., Peters et al., 2011b) although passive and active remote sensing of aerosols over clouds is now possible (Torres et al., 2007; Omar et al., 2009; Waquet et al., 2009; de Graaf et al., 2012). Notable areas of positive top-of-atmosphere RE_{ari} exerted by absorbing aerosols include the Arctic over ice surfaces (Stone et al., 2008) and seasonally over southeastern Atlantic stratocumulus clouds (Chand et al., 2009; de Graaf et al., 2012). While AOD and aerosol size are relatively well constrained, uncertainties in the aerosol single-scattering albedo (McComiskey et al., 2008; Loeb and Su, 2010) and vertical profile (e.g., Zarzycki and Bond, 2010) contribute significantly to the overall uncertainties in RE_{ari}. Consequently, diversity in large-scale numerical model estimates of RE_{ari} increases with aerosol absorption and between cloud-free and cloudy conditions (Stier et al., 2013).

7.3.4.2 Rapid Adjustments to Aerosol-Radiation Interactions

Aerosol-radiation interactions give rise to rapid adjustments (see Section 7.1), which are particularly pronounced for absorbing aerosols such as BC. Associated cloud changes are often referred to as the semi-direct aerosol effect (see Figure 7.3). The effective radiative forcing (ERF) from aerosol-radiation interactions is quantified in Section 7.5.2; only the corresponding processes governing rapid adjustments are discussed here. Impacts on precipitation are discussed in Section 7.6.3.

Since AR4, additional observational studies have found correlations between cloud cover and absorbing aerosols (e.g., Brioude et al., 2009; Wilcox, 2010), and eddy-resolving, regional and global scale modelling studies have helped confirm a causal link. Relationships between cloud and aerosol reveal a more complicated picture than initially anticipated (e.g., Hill and Dobbie, 2008; Koch and Del Genio, 2010; Zhuang et al., 2010; Sakaeda et al., 2011; Ghan et al., 2012).

Absorbing aerosols modify atmospheric stability in the boundary layer and free troposphere (e.g., Wendisch et al., 2008; Babu et al., 2011). The effect of this on cloud cover depends on the height of the aerosol relative to the cloud and the type of cloud (e.g., Yoshimori and Broccoli, 2008; Allen and Sherwood, 2010; Koch and Del Genio, 2010; Persad et al., 2012). Aerosol also reduces the downwelling solar radiation at the surface.

Together the changes in atmospheric stability and reduction in surface fluxes provide a means for aerosols to significantly modify the fraction of surface-forced clouds (Feingold et al., 2005; Sakaeda et al., 2011). These changes may also affect precipitation as discussed in Section 7.6.3.

Cloud cover is expected to decrease if absorbing aerosol is embedded in the cloud layer. This has been observed (Koren et al., 2004) and simulated (e.g., Feingold et al., 2005) for clouds over the Amazon forest in the presence of smoke aerosols. In the stratocumulus regime, absorbing aerosol above cloud top strengthens the temperature inversion, reduces entrainment and tends to enhance cloudiness. Satellite observations (Wilcox, 2010) and modelling (Johnson et al., 2004) of marine stratocumulus show a thickening of the cloud layer beneath layers of absorbing smoke aerosol, which induces a local negative forcing. The responses of other cloud types, such as those associated with deep convection, are not well determined.

Absorbing aerosols embedded in cloud drops enhance their absorption, which can affect the dissipation of cloud. The contribution to R_{Fari} is small (Stier et al., 2007; Ghan et al., 2012), and there is contradictory evidence regarding the magnitude of the cloud dissipation effect influencing ERF_{Fari} (Feingold et al., 2005; Ghan et al., 2012; Jacobson, 2012; Bond et al., 2013). Global forcing estimates are necessarily based on global models (see Section 7.5.2), although the accuracy of GCMs in this regard is limited by their ability to represent low cloud processes accurately. This is an area of concern as discussed in Section 7.2, and limits confidence in these estimates.

7.3.5 *Aerosol Responses to Climate Change and Feedback*

The climate drivers of changes in aerosols can be split into physical changes (temperature, humidity, precipitation, soil moisture, solar radiation, wind speed, sea ice extent, etc), chemical changes (availability of oxidants) and biological changes (vegetation cover and properties, plankton abundance and speciation, etc). The response of aerosols to climate change may constitute a feedback loop whereby climate processes amplify or dampen the initial perturbation (Carslaw et al., 2010; Raes et al., 2010). We assess here the relevance and strength of aerosol-climate feedbacks in the context of future climate change scenarios.

7.3.5.1 *Changes in Sea Spray and Mineral Dust*

Concentrations of sea spray will respond to changes in surface wind speed, atmospheric stability, precipitation, and sea ice cover (Struthers et al., 2011). Climate models disagree about the balance of effects, with estimates ranging from an overall 19% reduction in global sea salt burden from the present-day to year 2100 (Liao et al., 2006), to little sensitivity (Mahowald et al., 2006a), to a sizeable increase (Jones et al., 2007; Bellouin et al., 2011). In particular there is little understanding of how surface wind speed may change over the ocean in a warmer climate, and observed recent changes (e.g., Young et al., 2011; Section 2.7.2) may not be indicative of future changes. Given that sea spray particles comprise a significant fraction of CCN concentrations over the oceans, such large changes will feed back on climate through changes in cloud droplet number (Korhonen et al., 2010b).

Studies of the effects of climate change on dust loadings also give a wide range of results. Woodward et al. (2005) found a tripling of the dust burden in 2100 relative to present-day because of a large increase in bare soil fraction. A few studies projected moderate (10–20%) increases, or decreases (e.g., Tegen et al., 2004; Jacobson and Streets, 2009; Liao et al., 2009). Mahowald et al. (2006b) found a 60% decrease under a doubled CO₂ concentration due to the effect of CO₂ fertilization on vegetation. The large range reflects different responses of the atmosphere and vegetation cover to climate change forcings, and results in *low confidence* in these predictions.

7.3.5.2 *Changes in Sulphate, Ammonium and Nitrate Aerosols*

The DMS-sulphate-cloud-climate feedback loop could operate in numerous ways through changes in temperature, absorbed solar radiation, ocean mixed layer depth and nutrient recycling, sea-ice extent, wind speed, shift in marine ecosystems due to ocean acidification and climate change, and atmospheric processing of DMS into CCN. Although no study has included all the relevant effects, two decades of research have questioned the original formulation of the feedback loop (Leck and Bigg, 2007) and have provided important insights into this complex, coupled system (Ayers and Caine, 2007; Kloster et al., 2007; Carslaw et al.,

2010). There is now *medium confidence* for a weak feedback due to a weak sensitivity of the CCN population to changes in DMS emissions, based on converging evidence from observations and Earth System model simulations (Carslaw et al., 2010; Woodhouse et al., 2010; Quinn and Bates, 2011). Parameterizations of oceanic DMS production nevertheless lack robust mechanistic justification (Halloran et al., 2010) and as a result the sensitivity to ocean acidification and climate change remains uncertain (Bopp et al., 2004; Kim et al., 2010; Cameron-Smith et al., 2011).

Chemical production of sulphate increases with atmospheric temperature (Aw and Kleeman, 2003; Dawson et al., 2007; Kleeman, 2008), but future changes in sulphate are found to be more sensitive to simulated future changes in precipitation removal. Under fixed anthropogenic emissions, most studies to date predict a small (0–9%) reduction in global sulphate burden mainly because of future increases in precipitation (Liao et al., 2006; Racherla and Adams, 2006; Unger et al., 2006; Pye et al., 2009). However Rae et al. (2007) found a small increase in global sulphate burden from 2000–2100 because the simulated future precipitation was reduced in regions of high sulphate abundance.

Changes in temperature have a large impact on nitrate aerosol formation through shifting gas-particle equilibria. There is some agreement among global aerosol models that climate change alone will contribute to a decrease in the nitrate concentrations (Liao et al., 2006; Racherla and Adams, 2006; Pye et al., 2009; Bellouin et al., 2011) with the exception of Bauer et al. (2007) who found little change in nitrate for year 2030. It should be noted however that these modeling studies have reported that changes in precursor emissions are expected to increase nitrate concentrations in the future (Section 11.3.5). Besides the changes in meteorological parameters, climate change can also influence ammonium formation by changing concentrations of sulphate and nitrate, but the effect of climate change alone was found to be small (Pye et al., 2009).

7.3.5.3 Changes in Carbonaceous Aerosols

There is evidence that future climate change could lead to increases in the occurrence of wildfires because of changes in fuel availability, readiness of the fuel to burn and ignition sources (Mouillot et al., 2006; Marlon et al., 2008; Spracklen et al., 2009; Kloster et al., 2010; Pechony and Shindell, 2010). However vegetation dynamics may also play a role that is not well understood. Increased fire occurrence would increase aerosol emissions, but decrease BVOC emissions. This could lead to a small positive or negative net radiative effect and feedback (Carslaw et al., 2010).

A large fraction of SOA forms from the oxidation of isoprene, monoterpenes and sesquiterpenes from biogenic sources (Section 7.3.3.1). Emissions from vegetation can increase in a warmer atmosphere, everything else being constant (Guenther et al., 2006). Global aerosol models simulate an increase in isoprene emissions of 22–55% by 2100 in response to temperature change (Sanderson et al., 2003; Liao et al., 2006; Heald et al., 2008) and a change in global SOA burden of –6% to +100% through the climate-induced changes in aerosol processes and removal rates (Liao et al., 2006; Tsigaridis and Kanakidou, 2007; Heald et al., 2008). An observationally-based study suggest a small global feedback parameter of $-0.01 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$ despite larger regional effects (Paasonen et al., 2013). Increasing CO₂ concentrations, drought and surface ozone also affect BVOC emissions (Arneth et al., 2007; Peñuelas and Staudt, 2010), which adds significant uncertainty to future global emissions (Makkonen et al., 2012b). Future changes in vegetation cover, whether they are natural or anthropogenic, also introduce large uncertainty in emissions (Lathière et al., 2010; Wu et al., 2012). There is little understanding on how the marine source of organic aerosol may change with climate, notwithstanding the large range of emission estimates for the present day (Carslaw et al., 2010).

7.3.5.4 Synthesis

The emissions, properties and concentrations of aerosols or aerosol precursors could respond significantly to climate change, but there is little consistency across studies in the magnitude or sign of this response. The lack of consistency arises mostly from our limited understanding of processes governing the source of natural aerosols and the complex interplay of aerosols with the hydrological cycle. The feedback parameter as a result of the future changes in emissions of natural aerosols is mostly bracketed within $\pm 0.1 \text{ W m}^{-2} \text{ }^{\circ}\text{C}^{-1}$ (Carslaw et al., 2010). With respect to anthropogenic aerosols, Liao et al. (2009) showed a significant

positive feedback (feedback parameter of +0.04 to +0.15 W m⁻²°C⁻¹ on a global mean basis) while Bellouin et al. (2011) simulated a smaller negative feedback of -0.08 to -0.02 W m⁻²°C⁻¹. Overall we assess that models simulate relatively small feedback parameters (i.e., within ±0.2 W m⁻²°C⁻¹) with *low confidence*, however regional effects on the aerosol may be important.

7.4 Aerosol-Cloud Interactions

7.4.1 Introduction and Overview of Progress since AR4

This section assesses our understanding of aerosol-cloud interactions, emphasising the ways in which anthropogenic aerosol may be affecting the distribution and radiative properties of non- and weakly-precipitating clouds. The idea that anthropogenic aerosol is changing cloud properties, thus contributing a substantial forcing to the climate system, has been addressed to varying degrees in all of the previous IPCC assessment reports.

Since AR4, research has continued to articulate new pathways through which the aerosol may affect the radiative properties of clouds, as well as the intensity and spatial patterns of precipitation (e.g., Rosenfeld et al., 2008). Progress can be identified on four fronts: (i) global-scale modelling now represents a greater diversity of aerosol-cloud interactions, and with greater internal consistency; (ii) observational studies continue to document strong local correlations between aerosol and cloud properties or precipitation, but have become more quantitative and are increasingly identifying and addressing the methodological challenges associated with such correlations; (iii) regional-scale modelling is increasingly being used to assess regional influences of aerosol on cloud field properties and precipitation; (iv) fine-scale process models have begun to be used more widely, and among other things have shown how turbulent mixing, cloud and meso-scale circulations may buffer the effects of aerosol perturbations.

This section focuses on the microphysics of aerosol-cloud interactions in liquid, mixed-phase, and pure ice clouds. Their radiative implications are quantified in Section 7.5. This section also includes discussion of aerosol influences on light precipitation in shallow clouds but defers discussion of aerosol effects on more substantial precipitation from mixed-phase clouds to Section 7.6.4.

7.4.1.1 Classification of Hypothesised Aerosol-Cloud Interactions

Denman et al. (2007) catalogued several possible pathways via which the aerosol might affect clouds. Given the number of possible aerosol-cloud interactions, and the difficulty of isolating them individually, there is little value in attempting to assess each effect in isolation, especially since modelling studies suggest that the effects may interact and compensate (Stevens and Feingold, 2009; Morrison and Grabowski, 2011). Instead, all radiative consequences of aerosol-cloud interactions are grouped into an “effective radiative forcing due to aerosol-cloud interactions”, or ERF_{aci} (Figure 7.3). ERF_{aci} accounts for aerosol-related microphysical modifications to the cloud albedo (Twomey, 1977), as well as any secondary effects that result from clouds adjusting rapidly to changes in their environment (i.e., “lifetime effects”; Albrecht, 1989; Liou and Ou, 1989; Pincus and Baker, 1994). We do assess the physical underpinnings of the cloud albedo effect, but in contrast to previous assessments, no longer distinguish the resultant forcing. Note that ERF_{aci} includes potential radiative adjustments to the cloud system associated with aerosol-cloud interactions but does not include adjustments originating from aerosol-radiation interactions (ERF_{ari}). Possible contributions to ERF_{aci} from warm (liquid) clouds are discussed in Section 7.4.3, separately from those associated with adjustments by cold (ice or mixed-phase) clouds (Section 7.4.4). Figure 7.16 shows a schematic of many of the processes to be discussed in Sections 7.4, 7.5 and 7.6.

[INSERT FIGURE 7.16 HERE]

Figure 7.16: Schematic depicting the myriad aerosol-cloud-precipitation related processes occurring within a typical GCM grid box. The schematic conveys the importance of considering aerosol-cloud-precipitation processes as part of an interactive system encompassing a large range of spatiotemporal scales. Cloud types include low-level stratocumulus and cumulus where research focuses on aerosol activation, mixing between cloudy and environmental air, droplet coalescence and scavenging which results in cloud processing of aerosol particles, and new particle production near clouds; cirrus clouds where a key issue is ice nucleation through homogeneous and heterogeneous freezing; and deep convective clouds where some of the key questions relate to aerosol influences on liquid, ice, and liquid-ice pathways for precipitation formation, cold pool formation, and scavenging. These processes influence the shortwave and

longwave cloud radiative effect and hence climate. Primary processes that affect aerosol-cloud interactions are labeled in orange while secondary processes that result from and influence aerosol-cloud interactions are in grey.

7.4.1.2 *Advances and Challenges in Observing Aerosol-Cloud Interactions*

Since AR4, numerous field studies (e.g., Rauber et al., 2007; Wood et al., 2011b; Vogelmann et al., 2012) and laboratory investigations (e.g., Stratmann et al., 2009) of aerosol-cloud interactions have highlighted the numerous ways that the aerosol impacts cloud processes, and how clouds in turn modify the aerosol. The latter occurs along a number of pathways including aqueous chemistry, which adds aerosol mass to droplets (e.g., Schwartz and Freiberg, 1981; Ervens et al., 2011a); coalescence scavenging, whereby drop collision-coalescence diminishes the droplet (and aerosol) number concentration (Hudson, 1993) and changes the mixing state of the aerosol; new particle formation in the vicinity of clouds (Clarke et al., 1999); and aerosol removal by precipitation (see also Section 7.3.2.2).

Satellite-based remote sensing continues to be the primary source of global data for aerosol-cloud interactions but concerns persist regarding how measurement artefacts affect retrievals of both aerosol (Tanré et al., 1996; Tanré et al., 1997; Kahn et al., 2005; Jeong and Li, 2010) and cloud properties (Platnick et al., 2003; Yuekui and Di Girolamo, 2008) in broken cloud fields. Two key issues are that measurements classified as “cloud-free” may not be, and that aerosol measured in the vicinity of clouds is significantly different than it would be were the cloud field, and its proximate cause (high humidity), not present (e.g., Loeb and Schuster, 2008). The latter results from humidification effects on aerosol optical properties (Charlson et al., 2007; Su et al., 2008; Tackett and Di Girolamo, 2009; Twohy et al., 2009; Chand et al., 2012), contamination by undetectable cloud fragments (Koren et al., 2007) and the remote effects of radiation scattered by cloud edges on aerosol retrieval (Wen et al., 2007; Várnai and Marshak, 2009).

While most passive satellite retrievals are unable to distinguish aerosol layers above or below clouds from those intermingling with the cloud field, active space-based remote sensing (L'Ecuyer and Jiang, 2010) has begun to address this problem (Stephens et al., 2002; Anderson et al., 2005; Huffman et al., 2007; Chand et al., 2008; Winker et al., 2010). Spectral polarization and multi-angular measurements can discriminate between cloud droplets and aerosol particles and thus improve estimates of aerosol loading and absorption (Deuzé et al., 2001; Chowdhary et al., 2005; Mishchenko et al., 2007; Hasekamp, 2010).

Use of active remote sensing, both from monitoring ground stations (e.g., McComiskey et al., 2009; Li et al., 2011) and satellites (Costantino and Bréon, 2010), as well as aerosol proxies not influenced by cloud contamination of retrievals (Jiang et al., 2008; Berg et al., 2011) have emerged as a particular effective way of identifying whether aerosol and cloud perturbations are intermingled.

Because the aerosol is a strong function of air-mass history and origin, and is strongly influenced by cloud and precipitation processes (Clarke et al., 1999; Petters et al., 2006; Anderson et al., 2009), and both are affected by meteorology (Engström and Ekman, 2010; Boucher and Quaas, 2013), correlations between the aerosol and cloud, or precipitation, should not be taken as generally indicating a cloud response to the aerosol (e.g., Painemal and Zuidema, 2010). Furthermore, attempts to control for other important factors (air-mass history or cloud dynamical processes) are limited by a lack of understanding of large-scale cloud controlling factors in the first place (Anderson et al., 2009; Siebesma et al., 2009; Stevens and Brenguier, 2009). These problems are increasingly being considered in observationally-based inferences of aerosol effects on clouds and precipitation, but ascribing changes in cloud properties to changes in the aerosol remains a fundamental challenge.

7.4.1.3 *Advances and Challenges in Modelling Aerosol-Cloud Interactions*

Modelling of aerosol-cloud interactions must contend with the fact that the key physical processes are fundamentally occurring at the fine scale and cannot be represented adequately based on large-scale fields. There exist two distinct challenges: fundamental understanding of processes, and their representation in large-scale models.

Fine-scale LES and CRM models (Section 7.2.2.1) have greatly advanced as a tool for testing the physical mechanisms proposed to govern aerosol-cloud-precipitation interactions (e.g., Ackerman et al., 2009;

vanZanten et al., 2011). Their main limitation is that they are idealised, e.g., they do not resolve synoptic scale circulations or allow for representation of orography. A general finding from explicit numerical simulations of warm (liquid) clouds is that various aerosol impact mechanisms tend to be mediated (and often buffered) by interactions across scales not included in the idealised albedo and lifetime effects (Stevens and Feingold, 2009). Specific examples involve the interplay between the drop-size distribution and mixing processes that determine cloud macrostructure (Stevens et al., 1998; Ackerman et al., 2004; Bretherton et al., 2007; Wood, 2007; Small et al., 2009), or the dependence of precipitation development in stratiform clouds on details of the vertical structure of the cloud (Wood, 2007). Thus warm clouds may typically be less sensitive to aerosol perturbations in nature than in large-scale models, which do not represent all of these compensating processes. Hints of similar behaviour in mixed-phase (liquid and ice) stratus are beginning to be documented (Section 7.4.4.3) but process-level understanding and representation in models are less advanced.

Regional models include realism in the form of non-idealised meteorology, synoptic scale forcing, variability in land surface, and diurnal/monthly cycles (e.g., Iguchi et al., 2008; Bangert et al., 2011; Seifert et al., 2012; Tao et al., 2012), however at the expense of resolving fine-scale cloud processes. Regional models have brought to light the possibility of aerosol patchiness manifesting changes in circulation patterns via numerous mechanisms including changes in the radiative properties of cloud anvils (van den Heever et al., 2011), changes in the spatial distribution of precipitation (Lee, 2012; Section 7.6.2), or gradients in heating rates associated with aerosol-radiation interactions (Lau et al., 2006; Section 7.3.4.2).

GCMs, our primary tool for quantifying global-mean forcings, now represent an increasing number of hypothesised aerosol-cloud interactions, but at poor resolution. GCMs are being more closely scrutinised through comparisons to observations and to other models (Quaas et al., 2009; Penner et al., 2012). Historically, aerosol-cloud interactions in GCMs have been based on simple constructs (e.g., Twomey, 1977; Albrecht, 1989; Pincus and Baker, 1994). There has been significant progress on parameterizing aerosol activation (e.g., Ghan et al., 2011) and ice nucleation (Liu and Penner, 2005; Barahona and Nenes, 2008; DeMott et al., 2010; Hoose et al., 2010b); however these still depend heavily on unresolved quantities such as updraught velocity. Similarly, parameterizations of aerosol influences on cloud usually do not account for known non-monotonic responses of cloud amount and properties to aerosols (Section 7.4.3.2). Global models are now beginning to represent aerosol effects in convective, ice and mixed-phase clouds (e.g., Lohmann, 2008; Song and Zhang, 2011; Section 7.6.4). Nevertheless, for both liquid-only and mixed-phase clouds, these parameterisations are severely limited by the need to parameterize cloud-scale motions over a huge range of spatiotemporal scales (Section 7.2.3).

Although advances have been considerable, the challenges remain daunting. The response of cloud systems to aerosol is nuanced (e.g., vanZanten et al., 2011) and the representation of both clouds and aerosol-cloud interactions in large-scale models remains primitive (Section 7.2.3). Thus it is not surprising that large-scale models exhibit a range of manifestations of aerosol-cloud interactions, which limits quantitative inference (Quaas et al., 2009). This highlights the need to incorporate into GCMs the lessons learned from cloud-scale models, in a physically-consistent way. New “super-parameterisation” and probability distribution function approaches (Golaz et al., 2002; Rio and Hourdin, 2008; Section 7.2.2.2) hold promise, with recent results supporting the notion that aerosol forcing is smaller than simulated by standard climate models (Wang et al., 2011b; see Section 7.5.3).

7.4.1.4 Combined Modelling and Observational Approaches

Combined approaches, which attempt to maximize the respective advantage of models and observations, are beginning to add to understanding of aerosol-cloud interactions. These include inversions of the observed historical record using simplified climate models (e.g., Forest et al., 2006; Aldrin et al., 2012) but also the use of reanalysis and chemical transport models to help interpret satellite records (Chameides et al., 2002; Koren et al., 2010a; Mauger and Norris, 2010), field study data to help constrain fine-scale modelling studies (e.g., Ackerman et al., 2009; vanZanten et al., 2011), or satellite/surface-based climatologies to constrain large-scale modelling (Wang et al., 2012).

7.4.2 Microphysical Underpinnings of Aerosol-Cloud Interactions

7.4.2.1 *The Physical Basis*

The cloud albedo effect (Twomey, 1977) is the mechanism by which an increase in aerosol number concentration leads to an increase in the albedo of liquid clouds (reflectance of incoming solar radiation) by increasing the cloud droplet number concentration, decreasing the droplet size, and hence increasing total droplet surface area, with the liquid water content and cloud geometrical thickness hypothetically held fixed. Although only the change in the droplet concentration is considered in the original concept of the cloud albedo effect, a change in the shape of the droplet size distribution that is directly induced by the aerosols may also play a role (e.g., Feingold et al., 1997; Liu and Daum, 2002). In the Arctic, anthropogenic aerosol may influence the longwave emissivity of optically-thin liquid clouds and generate a positive forcing at the surface (Garrett and Zhao, 2006; Lubin and Vogelmann, 2006; Mauritsen et al., 2011), but top-of-atmosphere forcing is thought to be negligible.

7.4.2.2 *Observational Evidence for Aerosol-Cloud Interactions*

The physical basis of the albedo effect is fairly well understood, with research since AR4 generally reinforcing earlier work. Detailed in-situ aircraft observations show that droplet concentrations observed just above the cloud base generally agree with those predicted based on the aerosol properties and updraught velocity observed below the cloud (e.g., Fountoukis et al., 2007). Vertical profiles of cloud droplet effective radius also agree with those predicted by models that take into account the effect of entrainment (Lu et al., 2008), although uncertainties still remain in estimating the shape of the droplet size distribution (Brenguier et al., 2011), and the degree of entrainment mixing within clouds.

At relatively low aerosol loading (AOD less than about 0.3) there is ample observational evidence for increases in aerosol resulting in an increase in droplet concentration and decrease in droplet size (for constant liquid water) but uncertainties remain regarding the magnitude of this effect, and its sensitivity to spatial averaging. Based on simple metrics, there is a large range of physically plausible responses, with aircraft measurements (e.g., Twohy et al., 2005; Lu et al., 2007; Lu et al., 2008; Hegg et al., 2012) tending to show stronger responses than satellite-derived responses (McComiskey and Feingold, 2008; Nakajima and Schulz, 2009; Grandey and Stier, 2010). At high AOD and high aerosol concentration, droplet concentration tends to saturate (e.g., Verheggen et al., 2007) and, if the aerosol is absorbing, there may be reductions in droplet concentration and cloudiness (Koren et al., 2008). This absorbing effect originates from aerosol-radiation interactions and is therefore part of ERF_{aci} (Section 7.3.4.2). Negative correlation between AOD and ice particle size has also been documented in deep convective clouds (e.g., Sherwood, 2002; Jiang et al., 2008).

7.4.2.3 *Advances in Process Level Understanding*

At the heart of the albedo effect lie two fundamental issues. The first is aerosol activation and its sensitivity to aerosol and dynamical parameters. The primary controls on droplet concentration are the aerosol number concentration (particularly at diameters greater than about 60 nm) and cooling rate (proportional to updraught velocity). Aerosol size distribution can play an important role under high aerosol loadings, whereas aerosol composition tends to be much less important, except perhaps under very polluted conditions and low updraught velocities (e.g., Ervens et al., 2005; McFiggans et al., 2006). This is partially because aging tends to make particles more hygroscopic regardless of their initial composition, but also because more hygroscopic particles lead to faster water vapour uptake, which then lowers supersaturation, limiting the initial increase in activation.

The second issue is that the amount of energy reflected by a cloud system is a strong function of the amount of condensate. Simple arguments show that in a relative sense the amount of reflected energy is approximately two-and-a-half times more sensitive to changes in the liquid water path than to changes in droplet concentration (Boers and Mitchell, 1994). Since both these parameters experience similar ranges of relative variability, the magnitude of aerosol-cloud related forcing rests mostly on dynamical factors such as turbulent strength and entrainment that control cloud condensate, and a few key aerosol parameters such as aerosol number concentration and size distribution, and to a much lesser extent, composition.

7.4.3 *Forcing Associated with Adjustments in Liquid Clouds (ERF_{aci})*

7.4.3.1 *The Physical Basis for Adjustments in Liquid Clouds*

The adjustments giving rise to ERF_{aci} are multi-faceted and are associated with both albedo and so-called ‘lifetime’ effects (Figure 7.3). However this old nomenclature is misleading because it assumes a relationship between cloud lifetime and cloud amount or water content. Moreover, the effect of the aerosol on cloud amount may have nothing to do with cloud lifetime per se (e.g., Pincus and Baker, 1994).

The traditional view (Albrecht, 1989; Liou and Ou, 1989) has been that adjustment effects associated with aerosol-cloud-precipitation interactions will add to the initial albedo increase by increasing cloud amount. The chain of reasoning involves three steps: that droplet concentrations depend on the number of available CCN; that precipitation development is regulated by the droplet concentration; and that the development of precipitation reduces cloud amount (Stevens and Feingold, 2009). Of the three steps, the first has ample support in both observations and theory (Section 7.4.2.2). More problematic are the last two links in the chain of reasoning. Although increased droplet concentrations inhibit the initial development of precipitation (see Section 7.4.3.2.1), it is not clear that such an effect is sustained in an evolving cloud field. In the trade-cumulus regime, some modelling studies suggest the opposite, with increased aerosol concentrations actually promoting the development of deeper clouds and invigorating precipitation (Stevens and Seifert, 2008; see discussion of similar responses in deep convective clouds in Section 7.6.4). Others have shown alternating cycles of larger *and* smaller cloud water in both aerosol-perturbed stratocumulus (Sandu et al., 2008) and trade cumulus (Lee et al., 2012), pointing to the important role of environmental adjustment. There exists limited unambiguous observational evidence (exceptions to be given below) to support the original hypothesised cloud-amount effects, which are often assumed to hold universally and have dominated GCM parameterisation of aerosol-cloud interactions. GCMs lack the more nuanced responses suggested by recent work, which influences their ERF_{aci} estimates.

7.4.3.2 *Observational Evidence of Adjustments in Liquid Clouds*

Since observed effects generally include both the albedo effect and the adjustments, with few if any means of observing only one or the other in isolation, in this section we discuss and interpret observational findings that reflect both effects. Stratocumulus and trade cumulus regimes are discussed separately.

7.4.3.2.1 *Stratocumulus*

The cloud albedo effect is best manifested in so-called ship tracks, which are bright lines of clouds behind ships. Many ship tracks are characterized by an increase in the droplet concentration resulting from the increase in aerosol number concentration and an absence of drizzle size drops, which leads to a decrease in the droplet radius and an increase in the cloud albedo (Durkee et al., 2000), all else equal. However, liquid water changes are the primary determinant of albedo changes (Section 7.4.2.3; Chen et al., 2012), therefore adjustments are key to understanding radiative response. Coakley and Walsh (2002) showed that cloud water responses can be either positive or negative. This is supported by more recent shiptrack analyses based on new satellite sensors (Christensen and Stephens, 2011): aerosol intrusions result in weak decreases in liquid water (−6%) in overcast clouds, but significant increases in liquid water (+39%) and increases in cloud fraction in precipitating, broken stratocumulus clouds. The global ERF_{aci} of visible ship tracks has been estimated from satellite and found to be insignificant at about -0.5 mW m^{-2} (Schreier et al., 2007), although this analysis may not have identified all shiptracks. Some observational studies downwind of ship tracks have been unable to distinguish aerosol influences from meteorological influences on cloud microphysical or macrophysical properties (Peters et al., 2011a), although it is not clear whether their methodology had sufficient sensitivity to detect the aerosol effects. Notwithstanding evidence of shiptracks locally increasing the cloud fraction and albedo of broken cloud scenes quite significantly (e.g., Christensen and Stephens, 2011; Goren and Rosenfeld, 2012), their contribution to global ERF_{aci} is thought to be small. These ship track results are consistent with satellite studies of the influence of long-term degassing of low-lying volcanic aerosol on stratocumulus, which point to smaller droplet sizes but ambiguous changes in cloud fraction and cloud water (Gasso, 2008). The lack of clear evidence for a global increase in cloud albedo from shiptracks and volcanic plumes should be borne in mind when considering geoengineering methods that rely on cloud modification (Section 7.7.2.2).

The development of precipitation in stratocumulus, whether due to aerosol or meteorological influence can, in some instances, change a highly reflective closed-cellular cloud field to a weakly reflective broken open-

cellular field (Comstock et al., 2005; Stevens et al., 2005a; vanZanten et al., 2005; Sharon et al., 2006; Savic-Jovicic and Stevens, 2008; Wang and Feingold, 2009a). In some cases, compact regions (pockets) of open-cellular convection become surrounded by regions of closed-cellular convection. It is, however, noteworthy that observed precipitation rates can be similar in both open and closed-cell environments (Wood et al., 2011a). The lack of any apparent difference in the large-scale environment of the open cells, versus the surrounding closed cellular convection, suggests the potential for multiple equilibria (Baker and Charlson, 1990; Feingold et al., 2010). Therefore in the stratocumulus regime, the onset of precipitation due to a dearth of aerosol may lead to a chain of events that leads to a large-scale reduction of cloudiness in agreement with Liou and Ou (1989) and Albrecht (1989). The transition may be bidirectional: ship tracks passing through open-cell regions also appear to revert the cloud field to a closed-cell regime inducing a potentially strong ERFaci locally (Christensen and Stephens, 2011; Wang et al., 2011a; Goren and Rosenfeld, 2012).

7.4.3.2.2 *Trade-cumulus*

Precipitation from trade cumuli proves difficult to observe, as the clouds are small, and not easily observed by space-based remote sensing techniques (Stephens et al., 2008). Satellite remote sensing of trade cumuli influenced by aerosol associated with slow volcanic degassing points to smaller droplet size, decreased precipitation efficiency, increased cloud amount, and higher cloud tops (Yuan et al., 2011). Other studies show that in the trade cumulus regime cloud amount tends to increase with precipitation amount: e.g., processes that favour precipitation development also favour cloud development (Nuijens et al., 2009); precipitation-driven colliding outflows tend to regenerate clouds; and trade cumuli that support precipitation reach heights where wind shear increases cloud fraction (Zuidema et al., 2012).

While observationally-based study of the microphysical aspects of aerosol-cloud interactions has a long history, more recent assessment of the ability of detailed models to reproduce the associated radiative effect in cumulus cloud fields is beginning to provide the important link between aerosol-cloud interactions and total radiative forcing (Schmidt et al., 2009).

7.4.3.3 *Advances in Process Level Understanding*

Central to ERFaci is the question of how susceptible is precipitation to droplet concentration, and by inference, to the available aerosol. Some studies point to the droplet effective radius as a threshold indicator of the onset of drizzle (Rosenfeld and Gutman, 1994; Gerber, 1996; Rosenfeld et al., 2012). Others focus on the sensitivity of the conversion of cloud-water to rain-water (i.e., autoconversion) to droplet concentration, which is usually in the form of (droplet concentration) to the power $-\alpha$. Both approaches indicate that from the microphysical standpoint, an increase in the aerosol suppresses rainfall. Models and theory show α ranging from $\frac{1}{2}$ (Kostinski, 2008; Seifert and Stevens, 2010) to 2 (Khairoutdinov and Kogan, 2000), while observational studies suggest $\alpha = 1$ (approximately the inverse of drop concentration; Pawlowska and Brenguier, 2003; Comstock et al., 2005; vanZanten et al., 2005). Note that thicker liquid clouds amplify rain via accretion of cloud droplets by raindrops, a process that is relatively insensitive to droplet concentration, and therefore to aerosol perturbations (e.g., Khairoutdinov and Kogan, 2000). The balance of evidence suggests that $\alpha = \frac{1}{2}$ is more likely and that liquid water path (or cloud depth) has significantly more leverage over precipitation than does droplet concentration. Many GCMs assume a much stronger relationship between precipitation and cloud droplet number concentration (i.e., $\alpha = 2$) (Quaas et al., 2009).

Small-scale studies (Ackerman et al., 2004; Xue et al., 2008; Small et al., 2009) and satellite observations (Lebsock et al., 2008; Christensen and Stephens, 2011) tend to confirm two responses of the cloud liquid water to increasing aerosol. Under clean conditions when clouds are prone to precipitation, an increase in the aerosol tends to increase cloud amount as a result of aerosol suppression of precipitation. Under non-precipitating conditions, clouds tend to thin in response to increasing aerosol through a combination of droplet sedimentation (Bretherton et al., 2007) and evaporation-entrainment adjustments (e.g., Hill et al., 2009). Treatment of the subtlety of these responses and associated detail in small-scale cloud processes is not currently feasible in GCMs, although probability distribution function approaches are promising (Guo et al., 2010).

Since AR4, cloud resolving model simulation has begun to stress the importance of scale interactions when addressing aerosol-cloud interactions. Model domains on the order of 100 km allow mesoscale circulations to develop in response to changes in the aerosol. These dynamical responses may have a significant impact

on cloud morphology and radiative forcing. Examples include the significant changes in cloud albedo associated with transitions between closed and open cellular states discussed above, and the cloud-free, downdraught “shadows” that appear alongside ship tracks (Wang and Feingold, 2009b). Similar examples of large-scale changes in circulation associated with aerosol, and associated influence on precipitation are discussed in Section 7.6.4. These underscore the large gap between our process level understanding of aerosol-cloud-precipitation interactions and the ability of GCMs to represent them.

7.4.3.4 *Advances in and Insights Gained from Large-Scale Modelling Studies*

Regional models are increasingly including representation of aerosol-cloud interactions using sophisticated microphysical models (Bangert et al., 2011; Yang et al., 2011; Seifert et al., 2012). Some of these regional models are operational weather forecast models that undergo routine evaluation. Yang et al. (2011) show improved simulations of stratocumulus fields when aerosol-cloud interactions are introduced. Regional models are increasingly being used to provide the meteorological context for satellite observations of aerosol-cloud interactions (see Section 7.4.1.4) with some (e.g., Painemal and Zuidema, 2010) suggesting that droplet concentration differences, are primarily driven by synoptic scale influences rather than aerosol.

GCM studies that have explored sensitivity to autoconversion parameterization (Golaz et al., 2011) show that ER_{Faci} can vary by 1 W m^{-2} depending on the parameterization. Elimination of the sensitivity of rain formation to the autoconversion process has begun to be considered in GCMs (Posselt and Lohmann, 2009). Wang et al. (2012) have used satellite observations to constrain autoconversion and find a reduction in ER_{Faci} of about 33% relative to a standard GCM autoconversion parameterization. It is worth reiterating that these uncertainties are not necessarily associated with uncertainties in the physical process itself, but more so by the ability of a GCM to resolve the processes (see Section 7.4.1.3).

7.4.4 *Adjustments in Cold Clouds*

7.4.4.1 *The Physical Basis for Adjustments in Cold Clouds*

Mixed-phase clouds, containing both liquid water and ice particles, exist at temperatures between 0°C and -38°C . At warmer temperatures ice melts rapidly, whereas at colder temperatures liquid water freezes homogeneously. The formation of ice in mixed-phase clouds depends on heterogeneous freezing, initiated by IN (Section 7.3.3.4), which are typically solid or crystalline aerosol particles. In spite of their very low concentrations (on the order of 1 per litre), IN have an important influence on mixed-phase clouds. Mineral dust particles have been identified as good IN but far less is known about the IN ability of other aerosol types, and their preferred modes of nucleation. For example, the ice nucleating ability of BC particles remains controversial (Hoose and Möhler, 2012). Soluble matter can hinder glaciation by depressing the freezing temperature of super-cooled drops to the point where homogeneous freezing occurs (e.g., Girard et al., 2004; Baker and Peter, 2008). Hence anthropogenic perturbations to the aerosol have the potential to affect glaciation, water and ice optical properties, and their radiative effect.

Because the equilibrium vapour pressure with respect to ice is lower than that with respect to liquid, the initiation of ice in a supercooled liquid cloud will cause vapour to diffuse rapidly toward ice particles at the expense of the liquid water (Wegener-Bergeron-Findeisen process; e.g., Schwarzenbock et al., 2001; Verheggen et al., 2007; Hudson et al., 2010). This favours the depositional growth of ice crystals, the largest of which may sediment away from the water-saturated region of the atmosphere, influencing the subsequent evolution of the cloud. Hence anthropogenic perturbations to the IN can influence the rate at which ice forms, which in turn may regulate cloud amount (Lohmann, 2002b; Storelvmo et al., 2011; see also Section 7.2.3.2.2), cloud optical properties, and humidity near the tropopause.

Finally, formation of the ice-phase releases latent heat to the environment (influencing cloud dynamics), and provides alternate, complex pathways for precipitation to develop (e.g., Zubler et al., 2011, and Section 7.6.4).

7.4.4.2 *Observations of ER_{Faci} in Deep Convective Clouds*

As noted in Section 7.4.2.2, observations have demonstrated correlations between aerosol loading and ice crystal size but influence on cloud optical depth is unclear (e.g., Koren et al., 2005). Satellite remote sensing suggests that aerosol-related invigoration of deep convective clouds may generate more extensive anvils that radiate at cooler temperatures, are optically thinner, and generate a positive contribution to ERF_{aci} (Koren et al., 2010b). The global influence on ERF_{aci} is unclear.

7.4.4.3 *Observations of Aerosol Effects on Arctic Ice and Mixed-Phase Stratiform Clouds*

Arctic mixed-phase clouds have received a great deal of attention since AR4, with major field programs conducted in 2004 (Verlinde et al., 2007) and 2008 (Jacob et al., 2010; Brock et al., 2011; McFarquhar et al., 2011), in addition to long-term monitoring at high northern latitude stations (e.g., Shupe et al., 2008) and analysis of earlier field experiments (Uttal et al., 2002). Mixed-phase Arctic clouds persist for extended periods of time (days and even weeks; Zuidema et al., 2005), in spite of the inherent instability of the ice-water mix (see also Section 7.2.3.2.2). In spite of their low concentrations, IN have an important influence on cloud persistence, with clouds tending to glaciate and disappear rapidly when IN concentrations are relatively high and/or updraught velocities too small to sustain a liquid water layer (e.g., Ovchinnikov et al., 2011). The details of the heterogeneous ice-nucleation mechanism remain controversial but there is increasing evidence that ice forms in Arctic stratus via the liquid phase (immersion freezing) so that the CCN population also plays an important role (de Boer et al., 2011; Lance et al., 2011). If ice indeed forms via the liquid phase this represents a self-regulating feedback that helps sustain the mixed-phase clouds: as ice forms, liquid water (the source of the ice) is depleted, which restricts further ice formation and competition for water vapour via the Wegener-Bergeron-Findeisen process (Morrison et al., 2012).

7.4.4.4 *Advances in Process Level Understanding*

Since AR4 research on ice-microphysical processes has been very active as evidenced by the abovementioned field experiments (Section 7.4.4.3). The persistence of some mixed-phase stratiform clouds has prompted efforts to explain this phenomenon in a theoretical framework (Korolev and Field, 2008). Predicting cloud persistence may require a high level of understanding of very detailed processes. For example, ice particle growth by vapour diffusion depends strongly on crystal shape (Harrington et al., 2009), the details of which may have similar relative influence on glaciation times to the representation of ice nucleation mechanism (Ervens et al., 2011b). A recent review (Morrison et al., 2012) discusses the myriad processes that create a resilient mixed-phase cloud system, invoking the ideas of “buffering” seen in liquid clouds (Stevens and Feingold, 2009). Importantly, the Wegener-Bergeron-Findeisen process does not necessarily destabilise the cloud system, unless sufficient ice exists (Korolev, 2007). Bistability has also been observed in the mixed-phase Arctic cloud system; the resilient cloud state is sometimes interrupted by a cloud-free state (Stramler et al., 2011), however there is much uncertainty regarding the meteorological and microphysical conditions determining which of these states is preferred.

Significant effort has been expended on heterogeneous freezing parameterizations employed in cloud or larger-scale models. Some parameterizations are empirical (e.g., Lohmann and Diehl, 2006; Hoose et al., 2008; Phillips et al., 2008; Storelvmo et al., 2008a; DeMott et al., 2010; Gettelman et al., 2010; Salzmann et al., 2010), whereas others attempt to represent the processes explicitly (Jacobson, 2003) or ground the development of parameterisations in concepts derived from classical nucleation theory (Chen et al., 2008; Hoose et al., 2010b). The details of how these processes are treated have important implications for tropical anvils (Ekman et al., 2007; Fan et al., 2010).

Homogeneous ice nucleation in cirrus clouds (at temperatures lower than about -38°C) depends crucially on the cloud updraught velocity and hence the supersaturation with respect to ice. The onset relative humidities for nucleation have been parameterized using results of parcel model simulations (e.g., Sassen and Dodd, 1988; Barahona and Nenes, 2009), airborne measurements in cirrus or wave clouds (Heymsfield and Miloshevich, 1995; Heymsfield et al., 1998), extensions of classical homogeneous ice nucleation theory (Khvorostyanov and Sassen, 1998; Khvorostyanov and Curry, 2009), and data from laboratory measurements (e.g., Bertram et al., 2000; Koop et al., 2000; Mohler et al., 2003; Magee et al., 2006; Friedman et al., 2011). There is new evidence that although ice nucleation in cirrus has traditionally been regarded as homogeneous, the preferred freezing pathway may be heterogeneous because it occurs at lower onset relative humidities (or higher onset temperatures) than homogeneous nucleation (Jensen et al., 2010).

The onset relative humidities (or temperatures) for heterogeneous nucleation depend on the type and size of the IN (Section 7.3.3.4).

Cloud resolving modeling of deep convective clouds points to the potential for aerosol-related changes in cirrus anvils (e.g., Morrison and Grabowski, 2011; van den Heever et al., 2011; Storer and van den Heever, 2013), but the physical mechanisms involved and their influence on ERF_{aci} are poorly understood, and their global impact is unclear.

7.4.4.5 Advances in and Insights Gained from Large-Scale Modelling Studies

Since the AR4 mixed-phase and ice clouds have received significant attention, with effort on representation of both heterogeneous (mixed-phase clouds) and homogeneous (cirrus) freezing processes in GCMs (e.g., Lohmann and Kärcher, 2002; Storelvmo et al., 2008a). In GCMs the physics of cirrus clouds usually only involves ice-phase microphysical processes and are somewhat simpler than for mixed-phase clouds. Nevertheless, representation of aerosol-cloud interactions in mixed-phase and ice clouds is considerably less advanced than that involving liquid-only clouds.

Our poor understanding of the climatology and lifecycle of aerosol particles that can serve as IN complicates attempts to assess what constitutes an anthropogenic perturbation to the IN population, let alone the effect of such a perturbation. BC can impact background (i.e., non contrail) cirrus by affecting ice nucleation properties but the effect remains uncertain (Kärcher et al., 2007). The numerous GCM studies that have evaluated ERF_{aci} for ice clouds are summarised in Section 7.5.4.

7.4.5 Synthesis on Aerosol-Cloud Interactions

Earlier assessments considered the radiative implications of aerosol-cloud interactions as two complementary processes—albedo and lifetime effects—that together amplify forcing. Since then the complexity of cloud system responses to aerosol perturbations has become more fully appreciated. Recent work at the process scale has identified compensating adjustments that make the system less susceptible to perturbation than might have been expected based on the earlier albedo and lifetime effects. Increases in the aerosol can therefore result in either an increase or a decrease in aerosol-cloud related forcing depending on the particular environmental conditions. Because many current GCMs do not include the possibility of compensating effects that are not mediated by the large-scale state, there are grounds for expecting these models to overestimate the magnitude of ERF_{aci}. Nevertheless it is also possible that poorly understood and unrepresented interactions could cause real ERF_{aci} to differ in either direction from that predicted by current models. Forcing estimates are discussed in Section 7.5.3.

7.4.6 Impact of Cosmic Rays on Aerosols and Clouds

Many studies have reported observations that link solar activity to particular aspects of the climate system (e.g., Bond et al., 2001; Dengel et al., 2009; Eichler et al., 2009). Various mechanisms have been proposed that could amplify relatively small variations in total solar irradiance, such as changes in stratospheric and tropospheric circulation induced by changes in the spectral solar irradiance or an effect of the flux of cosmic rays on clouds. We focus in this subsection on the latter hypothesis while Box 10.2 discusses solar influences on the climate system more generally.

Solar activity variations influence the strength and three-dimensional structure of the heliosphere. High solar activity increases the deflection of low energy cosmic rays, which reduces the flux of cosmic rays impinging upon the Earth's atmosphere. It has been suggested that the ionization caused by cosmic rays in the troposphere has an impact on aerosols and clouds (e.g., Dickinson, 1975; Kirkby, 2007). This subsection assesses studies that either seek to establish a causal relationship between cosmic rays and aerosols or clouds by examining empirical correlations, or test one of the physical mechanisms that have been put forward to account for such a relationship.

7.4.6.1 Observed Correlations Between Cosmic Rays and Properties of Aerosols and Clouds

Correlation between the cosmic ray flux and cloud properties has been examined for decadal variations induced by the 11-year solar cycle, shorter variations associated with the quasi-periodic oscillation in solar activity centred on 1.68 years, or sudden and large variations known as Forbush decrease events. It should be noted that long-term variations in cloud properties are difficult to detect (Section 2.5.6) while short-term variations may be difficult to attribute to a particular cause. Moreover the cosmic ray flux co-varies with other solar parameters such as solar and UV irradiance. This makes any attribution of cloud changes to the cosmic ray flux problematic (Laken et al., 2011).

Some studies have shown co-variation between the cosmic ray flux and low-level cloud cover using global satellite data over periods of typically 5–10 years (Marsh and Svensmark, 2000; Pallé Bagó and Butler, 2000). Such correlations have not proved to be robust when extending the time period under consideration (Agee et al., 2012), and restricting the analysis to particular cloud types (Kernthaler et al., 1999) or locations (Udelhofen and Cess, 2001; Usoskin and Kovaltsov, 2008). The purported correlations have also been attributed to ENSO variability (Farrar, 2000; Laken et al., 2012) and artefacts of the satellite data cannot be ruled out (Pallé, 2005). Statistically significant (but weak) correlations between the diffuse fraction of surface solar radiation and the cosmic ray flux have been found at some locations in the UK over the 1951 to 2000 period (Harrison and Stephenson, 2006). Harrison (2008) also found a unique 1.68-year periodicity in surface radiation for two different UK sites between 1978 and 1990, potentially indicative of a cosmic ray effect of the same periodicity. Svensmark et al. (2009) found large global reductions in the aerosol Ångström exponent, liquid water path, and cloud cover after large Forbush decreases, but these results were not corroborated by other studies which found no statistically significant links between the cosmic ray flux and clouds at the global scale (Čalogović et al., 2010; Laken and Čalogović, 2011). Although some studies found statistically significant correlations between the cosmic ray flux and cloudiness at the regional scale (Laken et al., 2010; Rohs et al., 2010), these correlations were generally weak, cloud changes were small, and the results were sensitive to how the Forbush events were selected and composited (Kristjánsson et al., 2008; Laken et al., 2009).

7.4.6.2 *Physical Mechanisms Linking Cosmic Rays to Cloudiness*

The most widely studied mechanism proposed to explain the possible influence of the cosmic ray flux on cloudiness is the “ion-aerosol clear air” mechanism, in which atmospheric ions produced by cosmic rays facilitate aerosol nucleation and growth ultimately impacting CCN concentrations and cloud properties (Carslaw et al., 2002; Usoskin and Kovaltsov, 2008). The variability in atmospheric ionization rates due to changes in cosmic ray flux can be considered relatively well quantified (Bazilevskaya et al., 2008), whereas resulting changes in aerosol nucleation rates are very poorly known (Enghoff and Svensmark, 2008; Kazil et al., 2008). Laboratory experiments indicate that ionization induced by cosmic rays enhances nucleation rates under middle and upper tropospheric conditions, but not necessarily so in the continental boundary layer (Kirkby et al., 2011). Field measurements qualitatively support this view but cannot provide any firm conclusion due to the scarcity and other limitations of free-troposphere measurements (Arnold, 2006; Mirme et al., 2010), and due to difficulties in separating nucleation induced by cosmic rays from other nucleation pathways in the continental boundary layer (Hirsikko et al., 2011). Based on surface aerosol measurements at one site, Kulmala et al. (2010) found no connection between the cosmic ray flux and new particle formation or any other aerosol property over a solar cycle (1996–2008), although particles nucleated in the free troposphere are known to contribute to particle number and CCN concentrations in the boundary layer (Merikanto et al., 2009). Our understanding of the “ion-aerosol clear air” mechanism as a whole relies on a few model investigations that simulate changes in cosmic ray flux over a solar cycle (Pierce and Adams, 2009b; Snow-Kropla et al., 2011; Kazil et al., 2012) or during strong Forbush decreases (Bondo et al., 2010; Snow-Kropla et al., 2011; Dunne et al., 2012). Changes in CCN concentrations due to variations in the cosmic ray flux appear too weak to cause a significant radiative effect because the aerosol system is insensitive to a small change in the nucleation rate in the presence of pre-existing aerosols (see also Section 7.3.2.2).

A second pathway linking the cosmic ray flux to cloudiness has been proposed through the global electric circuit. A small direct current is able to flow vertically between the ionosphere and the Earth’s surface over fair-weather regions because of GCR-induced atmospheric ionization. Charge can accumulate at the upper and lower cloud boundaries as a result of the effective scavenging of ions by cloud droplets (Tinsley, 2008). This creates conductivity gradients at the cloud edges (Nicoll and Harrison, 2010), and may influence

droplet-droplet collisions (Khain et al., 2004), cloud droplet-particle collisions (Tinsley, 2008), and cloud droplet formation processes (Harrison and Ambaum, 2008). These microphysical effects may potentially influence cloud properties both directly and indirectly. Although Harrison and Ambaum (2010) observed a small reduction in downward LW radiation which they associated with variations in surface current density, supporting observations are extremely limited. Our current understanding of the relationship between cloud properties and the global electric circuit remains very low, and there is no evidence yet that associated cloud processes could be of climatic significance.

7.4.6.3 Synthesis

Correlations between cosmic ray flux and observed aerosol or cloud properties are weak and local at best, and do not prove to be robust on the regional or global scale. Although there is some evidence that ionization from cosmic rays may enhance aerosol nucleation in the free troposphere, there is *medium evidence* and *high agreement* that the cosmic ray-ionization mechanism is too weak to influence global concentrations of CCN or droplets or their change over the last century or during a solar cycle in any climatically significant way.

7.5 Radiative Forcing and Effective Radiative Forcing by Anthropogenic Aerosols

7.5.1 Introduction and Summary of AR4

In this section, aerosol forcing estimates are synthesized and updated from AR4. As depicted in Figure 7.3, RF refers to the radiative forcing either due to aerosol-radiation interactions (ari), formerly known as the direct aerosol forcing, or aerosol-cloud interactions (aci), formerly known as the first indirect aerosol forcing or cloud albedo effect in AR4. ERF refers to the effective radiative forcing and is typically estimated from experiments with fixed sea-surface temperatures (see Section 7.1.3 and Section 8.1). It includes rapid adjustments, such as changes to the cloud lifetime, cloud altitude, changes in lapse-rate due to absorbing aerosols and aerosol microphysical effects on mixed-phase, ice and convective clouds.

Chapter 2 of AR4 (Forster et al., 2007) assessed RFari to be $-0.5 \pm 0.4 \text{ W m}^{-2}$ and broke this down into components associated with several species. Land albedo changes associated with BC on snow were assessed to be $+0.1 \pm 0.1 \text{ W m}^{-2}$. The RFaci was assessed to be -0.70 W m^{-2} with a -1.8 to -0.3 W m^{-2} uncertainty range. These uncertainty estimates were based on a combination of model results and observations from remote sensing. The semi-direct effect and other aerosol indirect effects were assessed in Chapter 7 of AR4 (Denman et al., 2007) to contribute additional uncertainty. The combined total aerosol forcing was given as two distinct ranges: -0.2 to -2.3 W m^{-2} from models and a -0.1 to -1.7 W m^{-2} range from inverse estimates.

As discussed in Section 7.4, it is inherently difficult to separate RFaci from subsequent rapid cloud adjustments either in observations or model calculations (e.g., George and Wood, 2010; Lohmann et al., 2010; Mauger and Norris, 2010; Painemal and Zuidema, 2010). For this reason estimates of RFaci are of limited interest and are not assessed in this report. This chapter estimates RFari, ERFari, and ERFari+aci based purely on a priori approaches, and calculates ERFaci as the residual between ERFari+aci and ERFari assuming the two effects are additive. Inverse studies that estimate ERFari+aci from the observed rate of planetary energy uptake and estimates of climate feedbacks and other RFs are discussed in Section 10.8.

For consistency with AR4 and Chapter 8 of this report, all quoted ranges represent a 5–95% uncertainty range unless otherwise stated, and we evaluate the forcings between 1750 and approximately 2010. The reference year of 1750 is chosen to represent pre-industrial times, so changes since then broadly represent the anthropogenic effect on climate, although for several aerosol species (such as biomass burning) this does not quite equate to the anthropogenic effect as emissions started to be influenced by humans before the Industrial Revolution. Many studies estimate aerosol forcings between 1850 and present day and any conversion to a forcing between 1750 and the present day increases the uncertainty (Bellouin et al., 2008). This section principally discusses global forcing estimates and attributes them to aerosol species. Chapter 8 discusses regional forcings and additionally attributes aerosol forcing to emission sources.

7.5.2 Estimates of RF and ERF from Aerosol-Radiation Interactions (RFari and ERFari)

Building on our understanding of aerosol processes and their radiative effects (Section 7.3), this subsection assesses RFari and ERFari, including the forcings from absorbing aerosol (BC and dust) on snow and ice.

7.5.2.1 Radiative Forcing and Effective Radiative Forcing from All Aerosols

Observations can give useful constraints to aspects of the global RFari but cannot measure it directly (Section 7.3.4, Anderson et al., 2005; Kahn, 2012). Remote sensing observations, in-situ measurements of fine-mode aerosol properties and a better knowledge of bulk aerosol optical properties make the estimate of total RFari more robust than the RF for individual species (see Forster et al., 2007). Estimates of RFari are either taken from global aerosol models directly (Schulz et al., 2009; Myhre et al., 2013) or based mostly on observations, but using supplemental information from models (e.g., Myhre, 2009; Loeb and Su, 2010; Su et al., 2013). A number of studies (Bellouin et al., 2008; Zhao et al., 2008b; Myhre, 2009; Zhao et al., 2011) have improved aspects of the satellite-based RFari estimate over those quoted in AR4. Of these, only Myhre (2009) make the necessary adjustments to the observations to account for forcing in cloudy regions and pre-industrial concentrations to estimate a RFari of $-0.3 \pm 0.2 \text{ W m}^{-2}$.

A second phase of AeroCom model results gives an RFari estimate of -0.35 W m^{-2} , with a model range of about -0.13 to -0.60 W m^{-2} , after their forcings for 1850–2000 has been scaled by emissions to represent 1750–2010 changes (Myhre et al., 2013). Figure 7.17 shows the zonal mean total RFari for AeroCom phase II models for 1850–2000. Robust features are the maximum negative RF around 10°N – 50°N , at latitudes of highest aerosol concentrations, and a positive RF at higher latitudes due to the higher surface albedo there.

For observationally-based estimates, a variety of factors are important in constraining the radiative effect of aerosol (McComiskey et al., 2008; Loeb and Su, 2010; Kahn, 2012). Particularly important are the single scattering albedo (especially over land or above clouds) and the AOD (see Section 7.3.4.1). Errors in remotely-sensed, retrieved AOD can be 0.05 or larger over land (Remer et al., 2005; Kahn et al., 2010; Levy et al., 2010; Kahn, 2012). Loeb and Su (2010) found that the total uncertainty in forcing was dominated by the uncertainty in single scattering albedo, using single scattering albedo errors of ± 0.06 over ocean and ± 0.03 over land from Dubovik et al. (2000), and assuming errors can be added in quadrature. These retrieval uncertainties could lead to a 0.5 to 1.0 W m^{-2} uncertainty in RFari (Loeb and Su, 2010). However, model sensitivity studies and reanalyses can provide additional constraints leading to a reduced error estimate. Ma et al. (2012b) performed a sensitivity study in one model, finding a best estimate of RFari of -0.41 W m^{-2} with an asymmetrical uncertainty range of -0.08 to -0.61 W m^{-2} , with black carbon particle size and mixing state having the largest effect of the parameters investigated. In models, assumptions about surface albedo, background cloud distribution and radiative transfer contribute a relative standard deviation of 39% (Stier et al., 2013). Bellouin et al. (2013) quantified uncertainties in RFari using reanalysis data that combined MODIS satellite data over oceans with the global coverage of their model. This approach broke down the uncertainty in aerosol properties into a local and a regional error to find a RFari standard deviation of 0.3 W m^{-2} , not accounting for uncertainty in the pre-industrial reference. When cloudy-sky and pre-industrial corrections were applied an RFari best estimate of -0.4 W m^{-2} was suggested.

The overall forcing uncertainty in RFari consists of the uncertainty in the distribution of aerosol amount, composition and radiative properties (Loeb and Su, 2010; Myhre et al., 2013), the uncertainty in radiative transfer (Randles et al., 2013) and the uncertainty owing to the dependence of the forcing calculation on other uncertain parameters, such as clouds or surface albedos (Stier et al., 2013). To derive a best estimate and range for RFari we combine modelling and observationally based studies. The best estimate is taken as -0.35 W m^{-2} . This is the same as the AeroCom II model estimate, and also the average of the Myhre (2009) observationally-based estimate (-0.3 W m^{-2}) and the Bellouin et al. (2013) reanalysis estimate (-0.4 W m^{-2}). Models probably underestimate the positive RFari from BC and the negative forcing from OA aerosol (see Section 7.5.2.2), and currently there is no evidence that one of these opposing biases dominates over the other. The 5–95% range of RFari adopted in this assessment employs the Bellouin et al. (2013) uncertainty to account for retrieval error in observational quantities when constrained by global models, giving an uncertainty estimate of $\pm 0.49 \text{ W m}^{-2}$. This is at the low end of the uncertainty analysis of Loeb and Su (2010). However, our uncertainty is partly based on models, and to account for this aspect, it is combined in quadrature with a $\pm 0.1 \text{ W m}^{-2}$ uncertainty from non-aerosol related parameters following Stier et al. (2013). This gives an assessed RFari of $-0.35 \pm 0.5 \text{ W m}^{-2}$. This is a larger range than that exhibited by the AeroCom II models. It is also a smaller magnitude but slightly larger range than in AR4, with a more

positive upper bound. This more positive upper bound can be justified by the sensitivity to BC aerosol (Ma et al., 2012b and Section 7.5.2.3). Despite the larger range, there is increased confidence in this assessment due to dedicated modelling sensitivity studies, more robust observationally based estimates, and their better agreement with models.

[INSERT FIGURE 7.17 HERE]

Figure 7.17: Annual zonal mean top-of-atmosphere RFari (in W m^{-2}) due to all anthropogenic aerosols from the different AeroCom II models. No adjustment for missing species in certain models has been applied. The multi-model mean and 5th to 95th percentile range from AeroCom II models (Myhre et al., 2013) are shown with a black solid line and grey envelope. The estimates from Bellouin et al. (2013) and Su et al. (2013) are shown with dotted lines. The forcings are for the 1850 to 2000 period. See supplementary material for a figure with labelled individual AeroCom II model estimates.

ERFari adds the radiative effects from rapid adjustments onto RFari. Studies have evaluated the rapid adjustments separately as a semi-direct effect (see Section 7.3.4.2) and/or the ERFari has been directly evaluated. Rapid adjustments are principally caused by cloud changes. There is *high confidence* that the local heating caused by absorbing aerosols can alter clouds. However, there is *low confidence* in determining the sign and magnitude of the rapid adjustments at the global scale as current models differ in their responses and are known to inadequately represent some of the important relevant cloud processes (see Section 7.3.4). Existing estimates of ERFari nevertheless rely on such global models. Five GCMs were analysed for RFari and ERFari in Lohmann et al. (2010). Their rapid adjustments ranged from -0.3 to $+0.1 \text{ W m}^{-2}$. In a further study, Takemura and Uchida (2011) found a rapid adjustment of $+0.06 \text{ W m}^{-2}$. The sensitivity analysis of Ghan et al. (2012) found a -0.1 W m^{-2} to $+0.1 \text{ W m}^{-2}$ range over model variants, where an improved aging of the mixing state led to small negative rapid adjustment of around -0.1 W m^{-2} . Bond et al. (2013) assessed scaled RF and efficacy estimates from seven earlier studies focusing on BC and found a range of rapid adjustments between -0.2 W m^{-2} and -0.01 W m^{-2} . There is a potential additional rapid adjustment term from the effect of cloud drop inclusions (see Section 7.3.4.2). Based on Ghan et al. (2012) and Jacobson (2012), Bond et al. (2013) estimate an additional ERFari term of $+0.2 \text{ W m}^{-2}$, with an uncertainty range of -0.1 to $+0.9 \text{ W m}^{-2}$, however there is *very low confidence* in the sign or magnitude of this effect and we do not include it in our assessment. Overall a best estimate for the rapid adjustment is taken to be -0.1 W m^{-2} , with a 5–95% uncertainty range of -0.3 to $+0.1 \text{ W m}^{-2}$. The best estimate is based on Ghan et al. (2012) and the range on Lohmann et al. (2010). The uncertainties are added in quadrature to the estimate of RFari and rounded to give an overall assessment for ERFari of $-0.45 \pm 0.5 \text{ W m}^{-2}$.

7.5.2.2 Radiative Forcing by Species

AeroCom II studies have calculated aerosol distributions using 1850 and 2000 simulations with the same meteorology to isolate RFari for individual aerosol types (sulphate, BC fossil-fuel plus biofuel, OA fossil-fuel and biofuel, biomass burning or BB, SOA, nitrate). Many of these models account for internal mixing, so that partitioning RFari by species is not straightforward, and different modelling groups adopt different techniques (Myhre et al., 2013). Note also that due to internal mixing of aerosol types the total RFari is not necessarily the sum of the RFari from different types (Ocko et al., 2012). Unless otherwise noted in the text below, the best estimate and 5–95% ranges for individual types quoted in Figure 7.18 are solely based on the AeroCom II range (Myhre et al., 2013) and the estimates have been scaled by emissions to derive 1750–2010 RFari values. Note that although global numbers are presented here, these RF estimates all exhibit large regional variations, and individual aerosol species can contribute significantly to regional climate change despite rather small RF estimates (e.g., Wang et al., 2010b).

For sulphate, AeroCom II models give a RF median and 5–95% uncertainty range of -0.31 (-0.58 to -0.11) W m^{-2} for the 1850–2000 period, and -0.34 (-0.61 to -0.13) W m^{-2} for the 1750–2010 period. This estimate and uncertainty range are consistent with the AR4 estimate of $-0.4 \pm 0.2 \text{ W m}^{-2}$, which is retained as the best estimate for AR5.

RF from BC is evaluated in different ways in the literature. The BC RF in this report is from fossil fuel and biofuel sources, while open burning sources are attributed separately to the biomass-burning aerosol, which also includes other organic species (see Section 7.3.2). BC can also affect clouds and surface albedo (see Sections 7.5.2.2, 7.5.2.4 and Chapter 8). Here we only isolate the fossil fuel and biofuel RFari attributable to BC over 1750–2010. Two comprehensive studies have quantified the BC RFari and derive different central

estimates and uncertainty ranges. Myhre et al. (2013) quantify RF over 1850–2000 in the AeroCom II generation of models and scale these up using emissions to derive an RF estimate over 1750–2010 of $+0.23$ ($+0.06$ to $+0.48$) W m^{-2} for fossil fuel and biofuel emissions. Bond et al. (2013) employ an observationally weighted scaling of an earlier generation of AeroCom models, regionally scaling BC absorption to match absorption AOD as retrieved at available AERONET sites. They derive a RF of $+0.51$ ($+0.06$ to $+0.91$) W m^{-2} for fossil fuel and biofuel sources. There are known biases in BC RF estimates from aerosol models. BC concentrations are underestimated near source regions, especially in Asia, but overestimated in remote regions and at altitude (Figure 7.15). Models also probably underestimate the mass absorption cross-section probably because enhanced absorption due to internal mixing is insufficiently accounted for (see Section 7.3.3.2). Together these biases are expected to cause the modelled BC RF to be underestimated. The Bond et al. estimate accounted for these biases by scaling model results. However, there are a number of methodological difficulties associated with the absorption AOD retrieval from sunphotometer retrievals (see Section 7.3.3.2), the attribution of absorption AOD to BC, and the distribution and representativeness of AERONET stations for constraining global and relatively coarse-resolution models. Absorption by OA (see Section 7.3.3), which may amount to 20% of fine-mode aerosol absorption (Chung et al., 2012), is included into the BC RF estimate in Bond et al. but is now treated separately in most AeroCom II models, some of which have a global absorption AOD close to the Bond et al. estimate. We use our expert judgement here to adopt a BC RF estimate that is halfway between the two estimates and has a wider uncertainty range from combining distributions. This gives a BC RF estimate from fossil fuel and biofuel of $+0.4$ ($+0.05$ to $+0.8$) W m^{-2} .

The AeroCom II estimate of the SOA RFari is -0.03 (-0.27 to -0.02) W m^{-2} and the primary OA from fossil fuel and biofuel estimate is -0.05 (-0.09 to -0.02) W m^{-2} . An intercomparison of current chemistry climate models found two models outside of this range for SOA RFari with one model exhibiting a significant positive forcing from land-use and cover changes influencing biogenic emissions (Shindell et al., 2013). We therefore adjust the upper end of the range to account for this, giving an SOA RFari estimate of -0.03 (-0.27 to $+0.20$) W m^{-2} . Our assessment also scales the AeroComII estimate of the primary OA from fossil fuel and biofuel by 1.74 to -0.09 (-0.16 to -0.03) W m^{-2} to allow for the underestimate of emissions identified in Bond et al. (2013). For OA from natural burning, and for SOA, the natural radiative effects can be an order of magnitude larger than the RF (see Sections 7.3.2 and 7.3.4, and O'Donnell et al., 2011) and they could thus contribute to climate feedback (see Section 7.3.5).

The RFari from biomass burning includes both BC and OA species that contribute RFari of opposite sign, giving a net RFari close to zero (Bond et al., 2013; Myhre et al., 2013). The AeroCom II models give a 1750–2010 RFari of 0.00 (-0.08 to $+0.07$) W m^{-2} , and an estimate of $+0.0$ (-0.2 to $+0.2$) W m^{-2} is adopted in this assessment, doubling the model uncertainty range to account for a probable underestimate of their emissions (Bond et al., 2013). Combining information in Samset et al. (2013) and Myhre et al. (2013) would give a BC RFari contribution from biomass burning of slightly less than $+0.1$ W m^{-2} over 1850–2000 from the models. However, this ignores a significant contribution expected before 1850 and the probable underestimate in emissions. Our assessment therefore solely relies on Bond et al. (2013), giving a estimate of $+0.2$ ($+0.03$ to $+0.4$) W m^{-2} for the 1750–2010 BC contribution to the biomass burning RFari. This is a 50% larger forcing than the earlier generation of AeroCom models found (Schulz et al., 2006). Note that we also expect an OA RFari of the same magnitude with opposite sign.

The AeroCom II RF estimate for nitrate aerosol gives an RFari of -0.11 (-0.17 to -0.03) W m^{-2} , but comprises a relatively large 1850 to 1750 correction term. In these models ammonium aerosol is included within the sulphate and nitrate estimates. An intercomparison of current chemistry climate models found an RF range of -0.41 to -0.03 W m^{-2} over 1850–2000. Some of the models with strong RF did not exhibit obvious biases, whereas others did (Shindell et al., 2013). These sets of estimates are in good agreement with earlier estimates (e.g. Adams et al., 2001; Bauer et al., 2007; Myhre et al., 2009). Our assessment of the RFari from nitrate aerosol is -0.11 (-0.3 to -0.03) W m^{-2} . This is based on AeroCom II with an increased lower bound.

Anthropogenic sources of mineral aerosols can result from changes in land use and water use or climate change. Estimates of the RF from anthropogenic mineral aerosols are highly uncertain, because natural and anthropogenic sources of mineral aerosols are often located close to each other (Mahowald et al., 2009; Ginoux et al., 2012b). Using a compilation of observations of dust records over the 20th century with model

simulations, Mahowald et al. (2010) deduced a 1750–2000 change in mineral aerosol RFari including both natural and anthropogenic changes of $-0.14 \pm 0.11 \text{ W m}^{-2}$. This is consistent within the AR4 estimate of $-0.1 \pm 0.2 \text{ W m}^{-2}$ (Forster et al., 2007) which is retained here. Note that part of the dust RF could be due to feedback processes (see Section 7.3.5).

Overall the species breakdown of RFari is less certain than the total RFari. Fossil fuel and biofuel emissions contribute to RFari via: sulphate aerosol -0.4 (-0.6 to -0.2) W m^{-2} ; black carbon aerosol $+0.4$ ($+0.05$ to $+0.8$) W m^{-2} ; and primary and secondary organic aerosol -0.12 (-0.4 to $+0.1$) W m^{-2} (adding uncertainties in quadrature). Additional RFari contributions are via: biomass burning emissions, where black carbon and organic aerosol changes offset each other to give an estimate of $+0.0$ (-0.2 to $+0.2$) W m^{-2} ; nitrate aerosol -0.11 (-0.3 to -0.03) W m^{-2} ; and a contribution from mineral dust of -0.1 (-0.3 to $+0.1$) W m^{-2} that may not be entirely anthropogenic in origin. The sum of the RFari from these species agrees with, but is slightly weaker than, the best estimate of the better-constrained total RFari.

[INSERT FIGURE 7.18 HERE]

Figure 7.18: Annual mean top-of-atmosphere RFari (in W m^{-2}) due to different anthropogenic aerosol types, for the 1750 to 2010 period. Hatched whisker boxes show median (line), 5th to 95th percentile ranges (box) and min/max values (whiskers) from AeroCom II models (Myhre et al., 2013) corrected for the 1750–2010 period. Solid coloured boxes show the AR5 best estimates and 90% uncertainty ranges. BC FF is for black carbon from fossil fuel and biofuel, POA FF is for primary organic aerosol from fossil fuel and biofuel, BB is for biomass burning aerosols, and SOA is for secondary organic aerosols.

7.5.2.3 Absorbing Aerosol on Snow and Sea-Ice

Forster et al. (2007) estimated the RF for surface albedo changes from BC deposited on snow to be $+0.10 \pm 0.10 \text{ W m}^{-2}$, with a low level of understanding, based largely on studies from Hansen and Nazarenko (2004) and Jacobson (2004). Since AR4, observations of BC in snow have been conducted using several different measurement techniques (e.g., McConnell et al., 2007; Forsström et al., 2009; Ming et al., 2009; Xu et al., 2009; Doherty et al., 2010; Huang et al., 2011; Kaspari et al., 2011), providing data with which to constrain models. Laboratory measurements have confirmed the albedo reduction due to BC in snow (Hadley and Kirchstetter, 2012). The albedo effects of non-BC constituents have also been investigated but not rigorously quantified. Remote sensing can inform on snow impurity content in some highly polluted regions. However, it cannot be used to infer global anthropogenic radiative forcing because of numerous detection challenges (Warren, 2013).

Global modelling studies since AR4 have quantified present-day radiative effects from BC on snow of $+0.01$ to $+0.08 \text{ W m}^{-2}$ (Flanner et al., 2007; Hansen et al., 2007; Flanner et al., 2009; Koch et al., 2009a; Rypdal et al., 2009; Skeie et al., 2011; Wang et al., 2011c; Lee et al., 2013). These studies apply different BC emission inventories and atmospheric aerosol representations, include forcing from different combinations of terrestrial snow, sea-ice, and snow on sea-ice, and some include different rapid adjustment effects such as snow grain size evolution and melt-induced accumulation of impurities at the snow surface, observed on Tibetan glaciers (Xu et al., 2012) and in Arctic snow (Doherty et al., 2013). The forcing operates mostly on terrestrial snow and is largest during March–May, when boreal snow and ice are exposed to strong insolation (Flanner et al., 2007).

All climate modelling studies find that the Arctic warms in response to snow and sea-ice forcing. Additionally, estimates of the change in global mean surface temperature per unit forcing are 1.7–4.5 times greater for snow and sea-ice forcing than for CO_2 forcing (Hansen and Nazarenko, 2004; Hansen et al., 2005; Flanner et al., 2007; Flanner et al., 2009; Bellouin and Boucher, 2010). The Koch et al. (2009a) estimate is not included in this range due to the lack of a clear signal in their study. The greater response of global-mean temperature occurs primarily because all of the forcing energy is deposited directly into the cryosphere, whose evolution drives a positive albedo feedback on climate. Key sources of forcing uncertainty include BC concentrations in snow and ice, BC mixing state and optical properties, snow and ice coverage and patchiness, co-presence of other light-absorbing particles in the snow pack, snow effective grain size and its influence on albedo perturbation, the masking of snow surfaces by clouds and vegetation, and the accumulation of BC at the top of snowpack caused by melting and sublimation. Bond et al. (2013) derive a 1750–2010 snow and sea-ice RF estimate of $+0.046$ ($+0.015$ to $+0.094$) W m^{-2} for BC by i) considering forcing ranges from all relevant global studies, ii) accounting for biases caused by a) modelled Arctic BC-in-

snow concentrations using measurements from Doherty et al. (2010), and b) excluding mineral dust, which reduces BC forcing by approximately 20%, iii) combining in quadrature individual uncertainty terms from Flanner et al. (2007) plus that originating from the co-presence of dust, and iv) scaling the present-day radiative contributions from BB, biofuel, and fossil fuel BC emissions according to their 1750–2010 changes. Note that this RF estimate allows for some rapid adjustments in the snowpack but is not a full ERF as it does not account for adjustments in the atmosphere. For this RF, we adopt an estimate of $+0.04$ ($+0.02$ to $+0.09$) W m^{-2} and note that the surface temperature change is roughly three (two to four) times more responsive to this RF relative to CO_2 .

7.5.3 Estimate of ERF from Combined Aerosol-Radiation and Aerosol-Cloud Interactions (ERFari+aci)

In addition to ERFari, there are changes due to aerosol-cloud interactions (ERFaci). Because of nonlinearities in forcings and rapid adjustments, the total effective forcing ERFari+aci does not necessarily equal the sum of the ERFari and ERFaci calculated separately. Moreover a strict separation is often difficult in either state of the art models or observations. Therefore we first assess ERFari+aci and postpone our assessment of ERFaci to Section 7.5.4. For similar reasons, we focus primarily on ERF rather than RF.

ERFari+aci is defined as the change in the net radiation at the top-of-the-atmosphere from pre-industrial to present day. Climate model estimates of ERFari+aci in the literature differ for a number of reasons. (i) The reference years for pre-industrial and present-day conditions vary between estimates. Studies can use 1750, 1850, or 1890 for pre-industrial; early estimates of ERFari+aci used present day emissions for 1985, whereas most newer estimates use emissions for the year 2000. (ii) The processes they include also differ: aerosol-cloud interactions in large-scale liquid stratiform clouds are typically included, but studies can also include aerosol-cloud interactions for mixed-phase, convective clouds and/or cirrus clouds. (iii) The way in which ERFari+aci is calculated, can also differ between models, with some earlier studies only reporting the change in shortwave radiation. Changes in longwave radiation arise from rapid adjustments, or from aerosol-cloud interactions involving mixed-phase or ice clouds (e.g., Storelvmo et al., 2008b; Storelvmo et al., 2010; Ghan et al., 2012), and tend to partially offset changes in shortwave radiation. In the estimates discussed below and those shown in Figure 7.19, we refer to estimates of the change in net (shortwave plus longwave) top-of-atmosphere radiation whenever possible, but report changes in shortwave radiation when changes in net radiation are not available. While this mostly affects earlier studies, the subset of models that we concentrate on all include both shortwave and longwave radiative effects. However, for the sake of comparison, the satellite studies must be adjusted to account for missing longwave contributions as explained below.

Early GCM estimates of ERFari+aci only included aerosol-cloud interactions in liquid phase stratiform clouds; some of these were already considered in AR4. Grouping these early estimates with similar (liquid phase only) estimates from publications since the AR4 yields a median value of ERFari+aci of -1.5 W m^{-2} with a 5-95% range between -0.6 and -2.4 W m^{-2} (Figure 7.19). In those studies that attempt a more complete representation of aerosol-cloud interactions, by including aerosol-cloud interactions in mixed-phase and/or convective cloud, the magnitude of the ERF tends to be somewhat smaller (see Figure 7.19). The physical explanation for the mixed-phase reduction in the magnitude of the ERF is that some aerosols also act as IN causing supercooled clouds to glaciate and precipitate more readily. This reduction in cloud cover leads to less reflected shortwave radiation and a less negative ERFari+aci. This effect can however be offset if the IN become coated with soluble material making them less effective at nucleating ice, leading to less efficient precipitation production and more reflected shortwave radiation (Hoose et al., 2008; Storelvmo et al., 2008a). Models that have begun to incorporate aerosol-cloud interactions in convective clouds also have a tendency to reduce the magnitude of the ERF, but this effect is less systematic (Jacobson, 2003; Lohmann, 2008; Suzuki et al., 2008) and reasons for differences among the models in this category are less well understood.

For our expert judgment of ERFari+aci a subset of GCM studies, which strived for a more complete and consistent treatment of aerosol-cloud interactions (by incorporating either convective or mixed-phase processes) was identified and scrutinised. The ERFari+aci derived from these models is somewhat less negative than in the full suite of models, and ranges from -0.81 to -1.68 W m^{-2} with a median value of -1.38 W m^{-2} . Because in some cases a number of studies have been performed with the same GCM, in what might be described as an evolving effort, our assessment is further restricted to the best (usually most recent)

estimate by each modelling group (see black symbols in Figure 7.19 and Table 7.4). This ensures that no single GCM is given a disproportionate weight. Further, we consider only simulations not constrained by the historical temperature rise, motivated by the desire to emphasise a process-based estimate. Although it may be argued that greater uncertainty is introduced by giving special weight to models that only incorporate more comprehensive treatments of aerosol-cloud interactions, and for processes that (as Section 7.4 emphasises) are on the frontier of understanding, it should be remembered that aerosol-cloud interactions for liquid-phase clouds remain very uncertain. Although the understanding and treatment of aerosol-cloud interactions in convective or mixed-phase clouds are also very uncertain, as discussed in Section 7.4.4, we exercise our best judgment of their influence.

A less negative $ER_{Fari+aci}$ (-0.45 to -0.93 $W m^{-2}$ with a median of -0.85 $W m^{-2}$, Figure 7.19 and Table 7.4) is found in studies that use variability in the present day satellite record to infer aerosol-cloud interactions, or that constrain GCM parameterisations to optimize agreement with satellite observations. Because some groups have published multiple estimates as better information became available, only their latest study was incorporated into this assessment. Moreover, if a study did not report $ER_{Fari+aci}$ but only evaluated changes in ER_{Faci} , their individual estimate was combined with the average ER_{Fari} of -0.45 $W m^{-2}$ from Section 7.5.2. Likewise, those (all but one) studies that only accounted for changes in shortwave radiation when computing ER_{Faci} were corrected by adding a constant factor of $+0.2$ $W m^{-2}$, taken from the lower range of the modeled longwave effects which varied from $+0.2$ to $+0.6$ $W m^{-2}$ in the assessed models. These procedures result in the final estimates of $ER_{Fari+aci}$ shown as black symbols in Figure 7.19 and in Table 7.4. This resulted in a median $ER_{Fari+aci}$ of -0.85 $W m^{-2}$ for satellite-based $ER_{Fari+aci}$ estimates. Results of pure satellite-based studies are sensitive to the spatial scale of measurements (Grandey and Stier, 2010; McComiskey and Feingold, 2012; Section 7.4.2.2), as well as to how pre-industrial conditions and variations between pre-industrial and present-day conditions are inferred from the observed variability in present-day aerosol and cloud properties (Quaas et al., 2011; Penner et al., 2012). In addition, all (model and satellite-based) estimates of $ER_{Fari+aci}$ are very sensitive to the assumed pre-industrial or natural cloud droplet concentration (Hoose et al., 2009). The large spatial scales of satellite measurements relative to in-situ measurements generally suggest smaller responses in cloud droplet number increases for a given aerosol increase (Section 7.4.2.2). Satellite studies however show a strong effect of aerosol on cloud amount, which could be a methodological artefact as GCMs associate clouds with humidity and aerosol swelling (Quaas et al., 2010). There are thus possible biases in both directions, so the sign and magnitude of any net bias is not clear.

In large-scale models for which cloud-scale circulations are not explicitly represented, it is difficult to capture all relevant cloud controlling processes (Section 7.2.2). Because the response of clouds to aerosol perturbations depends critically on the interplay of poorly understood physical processes, global model-based estimates of aerosol-cloud interactions remain uncertain (Section 7.4). Moreover, the connection between the aerosol amount and cloud properties is too direct in the large-scale modelling studies (as it relies heavily on the autoconversion rate). Because of this, GCMs tend to overestimate the magnitude of the aerosol effect on cloud properties (Section 7.4.5, see also discussion in Section 7.5.4). This view has some support from studies that begin to incorporate some cloud, or cloud-system scale responses to aerosol-cloud interactions. For instance, in an attempt to circumvent some of difficulties of parameterising clouds, some groups (e.g., Wang et al., 2011b) have begun developing modelling frameworks that can explicitly represent cloud-scale circulations, and hence the spatio-temporal covariances of cloud-controlling processes. Another group (Khairoutdinov and Yang, 2013) has used the same cloud-resolving model in a radiative convective equilibrium approach, and compared the relative contribution of aerosol-cloud interactions to warming from the doubling of atmospheric carbon dioxide. In both studies a smaller (-1.1 and -0.8 $W m^{-2}$, respectively) $ER_{Fari+aci}$ than for the average GCM was found. Furthermore, the study best resolving the cloud-scale circulations (Wang et al., 2011b) found little change in cloud amount in response to changes in aerosol, consistent with other fine-scale modelling studies discussed in Section 7.4.

Based on the above considerations, we assess $ER_{Fari+aci}$ using expert judgement to be -0.9 $W m^{-2}$ with a 5–95% uncertainty range of -1.9 to -0.1 $W m^{-2}$ (*medium confidence*), and a *likely* range of -1.5 to -0.4 $W m^{-2}$. These ranges account for the GCM results by allowing for an $ER_{Fari+aci}$ somewhat stronger than what is estimated by the satellite studies with a longer tail in the direction of stronger effects, but (for reasons given above) give less weight to the early GCM estimates shown in Figure 7.19. The $ER_{Fari+aci}$ can be much larger regionally but the global value is consistent with several new lines of evidence suggesting less

negative estimates of aerosol-cloud interactions than the corresponding estimate in Chapter 7 of AR4 of -1.2 W m^{-2} . The AR4 estimate was mainly based on GCM studies that did not take secondary processes (such as aerosol effects on mixed-phase and/or convective clouds) into account, did not benefit as much from the use of the recent satellite record, and did not account for the effect of rapid adjustments on the longwave radiative budget. This uncertainty range is slightly smaller than the -2.3 to -0.2 W m^{-2} in AR4, with a less negative upper bound due to the reasons outlined above. The best estimate of $\text{ERF}_{\text{ari+aci}}$ is not only consistent with the studies allowing cloud-scale responses (Wang et al., 2011b; Khairoutdinov and Yang, 2013) but also is in line with the average $\text{ERF}_{\text{ari+aci}}$ from the CMIP5/ACCMIP models (about -1 W m^{-2} , see Table 7.5), which as a whole reproduce the observed warming of the 20th century (see Chapter 10). Studies that infer $\text{ERF}_{\text{ari+aci}}$ from the historical temperature rise are discussed in Chapter 10, Section 10.8.

[INSERT FIGURE 7.19 HERE]

Figure 7.19: (a) GCM studies and studies involving satellite estimates of RF_{ari} (red), ERF_{aci} (green) and $\text{ERF}_{\text{ari+aci}}$ (blue in grey-shaded box). Each symbol represents the best estimate per model and paper (see Table 7.3 for references). The values for RF_{ari} are obtained from the CMIP5 models. ERF_{aci} and $\text{ERF}_{\text{ari+aci}}$ studies from GCMs on liquid phase stratiform clouds are divided into those published prior to and included in AR4 (labeled AR4, triangles up), studies published after AR4 (labeled AR5, triangles down) and from the CMIP5/ACCMIP models (filled circles). GCM estimates that include adjustments beyond aerosol-cloud interactions in liquid phase stratiform clouds are divided into those including aerosol-cloud interactions in mixed-phase clouds (stars) and those including aerosol-cloud interactions in convective clouds (diamonds). Studies that take satellite data into account are labeled as "satellites". Studies highlighted in black are considered for our expert judgement of $\text{ERF}_{\text{ari+aci}}$. (b) Whisker boxes from GCM studies and studies involving satellite data of RF_{ari} , ERF_{aci} and $\text{ERF}_{\text{ari+aci}}$. They are grouped into RF_{ari} from CMIP5/ACCMIP GCMs (labeled CMIP5 in red), ERF_{aci} from GCMs (labeled AR4, AR5 in green), all estimates of $\text{ERF}_{\text{ari+aci}}$ shown in the upper panel (labeled "All" in blue), $\text{ERF}_{\text{ari+aci}}$ from GCMs highlighted in the upper panel (labeled "highlighted GCMs" in blue), $\text{ERF}_{\text{ari+aci}}$ from satellites highlighted in the upper panel (labeled "Highlighted Satellites" in blue), and our expert judgement based on estimates of $\text{ERF}_{\text{ari+aci}}$ from these GCM and satellite studies (labeled "Expert Judgement" in blue). Displayed are the averages (cross sign), median values (middle line), 17th and 83th percentiles (*likely* range shown as box boundaries) and 5th and 95th percentiles (whiskers). References for the individual estimates are provided in Table 7.3. Table 7.4 includes the values of the GCM and satellite studies considered for the expert judgement of $\text{ERF}_{\text{ari+aci}}$ that are highlighted in black.

[INSERT TABLE 7.3 HERE]

Table 7.3: List of references for each category of estimates displayed in Figure 7.19.

[INSERT TABLE 7.4 HERE]

Table 7.4: List of $\text{ERF}_{\text{ari+aci}}$ values (W m^{-2}) considered for the expert judgement of $\text{ERF}_{\text{ari+aci}}$ (black symbols in Figure 7.19). For the GCM studies only the best estimate per modelling group is used. For satellite studies the estimates are corrected for the ERF_{ari} and for the longwave component of $\text{ERF}_{\text{aci+ari}}$ when these are not included (see text).

[INSERT TABLE 7.5 HERE]

Table 7.5: Estimates of aerosol 1850–2000 ERF (in W m^{-2}) in some of the CMIP5 and ACCMIP models. The ERF are estimated from fixed-SST experiments using atmosphere-only version of the models listed. Different models include different aerosol effects. The CMIP5 and ACCMIP protocols differ, hence differences in forcing estimates for one model.

7.5.4 Estimate of ERF from Aerosol-Cloud Interactions Alone (ERF_{aci})

ERF_{aci} refers to changes in top-of-atmosphere radiation since pre-industrial times only due to aerosol-cloud interactions, i.e., albedo effects augmented by possible changes in cloud amount and lifetime. As stated in Section 7.5.1, we do not discuss RF_{aci} by itself because it is an academic construct. However, processes in GCMs that tend to affect RF_{aci} such as changes to the droplet size distribution breadth (e.g., Rotstayn and Liu, 2005) will also affect ERF_{aci} . Early studies evaluated just the change in shortwave radiation or cloud radiative effect for ERF_{aci} , but lately the emphasis has changed to report changes in net top-of-atmosphere radiation for ERF_{aci} . As discussed in Section 7.5.3, evaluating ERF_{aci} from changes in net top-of-atmosphere radiation is the only correct method, and therefore this is used whenever possible also in this section. However some earlier estimates of ERF_{aci} only reported changes in cloud radiative effect, which we show in Figure 7.19 as the last resort. However, estimates of changes in cloud radiative effect can differ quite substantially from those in net radiation if rapid adjustments to aerosol-cloud interactions induce changes in clear-sky radiation.

Cloud amount and lifetime effects manifest themselves in GCMs via their representation of autoconversion of cloud droplets to rain, a process that is inversely dependent on droplet concentration. Thus, ERF_{aci} and ERF_{ari+aci} have been found to be very sensitive to the autoconversion parameterization (Rotstayn, 2000; Golaz et al., 2011; Wang et al., 2012). GCMs probably underestimate the extent to which precipitation is formed via raindrop accretion of cloud droplets (Wood, 2005), a process that is insensitive to aerosol and droplet concentration. Indeed, models that remedy this imbalance in precipitation formation between autoconversion and accretion (Posselt and Lohmann, 2009; Wang et al., 2012) exhibit weaker ERF_{aci} in agreement with small-scale studies that typically do not show a systematic increase in cloud lifetime because of entrainment and because smaller droplets also evaporate more readily (Jiang et al., 2006; Bretherton et al., 2007). Bottom-up estimates of ERF_{aci} are shown in Figure 7.19. Their median estimate of -1.4 W m^{-2} is more negative than our expert judgement of ERF_{ari+aci} because of the limitations of these studies discussed above.

There is conflicting evidence for the importance of ERF_{aci} associated with cirrus, ranging from a statistically significant impact on cirrus coverage (Hendricks et al., 2005) to a very small effect (Liu et al., 2009). Penner et al. (2009) obtained a rather large negative R_{Faci} of anthropogenic ice-forming aerosol on upper tropospheric clouds of -0.67 to -0.53 W m^{-2} , however, they ignored potential compensating effects on lower lying clouds. A new study based on two GCMs and different ways to deduce ERF_{aci} on cirrus clouds estimates ERF_{aci} to be $+0.27 \pm 0.1 \text{ W m}^{-2}$ (Gettelman et al., 2012), thus rendering aerosol effects on cirrus clouds smaller than previously estimated and of opposite sign.

One reason for having switched to providing an expert judgment estimate of ERF_{ari+aci} rather than of ERF_{aci} is that the individual contributions are very difficult to disentangle. The individual components can only be isolated if linearity of ERF_{ari} and ERF_{aci} is assumed but there is no a priori reason why the ERFs should be additive because by definition they occur in a system that is constantly readjusting to multiple non-linear forcings. Nevertheless assuming additivity, ERF_{aci} could be obtained as the difference between ERF_{ari+aci} and ERF_{ari}. This yields an ERF_{aci} estimate of -0.45 W m^{-2} , i.e., much smaller than the median ERF_{aci} value of -1.4 W m^{-2} (see above and Figure 7.19). This discrepancy arises because the GCM estimates of ERF_{aci} do not consider secondary processes and because these studies are not necessarily conducted with the same GCMs that estimate ERF_{ari+aci}. This difference could also be a measure of the non-linearity of the ERFs. A 90% uncertainty range of -1.2 to 0 W m^{-2} is adopted for ERF_{aci}, which accounts for the error covariance between ERF_{ari} and ERF_{aci} and the larger uncertainty on the lower bound. In summary, there is much less confidence associated with the estimate of ERF_{aci} than with the estimate of ERF_{ari+aci}.

7.6 Processes Underlying Precipitation Changes

7.6.1 Introduction

In this section we outline some of the main processes thought to control the climatological distribution of precipitation and precipitation extremes. Emphasis is placed on large-scale constraints that relate to processes, such as changes in the water vapour mixing ratio that accompany warming, or changes in atmospheric heating rates that accompany changing greenhouse gas and aerosol concentrations, which are discussed earlier in this chapter. The fidelity with which large-scale models represent different aspects of precipitation, ranging from the diurnal cycle to extremes, is discussed in Section 9.4.1. Building on, and adding to, concepts developed here, Section 11.3.2 presents near term projections of changes in regional precipitation features. Projections of changes on longer timescales, again with more emphasis on regionally specific features and the coupling to the land surface, are presented in Section 12.4.5. The effect of processes discussed in this section on specific precipitation systems, such as the monsoon, the inter-tropical convergence zones, or tropical cyclones are presented in Chapter 14.

Precipitation is sustained by the availability of moisture and energy. In a globally-averaged sense the oceans provide an unlimited supply of moisture, so that precipitation formation is energetically limited (Mitchell et al., 1987). Locally precipitation can be greatly modified by limitations in the availability of moisture (for instance over land) and the effect of circulation systems, although these too are subject to local energetic constraints (Neelin and Held, 1987; Raymond et al., 2009). There are many ways to satisfy these constraints, and climate models still exhibit substantial biases in their representation of the spatio-temporal distribution

of precipitation (Stephens et al., 2010; Liepert and Previdi, 2012; Section 9.5). Nonetheless, through careful analysis, it is possible to identify robust features in the simulated response of precipitation to changes in precipitation drivers. In almost every case these can be related to well understood processes, as described below.

7.6.2 *The Effects of Global Warming on Large-Scale Precipitation Trends*

The atmospheric water vapour mixing ratio is expected to increase with temperature roughly following the saturation value (e.g., with increases in surface values ranging from 6–10% °C⁻¹ and larger increases aloft, see Section 7.2.4.1). Increases in global-mean precipitation are, however, constrained by changes in the net radiative cooling rate of the troposphere. GCMs, whose detailed treatment of radiative transfer provides a basis for calculating these energetic limitations, suggest that for the CO₂ forcing, globally-averaged precipitation increases with global mean surface temperature at about 1–3% °C⁻¹ (Mitchell et al., 1987; Held and Soden, 2006; Richter and Xie, 2008). Precipitation changes evince considerable regional variability about the globally averaged value; generally speaking precipitation is expected to increase in the wettest latitudes, whereas dry latitudes may even see a precipitation decrease (Mitchell et al., 1987; Allen and Ingram, 2002; Held and Soden, 2006). On smaller scales, or near precipitation margins, the response is less clear due to model-specific, and less well understood, regional circulation shifts (Neelin et al., 2006), but there is some evidence that the sub-tropical dry zones are expanding (Section 7.2.5.2 and Section 2.7.5), both as a result of the tropical convergence zones narrowing (Neelin et al., 2006; Chou et al., 2009), and the storm tracks moving poleward (Allen et al., 2012) and strengthening (O’Gorman and Schneider, 2008).

The “wet-get-wetter” and “dry-get-drier” response that is evident at large scales over oceans can be understood as a simple consequence of a change in the water vapour content carried by circulations, which otherwise are little changed (Mitchell et al., 1987; Held and Soden, 2006). Wet regions are wet because they import moisture from dry regions, increasingly so with warmer temperatures. These ideas have withstood additional analysis and scrutiny since AR4 (Chou et al., 2009; Seager et al., 2010; Muller and O’Gorman, 2011), are evident in 20th century precipitation trends (Allan and Soden, 2007; Zhang et al., 2007b; see Section 2.5.1) and are assessed on different timescales in Chapters 11 and 12. Because the wet-get-wetter argument implies that precipitation changes associated with warming are correlated with the present day pattern of precipitation, biases in the simulation of present-day precipitation will lead to biases in the projections of future precipitation change (Bony et al., 2013).

The wet-get-wetter and dry-get-drier response pattern is mitigated, particularly in the dry regions, by the anticipated slowdown of the atmospheric circulation (as also discussed in Section 7.2.5.3), as well as by gains from local surface evaporation. The slowdown within the descent regions can be partly understood as a consequence of the change in the dry static stability of the atmosphere with warming. And although this line of argument is most effective for explaining changes over the ocean (Chou et al., 2009; Bony et al., 2013), it can also be used to understand the GCM land responses to some extent (Muller and O’Gorman, 2011).

The non-uniform nature of surface warming induces regional circulation shifts that affect precipitation trends. In the tropics sea-surface temperatures warm more where winds are weak and thus are less effective in damping surface temperature anomalies, and precipitation systematically shifts to regions that warm more (Xie et al., 2010). The greater warming over land, and its regional variations, also affect the regional distributions of precipitation (Joshi et al., 2008). However, low understanding of soil-moisture-precipitation feedbacks complicates interpretations of local responses to warming over land (Hohenegger et al., 2009), so that the effect of warming on precipitation at the scale of individual catchments is not well understood. Some broad-scale responses, particularly over the ocean, are more robust and relatively well understood.

7.6.3 *Radiative Forcing of the Hydrological Cycle*

In the absence of a compensating temperature change, an increase in well-mixed greenhouse gas concentrations tends to reduce the net radiative cooling of the troposphere. This reduces the rainfall rate and the strength of the overturning circulation (Andrews et al., 2009; Bony et al., 2013), such that the increase in global-mean precipitation would be 1.5–3.5% °C⁻¹ due to temperature alone but is reduced by about 0.5% °C⁻¹ due to the effect of CO₂ (Lambert and Webb, 2008). The dynamic effects are similar to those that result from the effect of atmospheric warming on the lapse rate, which also reduces the strength of the atmospheric

overturning circulation (e.g., Section 7.6.2), and are robustly evident over a wide range of models and model configurations (Bony et al., 2013; see also Figure 7.20). These circulation changes influence the regional response, and are more pronounced over the ocean, because asymmetries in the land-sea response to changing concentrations of greenhouse gases (Joshi et al., 2008) amplify the maritime and dampen or even reverse the terrestrial signal (Wyant et al., 2012; Bony et al., 2013).

[INSERT FIGURE 7.20 HERE]

Figure 7.20: Illustration of the response of the large-scale atmospheric overturning to warming (adapted from Bony et al., 2013). The overturning intensity is shown on the y -axis and is measured by the difference between the mean motion in upward moving air and the mean motion in downward moving air. The warming is shown on the x -axis and is measured by the change in globally-averaged surface temperature, ΔT_s , after an abrupt quadrupling of atmospheric CO_2 . The grey region delineates responses for which ΔT_s is zero by definition. Nearly one half of the final reduction in the intensity of the overturning is evident before any warming is felt, and can be associated with a rapid adjustment of the hydrological cycle to changes in the atmospheric cooling rate accompanying a change in CO_2 . With warming the circulation intensity is further reduced. The rapid adjustment, as measured by the change in circulation intensity for zero warming, is different over land and ocean. Over land the increase in CO_2 initially causes an intensification of the circulation. The result is robust in the sense that it is apparent in all of the 15 CMIP5 models analysed, irrespective of the details of their configuration.

The dependence of the intensity of the hydrological cycle on the tropospheric cooling rate helps to explain why perturbations having the same radiative forcing do not produce the same precipitation responses. Apart from the relatively small increase in absorption by atmospheric water vapor, increased solar forcing does not directly affect the net tropospheric cooling rate. As a result the hydrological cycle mostly feels the subsequent warming through its influence on the rate of tropospheric cooling (Takahashi, 2009). This is why modeling studies suggest that solar radiation management (geoengineering) methods that maintain a constant surface temperature will lead to a reduction in globally averaged precipitation as well as different regional distributions of precipitation (Schmidt et al., 2012b; Section 7.7.3).

Changes in cloud radiative effects, and aerosol radiative forcing can also be effective in changing the net radiative heating rate within the troposphere (Lambert and Webb, 2008; Pendergrass and Hartmann, 2012). Most prominently, absorption of solar radiation by atmospheric aerosols is understood to reduce the globally averaged precipitation. But this effect may be offset by the tendency of absorbing aerosols to reduce the planetary albedo, thereby raising surface temperature, leading to more precipitation (Andrews et al., 2009). Heterogeneously distributed precipitation drivers such as clouds, aerosols and tropospheric ozone will also induce circulations that may amplify or dampen their local impact on the hydrological cycle (Ming et al., 2010; Allen et al., 2012; Shindell et al., 2012). Such regional effects are discussed further in Chapter 14 for the case of aerosols.

7.6.4 Effects of Aerosol-Cloud Interactions on Precipitation

Aerosol-cloud interactions directly influence the cloud microphysical structure, and only indirectly (if at all) the net atmospheric heating rate, and for this reason have mostly been explored in terms of their effect on the character and spatio-temporal distribution of precipitation, rather than on the globally-averaged amount of precipitation.

The sensitivity of simulated clouds to their microphysical development (e.g., Fovell et al., 2009; Parodi and Emanuel, 2009) suggests that they may be susceptible to the availability of CCN and IN. For instance, an increase in CCN favours smaller cloud droplets, which delays the onset of precipitation and the formation of ice particles in convective clouds (Rosenfeld and Woodley, 2001; Khain et al., 2005). It has been hypothesised that such changes may affect the vertical distribution and total amount of latent heating in ways that would intensify or invigorate convective storms, as measured by the strength and vertical extent of the convective updraughts (Andreae et al., 2004; Rosenfeld et al., 2008; Rosenfeld and Bell, 2011; Tao et al., 2012). Support for the idea that the availability of CCN influences the vigour of convective systems can be found in some modelling studies, but the strength, and even sign, of such an effect has been shown to be contingent on a variety of environmental factors (Seifert and Beheng, 2006; Fan et al., 2009; Khain, 2009; Seifert et al., 2012) as well as on modelling assumptions (Ekman et al., 2011).

Observational studies, based on large datasets that sample many convective systems, report systematic correlations between aerosol amount and cloud-top temperatures (Devasthale et al., 2005; Koren et al., 2010a; Li et al., 2011). Weekly cycles in cloud properties and precipitation, wherein convective intensity, cloud cover or precipitation increases during that part of the week when aerosol concentrations are largest, have also been reported (Bäumer and Vogel, 2007; Bell et al., 2008; Rosenfeld and Bell, 2011). Both types of studies have been interpreted in terms of an aerosol influence on convective cloud systems. However, whether or not these findings demonstrate that a greater availability of CCN systematically invigorates, or otherwise affects, convection remains controversial. Many of the weekly cycle studies are disputed on statistical or other methodological grounds (Barnet et al., 2009; Stjern, 2011; Tuttle and Carbone, 2011; Sanchez-Lorenzo et al., 2012; Yuter et al., 2013). Even in cases where relationships between aerosol amount and some measure of convective intensity appear to be unambiguous, the interpretation that this reflects an aerosol effect on the convection is less clear, as both aerosol properties and convection are strongly influenced by meteorological factors that are not well controlled for (e.g., Boucher and Quaas, 2013). Studies that have used CRMs to consider the net effect of aerosol-cloud interactions integrated over many storms, or in more of a climate context wherein convective heating must balance radiative cooling within the atmosphere, also do not support a strong and systematic invigoration effect resulting from very large (many fold) changes in the ambient aerosol (Morrison and Grabowski, 2011; van den Heever et al., 2011; Seifert et al., 2012; Khairoutdinov and Yang, 2013). Locally in space or time, however, radiative processes are less constraining, leaving open the possibility of stronger effects from localized or transient aerosol perturbations.

Because precipitation development in clouds is a time dependent process, which proceeds at rates that are partly determined by the cloud microphysical structure (Seifert and Zängl, 2010), aerosol-cloud interactions may lead to shifts in topographic precipitation to the leeward side of mountains when precipitation is suppressed, or to the windward side in cases when it is more readily initiated. Orographic clouds show a reduction in the annual precipitation over topographical barriers downwind of major urban areas in some studies (Givati and Rosenfeld, 2004; Jirak and Cotton, 2006) but not in others (Halfon et al., 2009). Even in cases where effects are reported, the results have proven sensitive to how the data is analysed (Alpert et al., 2008; Levin and Cotton, 2009).

In summary, it is unclear whether changes in aerosol-cloud interactions arising from changes in the availability of CCN or IN can affect, and possibly intensify, the evolution of individual precipitating cloud systems. Some observational and modelling studies suggest such an effect, but are undermined by alternative interpretations of the observational evidence, and a lack of robustness in the modelling studies. The evidence for systematic effects over larger areas and long-time periods is, if anything, more limited and ambiguous.

7.6.5 *The Physical Basis for Changes in Precipitation Extremes*

The physical basis for aerosol microphysical effects on convective intensity was discussed in the previous section. Here we briefly discuss process understanding of the effect of warming on precipitation extremes; observed trends supporting these conclusions are presented in Section 2.6.2.

[INSERT FIGURE 7.21 HERE]

Figure 7.21: Estimate (5–95% range) of the increase in precipitation amount per °C of global-mean surface temperature change. At left (blue) are climate model predictions of changes in time-averaged global precipitation; at centre and right (orange) are predictions or estimates of the typical or average increase in local 99.9th percentile extremes, over 24 hours (centre) and over one hour or less (right). Data are adapted from (A) GCM studies (Allen and Ingram, 2002; and Lambert and Webb, 2008, for time-average; O’Gorman and Schneider, 2009 for extremes), (B) long-term trends at many sites globally (Westra et al., 2013), (C) GCMs constrained by present-day observations of extremes (O’Gorman, 2012), (D) LES and CRM studies of radiative convective equilibrium (Muller et al., 2011; Roms, 2011).

Precipitation within individual storms is expected to increase with the available moisture content in the atmosphere or near the surface rather than with the global precipitation (Allen and Ingram, 2002; Held and Soden, 2006), which leads to a 6–10% °C⁻¹ increase, but with longer intervals between storms (O’Gorman and Schneider, 2009). Because GCMs are generally poor at simulating precipitation extremes (Stephens et al., 2010) and predicted changes in a warmer climate vary (Kharin et al., 2007; Sugiyama et al., 2010), they are not usually thought of as a source of reliable information regarding extremes. However, a recent study (O’Gorman, 2012) shows that GCM predictions of extremes can be constrained by observable relationships in the present day climate, and upon doing so become broadly consistent with the idea that extreme

precipitation increases by 6–10% °C of warming. Central estimates of sensitivity of extreme (99.9th percentile) daily rainfall to global temperature from this study were 10% °C⁻¹ in the tropics (O’Gorman, 2012), compared to 5% °C⁻¹ predicted by the models in the extratropics, where they may be more reliable (O’Gorman and Schneider, 2009). How precipitation extremes depend on temperature has also been explored using cloud resolving simulations (but only for tropical conditions) which produce similar increases in extreme instantaneous rain rate (Romps, 2011) and daily or hourly rain totals (Muller et al., 2011) within storms (Figure 7.21). Because these latter studies are confined to small domains, they may exclude important synoptic or larger-scale dynamical changes such as increases in flow convergence (Chou et al., 2009; Sugiyama et al., 2010).

By taking advantage of natural variability in the present day climate, a number of studies have correlated observed rainfall extremes with local temperature variations. In the extratropics, these studies document sensitivities of extreme precipitation to temperature much higher than those reported above (Lenderink and Van Meijgaard, 2008), but sensitivities vary with temperature (Lenderink et al., 2011), are often negative in the tropics (Hardwick Jones et al., 2010), and usually strengthen at the shortest (e.g., hourly or less) time scales (e.g., Haerter et al., 2010; Hardwick Jones et al., 2010). However, local temperature changes may not be a good proxy for global warming because they tend to co-vary with other meteorological factors (such as humidity, atmospheric stability, or wind direction) in ways that are uncharacteristic of changes in the mean temperature (see Section 7.2.5.7), and these other meteorological factors may dominate the observed signal (e.g., Haerter and Berg, 2009). Thus, the idea that precipitation extremes depend much more strongly on temperature than the 5–10 % increase per °C attributable to water vapour changes, remains controversial.

Following the AR4, studies have also continued to show that extremes in precipitation are associated with the coincidence of particular weather patterns (e.g., Lavers et al., 2011). We currently lack an adequate understanding of what controls the return time and persistence of such rare events.

From the above model and observational evidence, there is *high confidence* that the intensity of extreme precipitation events will increase with warming, at a rate well exceeding that of the mean precipitation. There is *medium confidence* that the increase is roughly 5–10% °C⁻¹ warming but may vary with time scale, location and season.

7.7 Solar Radiation Management and Related Methods

7.7.1 Introduction

Geoengineering –also called climate engineering– is defined as a broad set of methods and technologies that aim to deliberately alter the climate system in order to alleviate impacts of climate change (Keith, 2000; Izrael et al., 2009; Royal Society, 2009; IPCC, 2011). Two main classes of geoengineering are often considered. Solar Radiation Management (SRM) proposes to counter the warming associated with increasing greenhouse gas concentrations by reducing the amount of sunlight absorbed at the surface. A related method seeks to alter high-altitude cirrus clouds to reduce their greenhouse effect. Another class of geoengineering called Carbon Dioxide Removal (CDR) is discussed in Section 6.5. This section assesses how the climate system might respond to some proposed SRM methods and related methods thought to have the potential to influence the global energy budget by at least a few tenths of a W m⁻² but it does not assess technological or economical feasibility, or consider methods targeting specific climate impacts (MacCracken, 2009). Geoengineering is quite a new field of research, and there are relatively few studies focussed on it. Assessment of SRM is limited by: i) gaps in understanding of some important processes; ii) a relative scarcity of studies; and iii) a scarcity of studies using similar experimental design. This section discusses some aspects of SRM potential to mitigate global warming, outlines robust conclusions where they are apparent, and evaluates uncertainties and potential side effects. Additional impacts of SRM are assessed in Chapter 19, Section 19.5.4 of the WGII report, while some of the socio-economic issues are assessed in Chapters 3, 6 and 13 of the WGIII report.

7.7.2 Assessment of Proposed SRM Methods

A number of studies have suggested reducing the amount of sunlight reaching the Earth by placing solid or refractive disks, or dust particles, in outer space (Early, 1989; Mautner, 1991; Angel, 2006; Bewick et al.,

2012). Although we do not assess the feasibility of these methods, they provide an easily described mechanism for reducing sunlight reaching the planet, and motivate the idealised studies discussed in Section 7.7.3.

7.7.2.1 *Stratospheric Aerosols*

Some SRM methods propose increasing the amount of stratospheric aerosol to produce a cooling effect like that observed after strong explosive volcanic eruptions (Budyko, 1974; Crutzen, 2006). Recent studies have used numerical simulations and/or natural analogues to explore the possibility of forming sulphuric acid aerosols by injecting sulphur-containing gases into the stratosphere (Rasch et al., 2008b). Because aerosols eventually sediment out of the stratosphere (within roughly a year or less), these methods require replenishment to maintain a given level of RF. Research has also begun to explore the efficacy of other types of aerosol particles (Crutzen, 2006; Keith, 2010; Ferraro et al., 2011; Kravitz et al., 2012) but the literature is much more limited and not assessed here.

The RF depends on the choice of chemical species (gaseous SO₂, H₂SO₄ or sprayed aerosols), location(s), rate, and frequency of injection. The injection strategy affects particle size (Rasch et al., 2008a; Heckendorn et al., 2009; Pierce et al., 2010; English et al., 2012) with larger particles producing less RF (per unit mass) and more rapid sedimentation than smaller particles, affecting the efficacy of the method. The aerosol size distribution is controlled by an evolving balance between new particle formation, condensation of vapour on pre-existing particles, evaporation of particles, coagulation, and sedimentation. Models that more fully account for aerosol processes (Heckendorn et al., 2009; Pierce et al., 2010; English et al., 2012) found smaller aerosol burdens, larger particles and weaker RF than earlier studies that prescribed the particle size over the particle lifetime. Current modeling studies indicate that injection of sulphate aerosol precursors of at least 10 Mt S (approximately the amount of sulphur injected by the Mount Pinatubo eruption) would be needed annually to maintain a RF of -4 W m^{-2} , roughly equal but opposite to that associated with a doubling of atmospheric carbon dioxide (Heckendorn et al., 2009; Pierce et al., 2010; Niemeier et al., 2011). Stratospheric aerosols may affect high clouds in the tropopause region, and one study (Kuebbeler et al., 2012) suggests significant negative forcing would result, but this is uncertain given limited understanding of ice nucleation in high clouds (Section 7.4.4.4).

Along with its potential to mitigate some aspects of global warming, the potential side effects of SRM must also be considered. Tilmes et al. (2008; 2009) estimated that stratospheric aerosols SRM might increase chemical ozone loss at high latitudes and delay recovery of the Antarctic ozone hole (expected at the end of this century) by 30–70 years, with changes in column ozone of -3 to -10% in polar latitudes and $+3$ to $+5\%$ in the tropics. A high latitude ozone loss is expected to increase UV radiation reaching the surface there, although the effect would be partially compensated by the increase in attenuation by the aerosol itself (Vogelmann et al., 1992; Tilmes et al., 2012). A decrease in direct radiation and increase in diffuse radiation reaching the Earth's surface would occur and would be expected to increase photosynthesis in terrestrial ecosystems (Mercado et al., 2009; see Section 6.5.4) and decrease the efficiency of some solar energy technologies (see WGII AR5, Chapter 19, Section 19.5.4). Models indicate that stratospheric aerosol SRM would not pose a surface acidification threat with maximum acid deposition rates estimated to be at least 500 times less than the threshold of concern for the most sensitive land ecosystems (Kuylentierna et al., 2001; Kravitz et al., 2009); contributions to ocean acidification are also estimated to represent a very small fraction of that induced by anthropogenic CO₂ emissions (Kravitz et al., 2009). There are other known side effects that remain unquantified, and limited understanding (and limited study) make additional impacts difficult to anticipate.

7.7.2.2 *Cloud Brightening*

Boundary layer clouds act to cool the planet, and relatively small changes in albedo or areal extent of low cloud can have profound effects on the Earth's radiation budget (Section 7.2.1). Theoretical, modelling and observational studies show that the albedo of these types of cloud systems are susceptible to changes in their droplet concentrations, but the detection and quantification of RF attributable to such effects is difficult to separate from meteorological variability (Section 7.4.3.2). Nonetheless, by systematically introducing CCN into the marine boundary layer, it should be possible to locally increase boundary layer cloud albedo as discussed in Section 7.4.2. These ideas underpin the ideas of cloud brightening, for instance through the

direct injection (seeding) of sea-spray particles into cloud-forming air masses (Latham, 1990). An indirect cloud brightening mechanism through enhanced DMS production has also been proposed (Wingenter et al., 2007) but the efficacy of the DMS mechanism is disputed (Vogt et al., 2008; Woodhouse et al., 2008).

The seeding of cloud layers with a propensity to precipitate may change cloud structure (e.g., from open to closed cells) and/or increase liquid water content (Section 7.4.3.2.1), in either case changing albedo and producing strong negative forcing. A variety of methods have been used to identify which cloud regions are most susceptible to an aerosol change (Oreopoulos and Platnick, 2008; Salter et al., 2008; Alterskjær et al., 2012). Marine stratocumulus clouds with relatively weak precipitation are thought to be an optimal cloud type for brightening because of their relatively low droplet concentrations, their expected increase in cloud water in response to seeding (Section 7.4.3.2.1), and the longer lifetime of sea-salt particles in non- or weakly-precipitating environments. Relatively strong local ERFaci (-30 to -100 W m^{-2}) would be required to produce a global forcing of -1 to -5 W m^{-2} if only the more susceptible clouds were seeded.

Simple modelling studies suggest that increasing droplet concentrations in marine boundary layer clouds by a factor of five or so (to concentrations of 375 – 1000 cm^{-3}) could produce an ERFaci of about -1 W m^{-2} if 5% of the ocean surface area were seeded, and an ERFaci as strong as -4 W m^{-2} if that fraction were increased to 75% (Latham et al., 2008; Jones et al., 2009; Rasch et al., 2009). Subsequent studies with more complete treatments of aerosol-cloud interactions have produced both stronger (Alterskjær et al., 2012; Partanen et al., 2012) and weaker (Korhonen et al., 2010a) changes. Because the initial response to cloud seeding is local, high-resolution, limited-domain simulations are especially useful to explore the efficacy of seeding. One recent study of this type (Wang et al., 2011a) found that cloud brightening is sensitive to cloud-dynamical adjustments that are difficult to treat in current GCMs (Sections 7.4.3 and 7.5.3) and concluded that the seeding rates initially proposed for cloud seeding may be insufficient to produce the desired cloud brightening. Recent studies accounting for clear-sky brightening from increased aerosol concentrations (i.e., ERFari) also found an increase in the amplitude of the ERF by 30 to 50% (Hill and Ming, 2012; Partanen et al., 2012), thereby making the aerosol seeding more effective than previous estimates that neglected that effect.

In summary, evidence that cloud brightening methods are effective and feasible in changing cloud reflectivity is ambiguous and subject to many of the uncertainties associated with aerosol-cloud interactions more broadly. If cloud brightening were to produce large local changes in ERF, those changes would affect the local energy budget, with further impacts on larger-scale oceanic and atmospheric circulations. Possible side effects accompanying such large and spatially heterogeneous changes in ERF have not been systematically studied.

7.7.2.3 Surface Albedo Changes

A few studies have explored how planetary albedo might be increased by engineering local changes to the albedo of urban areas, croplands, grasslands, deserts and the ocean surface. Effects from whitening of urban areas have been estimated to yield a potential RF of -0.17 W m^{-2} (Hamwey, 2007) although subsequent studies (Lenton and Vaughan, 2009; Oleson et al., 2010; Jacobson and Ten Hoeve, 2012) suggest that this estimate may be at the upper end of what is achievable. Larger effects might be achievable by replacing native grassland or cropland with natural or bioengineered species with a larger albedo. A hypothetical 25% increase in grassland albedo could yield a RF as large as -0.5 W m^{-2} (Lenton and Vaughan, 2009), with the maximum effect in the mid-latitudes during summer (Ridgwell et al., 2009; Doughty et al., 2011). The feasibility of increasing crop and grassland albedo remains unknown, and there could be side effects on photosynthetic activity, carbon uptake and biodiversity. The low albedo and large extent of oceanic surfaces mean that only a small increase in albedo, e.g., by increasing the concentration of microbubbles in the surface layer of the ocean (Evans et al., 2010; Seitz, 2011), could be sufficient to offset several W m^{-2} of RF by greenhouse gases. Neither the extent of microbubble generation and persistence required for a significant climate impact, nor the potential side effects on the ocean circulation, air-sea fluxes and marine ecosystems have been assessed.

7.7.2.4 Cirrus Thinning

Although not strictly a form of SRM, proposals have been made to cool the planet by reducing the coverage or longwave opacity of high thin cirrus clouds, which act to warm the surface through their greenhouse effect (see Section 7.2.1.2). A proposal for doing so involves adding efficient IN in regions prone to forming thin cirrus cloud (Mitchell and Finnegan, 2009). To the extent such a proposal is feasible, one modelling study suggests that an ERF_{ci} of as strong as -2 W m^{-2} could be achieved (Storelvmo et al., 2013), with further negative forcing caused by a reduction in humidity of the upper troposphere associated with the cloud changes. However, lack of understanding of cirrus cloud formation processes, as well as ice microphysical processes (Section 7.4.4), makes it difficult to judge the feasibility of such a method, particularly in light of the fact that increasing ice nucleation can also increase cirrus opacity, under some circumstances producing an opposite, positive forcing (Storelvmo et al., 2013). Side effects specific to the "cirrus thinning" method have not been investigated.

7.7.3 *Climate Response to SRM Methods*

As discussed elsewhere in this and other chapters of this assessment, significant gaps remain in our understanding of the climate response to forcing mechanisms. Geoengineering is also a relatively new field of research. The gaps in understanding, scarcity of studies and diversity in the model experimental design make quantitative model evaluation and intercomparison difficult, hindering an assessment of the efficacy and side-effects of SRM. This motivates dividing the discussion into two sections, one that assesses idealised studies that focus on conceptual issues and searches for robust responses to simple changes in the balance between solar irradiance and CO₂ forcing, and another discussing studies that more closely emulate specific SRM methods.

7.7.3.1 *Climate Response in Idealised Studies*

Perhaps the simplest SRM experiment that can be performed in a climate model consists of a specified reduction of the total solar irradiance, which could approximate the radiative impact of space reflectors. Reductions in solar irradiance in particular regions (over land or ocean, or in polar or tropical regions) could also provide useful information. Idealised simulations often focus on the effects of a complete cancellation of the warming from greenhouse gases, but the rate of warming is occasionally explored by producing a negative RF that partially cancels the anthropogenic forcing (e.g., Eliseev et al., 2009). They can also provide insight into the climate response to other SRM methods, and can provide a simple baseline for examining other SRM techniques.

The most comprehensive and systematic evaluation of idealised SRM to date is the Geoengineering Model Intercomparison Project (Kravitz et al., 2011). Together with earlier model studies, this project found robust surface temperature reductions when the total solar irradiance is reduced: when this reduction compensates for CO₂ radiative forcing, residual effects appear regionally, but they are much smaller than the warming due to the CO₂ RF alone (Kravitz et al., 2011; Schmidt et al., 2012b, Figures 7.22a-b and 7.23a-d). The substantial warming from $4 \times \text{CO}_2$ at high latitudes (4°C – 18°C) is reduced to a warming of 0°C – 3°C near the winter pole. The residual surface temperature changes are generally positive at mid- and high-latitudes, especially over continents, and generally negative in the tropics (Bala et al., 2008; Lunt et al., 2008; Schmidt et al., 2012b). These anomalies can be understood in terms of the difference between the more uniform longwave forcing associated with changes in long-lived greenhouse gases and the less uniform shortwave forcing from SRM that has a stronger variation in latitude and season. The compensation between SRM and CO₂ forcing is inexact in other ways. For example, SRM will only change heating rates during the daytime, but increasing greenhouse effect changes temperatures during both day and night, influencing the diurnal cycle of surface temperature even if compensation for the diurnally-averaged surface temperature is correct.

Although increasing CO₂ concentrations lead to a positive RF that warms the entire troposphere, SRM produces a negative RF that tends to cool the surface. The combination of RFs produces an increase in stability that leads to less global precipitation as seen in Figures 7.22c-d and 7.23e-g (Bala et al., 2008; Andrews et al., 2010; Schmidt et al., 2012b) and discussed in Section 7.6.3. The reduction in precipitation shows similarities to the climate response induced by the Pinatubo eruption (Trenberth and Dai, 2007). Although the impact of changes in the total solar irradiance on global mean precipitation is well understood and robust in models, there is less understanding and agreement among models in the spatial pattern of the precipitation changes. Modelling studies suggest that some residual patterns may be robust (e.g.,

approximately 5% reduction in precipitation over SE Asia and the Pacific Warm Pool in JJA), but a physical explanation for these changes is lacking. Some model results indicate that an asymmetric hemispheric SRM forcing would induce changes in some regional precipitation patterns (Haywood et al., 2013).

[INSERT FIGURE 7.22 HERE]

Figure 7.22: Zonally- and annually-averaged change in surface air temperature ($^{\circ}\text{C}$) for (a) an abrupt $4 \times \text{CO}_2$ experiment and (b) an experiment where the $4 \times \text{CO}_2$ forcing is balanced by a reduction in the total solar irradiance to produce a global top-of-atmosphere flux imbalance of less than $\pm 0.1 \text{ W m}^{-2}$ during the first 10 years of the simulation (GeoMIP G1 experiment; Kravitz et al., 2011). (c) and (d) Same as (a) and (b) but for the change in precipitation (mm day^{-1}). The multi-model ensemble mean is shown with a thick black solid line. All changes are relative to the pre-industrial control experiment and averaged over years 11–50. The figure extends the results from Schmidt et al. (2012b) and shows the results from an ensemble of 12 coupled ocean-atmosphere general circulation models.

[INSERT FIGURE 7.23 HERE]

Figure 7.23: Multi-model mean of the change in surface air temperature ($^{\circ}\text{C}$) averaged over December, January and February months for (a) an abrupt $4 \times \text{CO}_2$ simulation and (b) an experiment where the $4 \times \text{CO}_2$ forcing is balanced by a reduction in the total solar irradiance to produce a global top-of-atmosphere flux imbalance of less than $\pm 0.1 \text{ W m}^{-2}$ during the first 10 years of the simulation (GeoMIP G1 experiment; Kravitz et al., 2011). (c-d) same as (a-b) but for the June, July and August months. (e-h) same as (a-d) but for the change in precipitation (mm day^{-1}). All changes are relative to the pre-industrial control experiment and averaged over years 11–50. The figure extends the results from Schmidt et al. (2012b) and shows the results from an ensemble of 12 coupled ocean-atmosphere general circulation models. Stippling denotes agreement on the sign of the temperature anomaly in at least 9 out of the 12 models.

High CO_2 concentrations from anthropogenic emissions will persist in the atmosphere for more than a thousand years in the absence of active efforts to remove atmospheric CO_2 (see Chapter 6). If SRM were used to counter positive forcing, it would be needed as long as the CO_2 concentrations remained high (Boucher et al., 2009). If greenhouse gas concentrations continued to increase, then the scale of SRM to offset the resulting warming would need to increase proportionally, amplifying residual effects from increasingly imperfect compensation. Figure 7.24 shows projections of the globally-averaged surface temperature and precipitation changes associated with a $1\% \text{ yr}^{-1}$ CO_2 increase, with and without SRM. The scenario includes a hypothetical, abrupt termination of SRM at year 50, which could happen due to any number of unforeseeable circumstances. After this event, all the simulations predict a return to temperature levels consistent with the CO_2 forcing within one to two decades, albeit with a rapid rate of temperature change (see also Irvine et al., 2012). Precipitation, which drops by 1% over the SRM period, rapidly returns to levels consistent with the CO_2 forcing upon SRM termination. The very rapid warming would probably affect ecosystem and human adaptation, and would also weaken carbon sinks, accelerating atmospheric CO_2 accumulation and contributing to further warming (Matthews and Caldeira, 2007).

Research suggests that this “termination effect” might be avoided if SRM were used at a modest level and for a relatively short period of time (less than a century) when combined with aggressive carbon dioxide removal efforts to minimize the probability that the global mean temperature might exceed some threshold (Matthews, 2010; Smith and Rasch, 2012).

[INSERT FIGURE 7.24 HERE]

Figure 7.24: Timeseries of globally-averaged (a) surface temperature ($^{\circ}\text{C}$) and (b) precipitation (mm day^{-1}) changes relative to each model’s $1 \times \text{CO}_2$ reference simulation. Solid lines are for simulations using SRM through an increasing reduction of the total solar irradiance to balance a $1\% \text{ yr}^{-1}$ increase in CO_2 concentration until year 50 after which SRM is stopped for the next 20 years (GeoMIP G2 experiment; Kravitz et al., 2011). Dashed lines are for $1\% \text{ CO}_2$ increase simulations with no SRM. The multi-model ensemble mean is shown with thick black lines.

7.7.3.2 Climate Response to Specific SRM Methods

Several studies examined the model response to more realistic stratospheric aerosol SRM (Rasch et al., 2008b; Robock et al., 2008; Jones et al., 2010; Fyfe et al., 2013). These studies produced varying aerosol burdens, and RF and model responses also varied more strongly than in the idealised experiments above. Although these studies differ in details, their climate responses were generally consistent with the idealised experiments described above.

Studies treating the interaction between the carbon cycle, the hydrologic cycle, and SRM indicate that SRM could affect the temperature-driven suppression of some carbon sinks, and that the increased stomatal resistance with increased CO₂ concentrations combined with less warming, may further affect the hydrological cycle over land (Matthews and Caldeira, 2007; Fyfe et al., 2013), with larger impacts on precipitation for stratospheric aerosol SRM than for a uniform reduction in incoming sunlight.

Coupled ocean-atmosphere-sea ice models have also been used to assess the climate impacts of cloud brightening due to droplet concentration changes (Jones et al., 2009; Rasch et al., 2009; Baughman et al., 2012; Hill and Ming, 2012). The patterns of temperature and precipitation change differ substantially between models. These studies showed larger residual temperature changes than the idealised SRM studies, with more pronounced cooling over the regions of enhanced albedo. The cooling over the seeded regions (the marine stratocumulus regions) and a warmer North Pacific adjacent to a cooler northwestern Canada, produced a sea surface temperature response with a La Niña-like pattern. One study has noted regional shifts in the potential hurricane intensity and hurricane genesis potential index in the Atlantic Ocean and South China Sea in response to cloud brightening (Baughman et al., 2012), due primarily to decreases in vertical wind shear, but overall the investigation and identification of robust side-effects has not been extensively explored.

Irvine et al. (2011) tested the impact of increasing desert albedo up to 0.80 in a climate model. This cooled surface temperature by -1.1°C (versus -0.22°C and -0.11°C for their largest crop and urban albedo change) and produced very significant changes in regional precipitation patterns.

7.7.4 *Synthesis on SRM Methods*

Theory, model studies and observations suggest that some SRM methods may be able to counteract a portion of global warming effects (on temperature, sea ice, and precipitation) due to high concentrations of anthropogenic greenhouse gases. But the level of understanding about SRM is low, and it is difficult to assess feasibility and efficacy because of remaining uncertainties in important climate processes and the interactions among those processes. Although SRM research is still in its infancy, enough is known to identify some potential benefits, which must be weighed against known side effects (there could also be side effects that have not yet been identified). All studies suggest there would be a small but measurable decrease in global precipitation from SRM. Other side effects are specific to specific methods, and a number of research areas remain largely unexplored. There are also features that develop as a consequence of the combination of high CO₂ and SRM (e.g., effects on evapotranspiration and precipitation). SRM only counters some consequences of elevated CO₂ concentrations; it does not in particular address ocean acidification.

Many model studies indicate that stratospheric aerosol SRM could counteract some changes resulting from greenhouse gas increases that produce a radiative forcing as strong as 4 W m^{-2} , but they disagree on details. Marine cloud brightening SRM has received less attention, and there is no consensus on its efficacy, in large part due to the high level of uncertainty about cloud radiative responses to aerosol changes. There have been fewer studies and much less attention focused on all other SRM methods, and it is not currently possible to provide a general assessment of their specific efficacy, scalability, side effects and risks.

There is robust agreement among models that the compensation between greenhouse gas warming and SRM cooling is imprecise. SRM would not produce a future climate identical to the present (or pre-industrial) climate. Nonetheless, although models disagree on details, they consistently suggest that a climate with SRM and high atmospheric CO₂ levels would be closer to that of the last century than a world with elevated CO₂ concentrations and no SRM (Lunt et al., 2008; Ricke et al., 2010; Moreno-Cruz et al., 2011), as long as the SRM could be continuously sustained and calibrated to offset the forcing by greenhouse gases. Aerosol-based methods would however require a continuous program of replenishment to achieve this. If CO₂ concentrations and SRM were increased in concert, the risks and residual climate change produced by the imprecise compensation between SRM and CO₂ forcing would also increase. If SRM were terminated for any reason, a rapid increase in surface temperatures (within a decade or two) to values consistent with the high greenhouse-gas forcing would result. This rate of climate change would far exceed what would have occurred without geoengineering, causing any impacts related to the rate of change to be correspondingly greater than they would have been without geoengineering. In contrast, SRM in concert with aggressive CO₂

mitigation might conceivably help avoid transitions across climate thresholds or tipping points that would be unavoidable otherwise.

[START FAQ 7.1 HERE]

FAQ 7.1: How do Clouds Affect Climate and Climate Change?

Clouds strongly affect the current climate, but observations alone cannot yet tell us how they will affect a future, warmer climate. Comprehensive prediction of changes in cloudiness requires a global climate model. Such models simulate cloud fields that roughly resemble those observed, but important errors and uncertainties remain. Different climate models produce different projections of how clouds will change in a warmer climate. Based on all available evidence, it seems likely that the net cloud-climate feedback amplifies global warming. If so, the strength of this amplification remains uncertain.

Since the 1970s, scientists have recognised the critical importance of clouds for the climate system, and for climate change. Clouds affect the climate system in a variety of ways. They produce precipitation (rain and snow) that is necessary for most life on land. They warm the atmosphere as water vapour condenses. Although some of the condensed water re-evaporates, the precipitation that reaches the surface represents a net warming of the air. Clouds strongly affect the flows of both sunlight (warming the planet) and infrared light (cooling the planet as it is radiated to space) through the atmosphere. Finally, clouds contain powerful updraughts that can rapidly carry air from near the surface to great heights. The updraughts carry energy, moisture, momentum, trace gases, and aerosol particles. For decades, climate scientists have been using both observations and models to study how clouds change with the daily weather, with the seasonal cycle, and with year-to-year changes such as those associated with El Niño.

All cloud processes have the potential to change as the climate state changes. Cloud feedbacks are of intense interest in the context of climate change. Any change in a cloud process that is caused by climate change—and in turn influences climate—represents a cloud-climate feedback. Because clouds interact so strongly with both sunlight and infrared light, small changes in cloudiness can have a potent effect on the climate system.

Many possible types of cloud-climate feedbacks have been suggested, involving changes in cloud amount, cloud-top height, and/or cloud reflectivity (see FAQ7.1, Figure 1). The literature shows consistently that high clouds amplify global warming as they interact with infrared light emitted by the atmosphere and surface. There is more uncertainty however about the feedbacks associated with low-altitude clouds, and about cloud feedbacks associated with amount and reflectivity in general.

[INSERT FAQ 7.1, FIGURE 1 HERE]

FAQ 7.1, Figure 1: Schematic of important cloud feedback mechanisms.

Thick high clouds efficiently reflect sunlight, and both thick and thin high clouds strongly reduce the amount of infrared light that the atmosphere and surface emit to space. The compensation between these two effects makes the surface temperature somewhat less sensitive to changes in high cloud amount than to changes in low cloud amount. This compensation could be disturbed if there were a systematic shift from thick high cloud to thin cirrus cloud or vice versa; while this possibility cannot be ruled out, it is not currently supported by any evidence. On the other hand, changes in the altitude of high clouds (for a given high-cloud amount) can strongly affect surface temperature. An upward shift in high clouds reduces the infrared light that the surface and atmosphere emit to space, but has little effect on the reflected sunlight. There is strong evidence of such a shift in a warmer climate. This amplifies global warming by preventing some of the additional infrared light emitted by the atmosphere and surface from leaving the climate system.

Low clouds reflect a lot of sunlight back to space but, for a given state of the atmosphere and surface, they have only a weak effect on the infrared light that is emitted to space by the Earth. As a result, they have a net cooling effect on the present climate; to a lesser extent, the same holds for mid-level clouds. In a future climate warmed by increasing greenhouse gases, most IPCC-assessed climate models simulate a decrease in low and mid-level cloud amount, which would increase the absorption of sunlight and so tend to increase the warming. The extent of this decrease is quite model-dependent, however.

There are also other ways that clouds may change in a warmer climate. Changes in wind patterns and storm tracks could affect the regional and seasonal patterns of cloudiness and precipitation. Some studies suggest that the signal of one such trend seen in climate models—a poleward migration of the clouds associated with mid-latitude storm tracks—is already detectable in the observational record. By shifting clouds into regions receiving less sunlight, this could also amplify global warming. More clouds may be made of liquid drops, which are small but numerous and reflect more sunlight back to space than a cloud composed of the same mass of larger ice crystals. Thin cirrus cloud, which exerts a net warming effect and is very hard for climate models to simulate, could change in ways not simulated by models although there is no evidence for this. Other processes may be regionally important, e.g., interactions between clouds and the surface can change over the ocean where sea ice melts, and over land where plant transpiration is reduced.

There is as yet no broadly accepted way to infer global cloud feedbacks from observations of long-term cloud trends or shorter-timescale variability. Nevertheless, all the models used for the current assessment (and the preceding two IPCC assessments) produce net cloud feedbacks that either enhance anthropogenic greenhouse warming or have little overall effect. Feedbacks are not “put into” the models, but emerge from the functioning of the clouds in the simulated atmosphere and their effects on the flows and transformations of energy in the climate system. The differences in the strengths of the cloud feedbacks produced by the various models largely account for the different sensitivities of the models to changes in greenhouse gas concentrations.

[START FAQ 7.2 HERE]

FAQ 7.2: How do Aerosols Affect Climate and Climate Change?

Atmospheric aerosols are composed of small liquid or solid particles suspended in the atmosphere, other than larger cloud and precipitation particles. They come from natural and anthropogenic sources, and can affect the climate in multiple and complex ways through their interactions with radiation and clouds. Overall, models and observations indicate that anthropogenic aerosols have exerted a cooling influence on the Earth since pre-industrial times, which has masked some of the global mean warming from greenhouse gases that would have occurred in their absence. The projected decrease in emissions of anthropogenic aerosols in the future, in response to air quality policies, would eventually unmask this warming.

Atmospheric aerosols have a typical lifetime of one day to two weeks in the troposphere, and about one year in the stratosphere. They vary greatly in size, chemical composition and shape. Some aerosols, such as dust and sea spray, are mostly or entirely of natural origin, while other aerosols, such as sulphates and smoke, come from both natural and anthropogenic sources.

Aerosols affect climate in many ways. First, they scatter and absorb sunlight, which modifies the Earth's radiative balance (see FAQ.7.2, Figure 1). Aerosol scattering generally makes the planet more reflective, and tends to cool the climate, while aerosol absorption has the opposite effect, and tends to warm the climate system. The balance between cooling and warming depends on aerosol properties and environmental conditions. Many observational studies have quantified local radiative effects from anthropogenic and natural aerosols, but determining their global impact requires satellite data and models. One of the remaining uncertainties comes from black carbon, an absorbing aerosol that not only is more difficult to measure than scattering aerosols, but also induces a complicated cloud response. Most studies agree, however, that the overall radiative effect from anthropogenic aerosols is to cool the planet.

[INSERT FAQ 7.2, FIGURE 1 HERE]

FAQ 7.2, Figure 1: Overview of interactions between aerosols and solar radiation and their impact on climate. The left panels show the instantaneous radiative effects of aerosols, while the right panels show their overall impact after the climate system has responded to their radiative effects.

Aerosols also serve as condensation and ice nucleation sites, on which cloud droplets and ice particles can form (see FAQ.7.2, Figure 2). When influenced by more aerosol particles, clouds of liquid water droplets

tend to have more, but smaller droplets, which causes these clouds to reflect more solar radiation. There are however many other pathways for aerosol-cloud interactions, particularly in ice—or mixed liquid and ice—clouds, where phase changes between liquid and ice water are sensitive to aerosol concentrations and properties. The initial view that an increase in aerosol concentration will also increase the amount of low clouds has been challenged because a number of counteracting processes come into play. Quantifying the overall impact of aerosols on cloud amounts and properties is understandably difficult. Available studies, based on climate models and satellite observations, generally indicate that the net effect of anthropogenic aerosols on clouds is to cool the climate system.

[INSERT FAQ 7.2, FIGURE 2 HERE]

FAQ 7.2, Figure 2: Overview of aerosol-cloud interactions and their impact on climate. Panels (a) and (b) represent a clean and a polluted low-level cloud, respectively.

Since aerosols are distributed unevenly in the atmosphere, they can heat and cool the climate system in patterns that can drive changes in the weather. These effects are complex, and hard to simulate with current models, but several studies suggest significant effects on precipitation in certain regions.

Because of their short lifetime, the abundance of aerosols—and their climate effects—have varied over time, in rough concert with anthropogenic emissions of aerosols and their precursors in the gas phase such as SO₂ and some volatile organic compounds. Since anthropogenic aerosol emissions have increased substantially over the industrial period, this has counteracted some of the warming that would otherwise have occurred from increased concentrations of well mixed greenhouse gases. Aerosols from large volcanic eruptions that enter the stratosphere, such as those of El Chichón and Pinatubo, have also caused cooling periods that typically last a year or two.

Over the last two decades, anthropogenic aerosol emissions have decreased in some developed countries, but increased in many developing countries. The impact of aerosols on the global-mean surface temperature over this particular period is therefore thought to be small. It is projected, however, that emissions of anthropogenic aerosols will ultimately decrease in response to air quality policies, which would suppress their cooling influence on the Earth's surface, thus leading to increased warming.

[START FAQ 7.3 HERE]

FAQ 7.3: Could Geoengineering Counteract Climate Change and What Side Effects Might Occur?

Geoengineering—also called climate engineering—is defined as a broad set of methods and technologies that aim to deliberately alter the climate system in order to alleviate impacts of climate change. Two distinct categories of geoengineering methods are usually considered: Solar Radiation Management (SRM, assessed in Chapter 7, Section 7.7) aims to offset the warming from anthropogenic greenhouse gases by making the planet more reflective while Carbon Dioxide Removal (CDR, assessed in Chapter 6, Section 6.5) aims at reducing the atmospheric CO₂ concentration. The two categories operate on different physical principles and on different timescales. Models suggest that if SRM methods were realisable they would be effective in countering increasing temperatures, and would be less, but still, effective in countering some other climate changes. SRM would not counter all effects of climate change, and all proposed geoengineering methods also carry risks and side effects. Additional consequences cannot yet be anticipated as the level of scientific understanding about both SRM and CDR is low. There are also many (political, ethical, and practical) issues involving geoengineering that are beyond the scope of this report.

Carbon Dioxide Removal (CDR) Methods

CDR methods aim at removing CO₂ from the atmosphere by deliberately modifying carbon cycle processes, or by industrial (e.g., chemical) approaches. The carbon withdrawn from the atmosphere would then be stored in land, ocean or in geological reservoirs. Some CDR methods rely on biological processes, such as large-scale afforestation/reforestation, carbon sequestration in soils through biochar, bioenergy with carbon capture and storage (BECCS) and ocean fertilization. Others would rely on geological processes, such as

accelerated weathering of silicate and carbonate rocks—on land or in the ocean (see FAQ.7.3, Figure 1). The CO₂ removed from the atmosphere would then be stored in organic form in land reservoirs, or in inorganic form in oceanic and geological reservoirs, where it would have to be stored for at least hundreds of years for CDR to be effective.

[INSERT FAQ 7.3, FIGURE 1 HERE]

FAQ 7.3, Figure 1: Overview of some proposed geoengineering methods as they have been suggested. Carbon Dioxide Removal methods (see Chapter 6, Section 6.5 for details): (A) nutrients are added to the ocean (ocean fertilization), which increases oceanic productivity in the surface ocean and transports a fraction of the resulting biogenic carbon downward, (B) alkalinity from solid minerals is added to the ocean, which causes more atmospheric CO₂ to dissolve in the ocean, (C) the weathering rate of silicate rocks is increased, and the dissolved carbonate minerals are transported to the ocean, (D) atmospheric CO₂ is captured chemically, and stored either underground or in the ocean, (E) biomass is burned at an electric power plant with carbon capture, and the captured CO₂ is stored either underground or in the ocean and (F) CO₂ is captured through afforestation and reforestation to be stored in land ecosystems. Solar Radiation Management methods (see Chapter 7, Section 7.7 for details): (G) reflectors are placed in space to reflect solar radiation, (H) aerosols are injected in the stratosphere, (I) marine clouds are seeded in order to be made more reflective, (J) microbubbles are produced at the ocean surface to make it more reflective, (K) more reflective crops are grown, and (L) roofs and other built structures are whitened.

CDR methods would reduce the radiative forcing of CO₂ inasmuch as they are effective at removing CO₂ from the atmosphere and keeping the removed carbon away from the atmosphere. Some methods would also reduce ocean acidification (see FAQ 3.2), but other methods involving oceanic storage might instead increase ocean acidification if the carbon is sequestered as dissolved CO₂. A major uncertainty related to the effectiveness of CDR methods is the storage capacity and the permanence of stored carbon. Permanent carbon removal and storage by CDR would decrease climate warming in the long term. However, non-permanent storage strategies would allow CO₂ to return back to the atmosphere where it would once again contribute to warming. An intentional removal of CO₂ by CDR methods will be partially offset by the response of the oceanic and terrestrial carbon reservoirs if the CO₂ atmospheric concentration is reduced. This is because some oceanic and terrestrial carbon reservoirs will outgas to the atmosphere the anthropogenic CO₂ that had previously been stored. To completely offset past anthropogenic CO₂ emissions, CDR techniques would therefore need to remove not just the CO₂ that has accumulated in the atmosphere since pre-industrial times, but also the anthropogenic carbon previously taken up by the terrestrial biosphere and the ocean.

Biological and most chemical weathering CDR methods cannot be scaled up indefinitely and are necessarily limited by various physical or environmental constraints such as competing demands for land. Assuming a maximum CDR sequestration rate of 200 PgC per century from a combination of CDR methods, it would take about one and half centuries to remove the CO₂ emitted in the last 50 years, making it difficult—even for a suite of additive CDR methods—to mitigate climate change rapidly. Direct air capture methods could in principle operate much more rapidly, but may be limited by large-scale implementation, including energy use and environmental constraints.

CDR could also have climatic and environmental side effects. For instance, enhanced vegetation productivity may increase emissions of N₂O, which is a more potent greenhouse gas than CO₂. A large-scale increase in vegetation coverage, for instance through afforestation or energy crops, could alter surface characteristics, such as surface reflectivity and turbulent fluxes. Some modelling studies have shown that afforestation in seasonally snow-covered boreal regions could in fact accelerate global warming, whereas afforestation in the tropics may be more effective at slowing global warming. Ocean-based CDR methods that rely on biological production (i.e., ocean fertilization) would have numerous side effects on ocean ecosystems, ocean acidity and may produce emissions of non-CO₂ greenhouse gases.

Solar Radiation Management (SRM) Methods

The globally-averaged surface temperature of the planet is strongly influenced by the amount of sunlight absorbed by the Earth's atmosphere and surface, which warms the planet, and by the existence of the greenhouse effect, the process by which greenhouse gases and clouds affect the way energy is eventually radiated back to space. An increase in the greenhouse effect leads to a surface temperature rise until a new equilibrium is found. If less incoming sunlight is absorbed because the planet has been made more reflective,

or if energy can be emitted to space more effectively because the greenhouse effect is reduced, the average global surface temperature will be reduced.

Suggested geoengineering methods that aim at managing the Earth's incoming and outgoing energy flows are based on this fundamental physical principle. Most of these methods propose to either reduce sunlight reaching the Earth or increase the reflectivity of the planet by making the atmosphere, clouds or the surface brighter (see FAQ 7.3, Figure 1). Another technique proposes to suppress high-level clouds called cirrus, as these clouds have a strong greenhouse effect. Basic physics tells us that if any of these methods change energy flows as expected, then the planet will cool. The picture is complicated, however, because of the many and complex physical processes which govern the interactions between the flow of energy, the atmospheric circulation, weather and the resulting climate.

While the globally-averaged surface temperature of the planet will respond to a change in the amount of sunlight reaching the surface or a change in the greenhouse effect, the temperature at any given location and time is influenced by many other factors and the amount of cooling from SRM will not in general equal the amount of warming caused by greenhouse gases. For example, SRM will only change heating rates during the daytime, but increasing greenhouse gases can change temperatures during both day and night. This inexact compensation can influence the diurnal cycle of surface temperature, even if the average surface temperature is unchanged. As another example, model calculations suggest that a uniform decrease in sunlight reaching the surface might offset global mean CO₂-induced warming, but some regions will cool less than others. Models suggest that if anthropogenic greenhouse warming were completely compensated by stratospheric aerosols, then polar regions would be left with a small residual warming, while tropical regions would become a little cooler than in pre-industrial times.

SRM could theoretically counteract anthropogenic climate change rapidly, cooling the Earth to pre-industrial levels within one or two decades. This is known from climate models but also from the climate records of large volcanic eruptions. The well-observed eruption of Mt Pinatubo in 1991 caused a temporary increase in stratospheric aerosols and a rapid decrease in surface temperature of about 0.5°C.

Climate consists of many factors besides surface temperature. Consequences for other climate features, such as rainfall, soil moisture, river flow, snowpack and sea ice, and ecosystems may also be important. Both models and theory show that compensating an increased greenhouse effect with SRM to stabilize surface temperature would somewhat lower the globally-averaged rainfall (see FAQ 7.3, Figure 2 for an idealised model result), and there also could be regional changes. Such imprecise compensation in regional and global climate patterns makes it improbable that solar radiation management will produce a future climate that is “just like” the one we experience today, or have experienced in the past. However, available climate models indicate that a geoengineered climate with SRM and high atmospheric CO₂ levels would be generally closer to 20th century climate than a future climate with elevated CO₂ concentrations and no SRM.

SRM techniques would probably have other side effects. For example, theory, observation and models suggest that stratospheric sulphate aerosols from volcanic eruptions and natural emissions deplete stratospheric ozone, especially while chlorine from CFC emissions resides in the atmosphere. Stratospheric aerosols introduced for SRM are expected to have the same effect. Ozone depletion would increase the amount of ultraviolet light reaching the surface damaging terrestrial and marine ecosystems. Stratospheric aerosols would also increase the ratio of direct to diffuse sunlight reaching the surface, which generally increases plant productivity. There has also been some concern that sulphate aerosol SRM would increase acid rain, but model studies suggest that acid rain is probably not a major concern since the rate of acid rain production from stratospheric aerosol SRM would be much smaller than values currently produced by pollution sources. SRM will also not address the ocean acidification associated with increasing atmospheric CO₂ concentrations and its impacts on marine ecosystems.

Without conventional mitigation efforts or potential CDR methods, high CO₂ concentrations from anthropogenic emissions will persist in the atmosphere for as long as a thousand years, and SRM would have to be maintained as long as CO₂ concentrations were high. Stopping SRM while CO₂ concentrations are still high would lead to a very rapid warming over one or two decades (see FAQ 7.3, Figure 2), severely stressing ecosystem and human adaptation.

[INSERT FAQ 7.3, FIGURE 2 HERE]

FAQ 7.3, Figure 2: Change in globally-averaged (a) surface temperature (°C) and (b) precipitation (%) in two idealised experiments. Solid lines are for simulations using Solar Radiation Management (SRM) to balance a 1% yr⁻¹ increase in CO₂ concentration until year 50, after which SRM is stopped. Dashed lines are for simulations with a 1% yr⁻¹ increase in CO₂ concentration and no SRM. The pink and blue envelopes show the 25th to 75th percentiles from eight different models.

If SRM were used in order to avoid some consequences of increasing CO₂ concentrations, the risks, side effects and shortcomings would clearly increase as the scale of SRM increase. Approaches have been proposed to use a time-limited amount of SRM along with aggressive strategies for reducing CO₂ concentrations to help avoid transitions across climate thresholds or tipping points that would be unavoidable otherwise; assessment of such approaches would require a very careful risk benefit analysis that goes much beyond this report.

1 **Tables**

2

3 **Table 7.1: (a)** Global and regional anthropogenic emissions of aerosols and aerosol precursors. The average, minimum and maximum values are from a range of available
 4 inventories (Cao et al., 2006; European Commission et al., 2009; Sofiev et al., 2009; Lu et al., 2010; Granier et al., 2011 and references therein; Lu et al., 2011; Knorr et al., 2012). It
 5 should be noted that the min-max range is not a measure of uncertainties which are often difficult to quantify. Units are Tg yr⁻¹ and TgS yr⁻¹ for SO₂. NMVOCs stand for non-
 6 methane volatile organic compounds. **(b)** Global natural emissions of aerosols and aerosol precursors. Dust and sea-spray estimates span the range in the historical CMIP5
 7 simulations. The ranges for monoterpenes and isoprene are from Arneeth et al. (2008). There are other BVOCs such as sesquiterpenes, alcohols and aldehydes which are not listed
 8 here. Marine POA and terrestrial PBAP emission ranges are from Gantt et al. (2011) and Burrows et al. (2009), respectively. Note that emission fluxes from mineral dust, sea spray
 9 and terrestrial PBAP are highly sensitive to the cut-off radius. The conversion rate of BVOCs to SOA is also indicated using the range from Spracklen et al. (2011) and a lower
 10 bound from Kanakidou et al. (2005). Units are Tg yr⁻¹ except for BVOCs (monoterpenes and isoprene) in TgC yr⁻¹ and dimethylsulphide (DMS) in TgS yr⁻¹.

Source	Natural Global	
	Min	Max
Sea spray	1400	6800
including marine POA	2	20
Mineral dust	1000	4000
Terrestrial PBAP	50	1000
including spores		28
Dimethylsulphide (DMS)	10	40
Monoterpenes	30	120
Isoprene	410	600
SOA production from all BVOCs	20	380

Table 7.2: Key aerosol properties of the main aerosol species in the troposphere. Terrestrial primary biological aerosol particles (PBAP), brown carbon and marine primary organic aerosols (POA) are particular types of organic aerosols (OA) but are treated here as separate components because of their specific properties. The estimated lifetimes in the troposphere are based on the AeroCom models, except for terrestrial PBAP which are treated by analogy to other coarse mode aerosol types.

Aerosol Species	Size Distribution	Main Sources	Main Sinks	Tropospheric Lifetime	Key Climate Relevant Properties
Sulphate	Primary: Aitken, accumulation and coarse modes Secondary: Nucleation, Aitken, and accumulation modes	Primary: marine and volcanic emissions. Secondary: oxidation of SO ₂ and other S gases from natural and anthropogenic sources	Wet deposition Dry deposition	~ 1 week	Light scattering. Very hygroscopic. Enhances absorption when deposited as a coating on black carbon. CCN active.
Nitrate	Accumulation and coarse modes	Oxidation of NO _x	Wet deposition Dry deposition	~ 1 week	Light scattering. Hygroscopic. CCN active.
Black carbon	Freshly emitted: <100 nm Aged: accumulation mode	Combustion of fossil fuels, biofuels and biomass	Wet deposition Dry deposition	1 week to 10 days	Large mass absorption efficiency in the shortwave. CCN active when coated. May be IN active.
Organic aerosol	POA: Aitken and accumulation modes. SOA: nucleation, Aitken and mostly accumulation modes. Aged OA: accumulation mode	Combustion of fossil fuel, biofuel and biomass. Continental and marine ecosystems. Some anthropogenic and biogenic non-combustion sources	Wet deposition Dry deposition	~ 1 week	Light scattering. Enhances absorption when deposited as a coating on black carbon. CCN active (depending on aging time and size).
... of which brown carbon	Freshly emitted: 100–400 nm Aged: accumulation mode	Combustion of biofuels and biomass. Natural humic-like substances from the biosphere	Wet deposition Dry deposition	~ 1 week	Medium mass absorption efficiency in the UV and visible. Light scattering.
... of which terrestrial PBAP	Mostly coarse mode	Terrestrial ecosystems	Sedimentation Wet deposition Dry deposition	1 day to 1 week depending on size	May be IN active. May form giant CCN
Mineral dust	Coarse and super-coarse modes, with a small accumulation mode	Wind erosion, soil resuspension. Some agricultural practices and industrial activities (cement)	Sedimentation Dry deposition Wet deposition	1 day to 1 week depending on size	IN active. Light scattering and absorption. Greenhouse effect.
Sea spray	Coarse and accumulation modes	Breaking of air bubbles induced e.g., by wave breaking. Wind erosion.	Sedimentation Wet deposition Dry deposition	1 day to 1 week depending on size	Light scattering. Very hygroscopic. CCN active. Can include primary organic compounds in smaller size range
... of which marine POA	Preferentially Aitken and accumulation modes	Emitted with sea spray in biologically active oceanic regions	Sedimentation Wet deposition Dry deposition	~ 1 week	CCN active.

1 **Table 7.5:** Estimates of aerosol 1850–2000 ERF (in $W m^{-2}$) in some of the CMIP5 and ACCMIP models. The ERF are
 2 estimated from fixed-SST experiments using atmosphere-only version of the models listed. Different models include
 3 different aerosol effects. The CMIP5 and ACCMIP protocols differ, hence differences in forcing estimates for one
 4 model.

Modelling Group	Model Name	ERFari+aci from All Anthropogenic Aerosols	ERFari+aci from Sulphate Aerosols Only
CCCma	CanESM2	−0.87	−0.90
CSIRO-QCCCE	CSIRO-Mk3-6-0 ^b	−1.41	−1.10
GFDL	GFDL-AM3	−1.60 (−1.44 ^a)	−1.62
GISS	GISS-E2-R ^b	−1.10 ^a	−0.61
GISS	GISS-E2-R-TOMAS ^b	−0.76 ^a	
IPSL	IPSL-CM5A-LR	−0.72	−0.71
LASG-IAP	FGOALS-s2 ^c	−0.38	−0.34
MIROC	MIROC-CHEM ^b	−1.24 ^a	
MIROC	MIROC5	−1.28	−1.05
MOHC	HadGEM2-A	−1.22	−1.16
MRI	MRI-CGM3	−1.10	−0.48
NCAR	NCAR-CAM5.1 ^b	−1.44 ^a	
NCC	NorESM1-M	−0.99	
Ensemble mean		−1.08	
Standard deviation		+0.32	

6 Notes:

7 (a) From ACCMIP (Shindell et al., 2013).

8 (b) These models include the BC on snow effect.

9 (c) This model does not include the ERF from aerosol-cloud interactions.

Figures

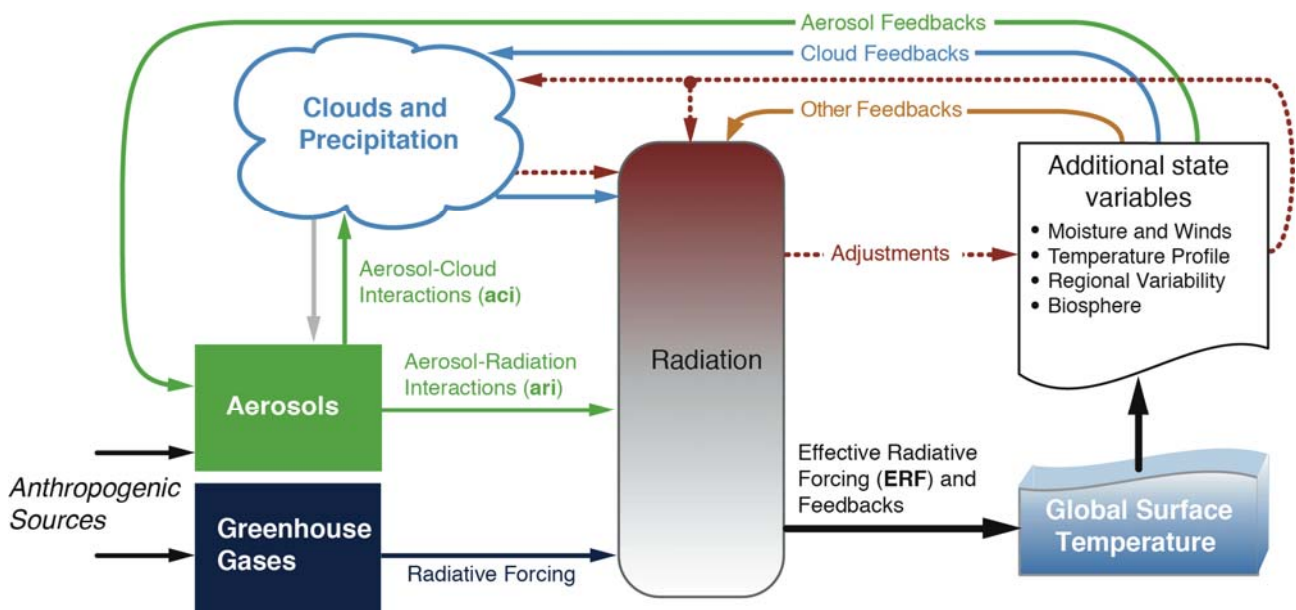

Figure 7.1: Overview of forcing and feedback pathways involving greenhouse gases, aerosols and clouds. Forcing agents are in the green and dark blue boxes, with forcing mechanisms indicated by the straight green and dark blue arrows. The forcing is modified by rapid adjustments whose pathways are independent of changes in the globally averaged surface temperature and are denoted by brown dashed arrows. Feedback loops, which are ultimately rooted in changes ensuing from changes in the surface temperature, are represented by curving arrows (blue denotes cloud feedbacks; green denotes aerosol feedbacks; and orange denotes other feedback loops such as those involving the lapse rate, water vapour and surface albedo). The final temperature response depends on the effective radiative forcing (ERF) that is felt by the system, i.e., after accounting for rapid adjustments, and the feedbacks.

Figure 7.2: RF and ERF estimates derived by two methods, for the example of $4 \times \text{CO}_2$ experiments in one climate model. N is the net energy imbalance at the top of atmosphere and ΔT the global-mean surface temperature change. The fixed sea-surface temperature ERF estimate is from an atmosphere-land model averaged over 30 years. The regression estimate is from 150 years of a coupled model simulation after an instantaneous quadrupling of CO_2 , with the N from individual years in this regression shown as black diamonds. The stratospherically-adjusted RF is the tropopause energy imbalance from otherwise identical radiation calculations at $1 \times$ and $4 \times \text{CO}_2$ concentrations. Figure follows Andrews et al. (2012). See also Figure 8.1.

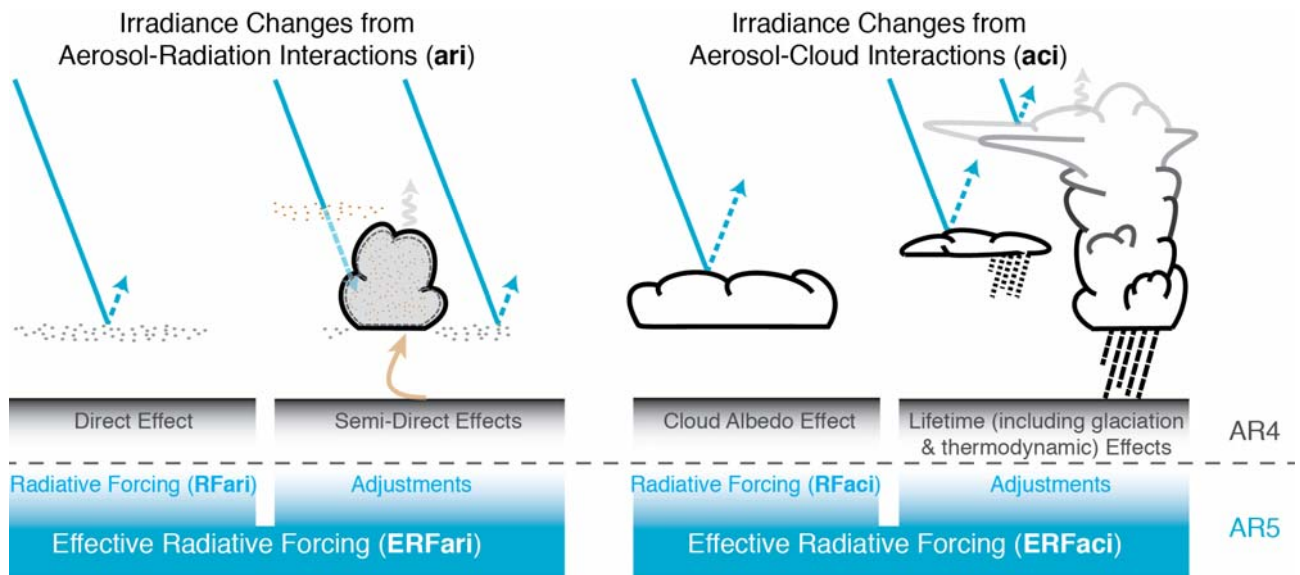

Figure 7.3: Schematic of the new terminology used in this assessment report (AR5) for aerosol-radiation and aerosol-cloud interactions and how they relate to the terminology used in AR4. The blue arrows depict solar radiation, the grey arrows terrestrial radiation, and the brown arrow symbolises the importance of couplings between the surface and the cloud layer for rapid adjustments. See text for further details.

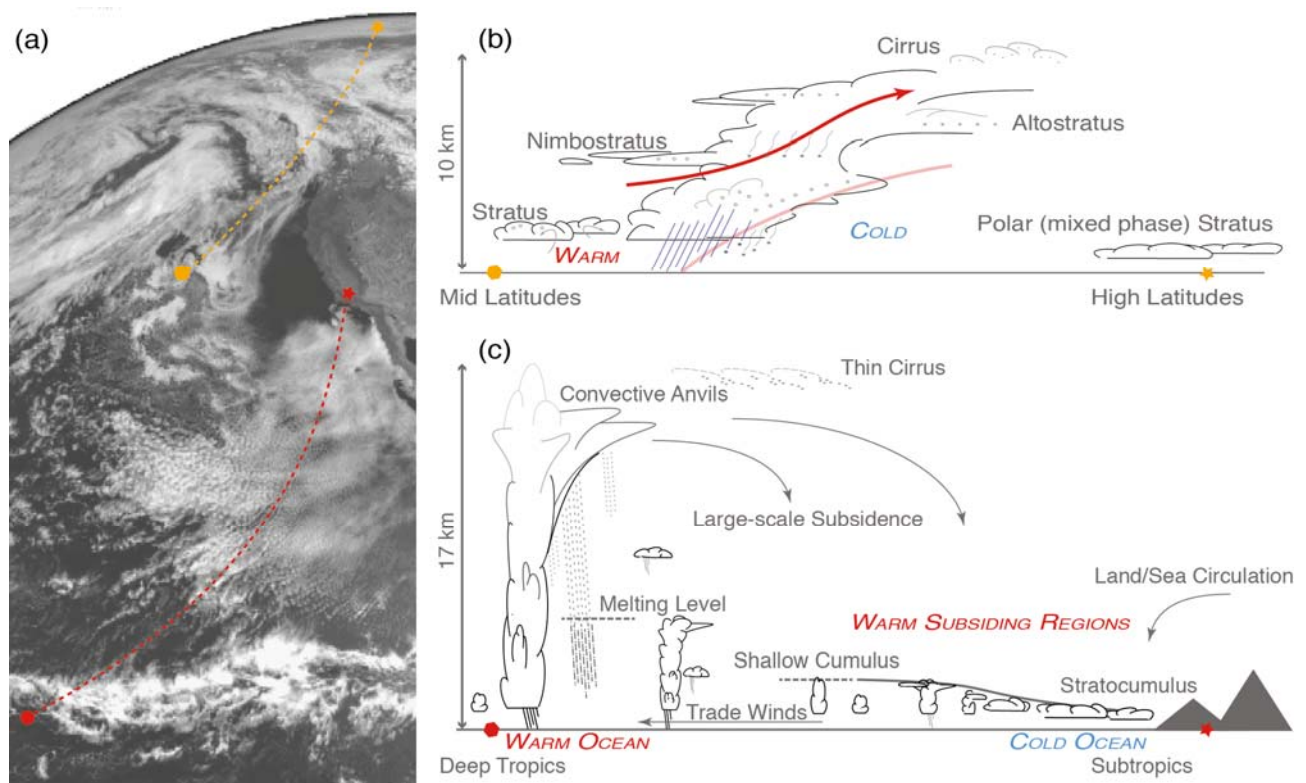

Figure 7.4: Diverse cloud regimes reflect diverse meteorology. (a) A visible-wavelength geostationary satellite image shows (from top to bottom) expanses and long arcs of cloud associated with extratropical cyclones, subtropical coastal stratocumulus near Baja California breaking up into shallow cumulus clouds in the central Pacific, and mesoscale convective systems outlining the Pacific intertropical convergence zone (ITCZ). (b) A schematic section along the dashed line from the orange star to the orange circle in panel (a), through a typical warm front of an extratropical cyclone. It shows (from right to left) multiple layers of upper-tropospheric ice (cirrus) and mid-tropospheric water (altostratus) cloud in the upper-tropospheric outflow from the frontal zone, an extensive region of nimbostratus associated with frontal uplift and turbulence-driven boundary layer cloud in the warm sector. (c) A schematic section along the dashed line from the red star to the red circle in panel (a), along the low-level trade wind flow from a subtropical west coast of a continent to the ITCZ. It shows (from right to left) typical low-latitude cloud mixtures, shallow stratocumulus trapped under a strong subsidence inversion above the cool waters of the oceanic upwelling zone near the coast, and shallow cumulus over warmer waters further offshore transitioning to precipitating cumulonimbus cloud systems with extensive cirrus anvils associated with rising air motions in the ITCZ.

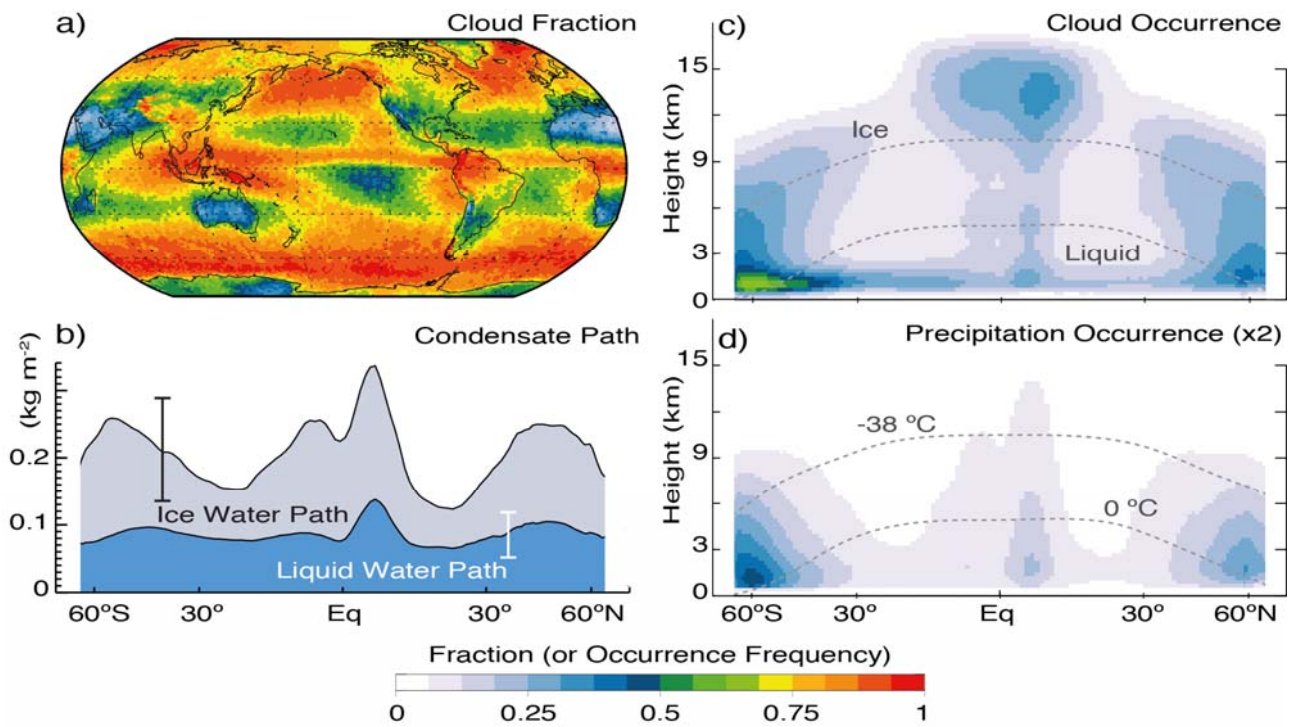

Figure 7.5: (a) Annual mean cloud fractional occurrence (CloudSat/CALIPSO 2B-GEOPROF-LIDAR dataset for 2006–2011; Mace et al., 2009); (b) annual zonal mean liquid water path (blue shading, microwave radiometer dataset for 1988–2005 from O’Dell et al. (2008)) and total water path (ice path shown with grey shading, from CloudSat 2C-ICE dataset for 2006–2011 from Deng et al. (2010) over oceans). The 90% uncertainty ranges, assessed to be approximately 60–140% of the mean for the liquid and total water paths, are schematically indicated by the error bars. (c-d) latitude-height sections of annual zonal mean cloud (including precipitation falling from cloud) occurrence and precipitation (attenuation-corrected radar reflectivity >0 dBZ) occurrence; the latter has been doubled to make use of a common colour scale (2B-GEOPROF-LIDAR dataset). The dashed curves show the annual-mean 0°C and -38°C isotherms.

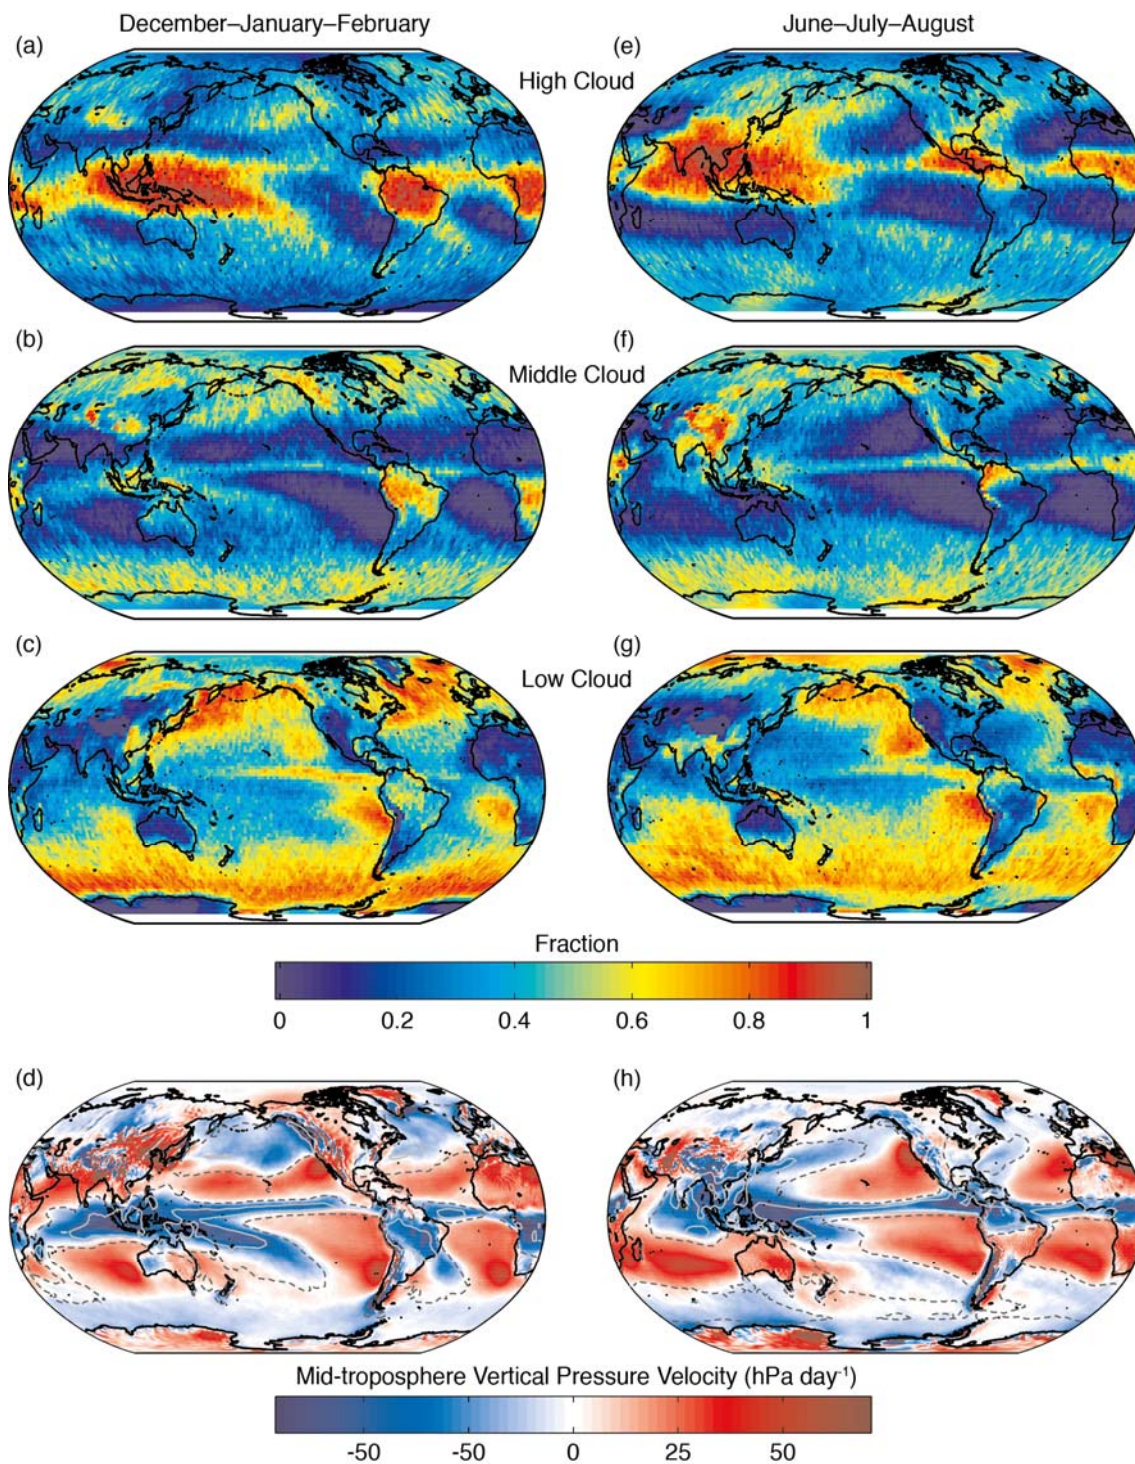

Figure 7.6: (a-d) December-January-February mean high, middle and low cloud cover from CloudSat/CALIPSO 2B-GEOPROF R04 and 2B-GEOPROF-LIDAR P1.R04 datasets for 2006–2011 (Mace et al., 2009), 500 hPa vertical pressure velocity (colours, from ERA-Interim for 1979–2010; Dee et al., 2011), and GPCP (Global Precipitation Climatology Project) version 2.2 precipitation rate (1981–2010, grey contours at 3 mm day⁻¹ in dash and 7 mm day⁻¹ in solid); (e-h) same as (a-d), except for June-July-August. For low clouds, the CALIPSO-only GOCCP dataset for 2007–2010 (Chepfer et al., 2010) is used at locations where it indicates a larger fractional cloud cover, because the GEOPROF dataset removes some clouds with tops at altitudes below 750 m. Low cloud amounts are probably underrepresented in regions of high cloud (Chepfer et al., 2008), although not as severely as with earlier satellite instruments.

Figure 7.7: Distribution of annual-mean top of atmosphere (a) shortwave, (b) longwave, (c) net cloud radiative effects averaged over the period 2001–2011 from the CERES-EBAF -TOA-Ed2.6r dataset (Loeb et al., 2009) and (d) precipitation rate (1981–2000 average from the GPCP version 2.2 dataset; Adler et al., 2003).

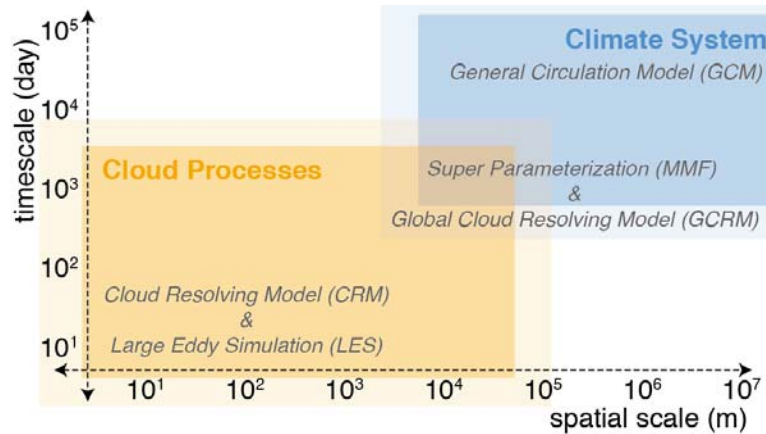

Figure 7.8: Model and simulation strategy for representing the climate system and climate processes at different space and time scales. Also shown are the ranges of space and time scales usually associated with cloud processes (orange, lower left) and the climate system (blue, upper right). Classes of models are usually defined based on the range of spatial scales they represent, which in the figure is roughly spanned by the text for each model class. The temporal scales simulated by a particular type of model vary more widely. For instance, climate models are often run for a few time steps for diagnostic studies, or can simulate millennia. Hence the figure indicates the typical timescales for which a given model is used. Computational power prevents one model from covering all time and space scales. Since the AR4 the development of global cloud resolving models (GCRM), and hybrid approaches such as GCMs using the "super-parameterization" approach (sometimes called the multiscale modelling framework or MMF), have helped fill the gap between climate system and cloud process models.

Figure 7.9: Clear-sky feedback parameters predicted by CMIP3 GCMs, with boxes showing interquartile range and whiskers showing extreme values. At left is shown the total radiative response including the Planck response. In the darker shaded region is shown the traditional breakdown of this into a Planck response and individual feedbacks from water vapour and lapse rate. In the lighter-shaded region at right are the equivalent three parameters calculated in an alternative, relative humidity-based framework. In this framework all three components are both weaker and more consistent among the models. Data are from Held and Shell (2012).

Figure 7.10: Cloud feedback parameters as predicted by GCMs for responses to CO_2 increase including rapid adjustments. Total feedback shown at left, with centre light-shaded section showing components attributable to clouds in specific height ranges (see Section 7.2.1.1), and right dark-shaded panel those attributable to specific cloud property changes where available. Type attribution reported for CMIP3 does not conform exactly to the definition used in CFMIP but is shown for comparison, with their “mixed” category assigned to middle cloud. CFMIP data (original and CFMIP2) are from Zelinka et al. (2012a, 2012b; 2013); CMIP3 from Soden and Vecchi (2011); and CMIP5 from Tomassini et al. (2013).

Figure 7.11: Robust cloud responses to greenhouse warming (those simulated by most models and possessing some kind of independent support or understanding). The tropopause and melting level are shown by the thick solid and thin grey dashed lines, respectively. Changes anticipated in a warmer climate are shown by arrows, with red colour indicating those making a robust positive feedback contribution and grey indicating those where the feedback contribution is small and/or highly uncertain. No robust mechanisms contribute negative feedback. Changes include rising high cloud tops and melting level, and increased polar cloud cover and/or optical thickness (*high confidence*); broadening of the Hadley Cell and/or poleward migration of storm tracks, and narrowing of rainfall zones such as the ITCZ (*medium confidence*); and reduced low-cloud amount and/or optical thickness (*low confidence*). Confidence assessments are based on degree of GCM consensus, strength of independent lines of evidence from observations or process models, and degree of basic understanding.

Figure 7.12: Overview of atmospheric aerosol and environmental variables and processes influencing aerosol-radiation and aerosol-cloud interactions. Gas-phase variables and processes are highlighted in red while particulate-phase variables and processes appear in green. Although this figure shows a linear chain of processes from aerosols to forcings (ERFari and ERFaci), it is increasingly recognised that aerosols and clouds form a coupled system with two-way interactions (see Figure 7.16).

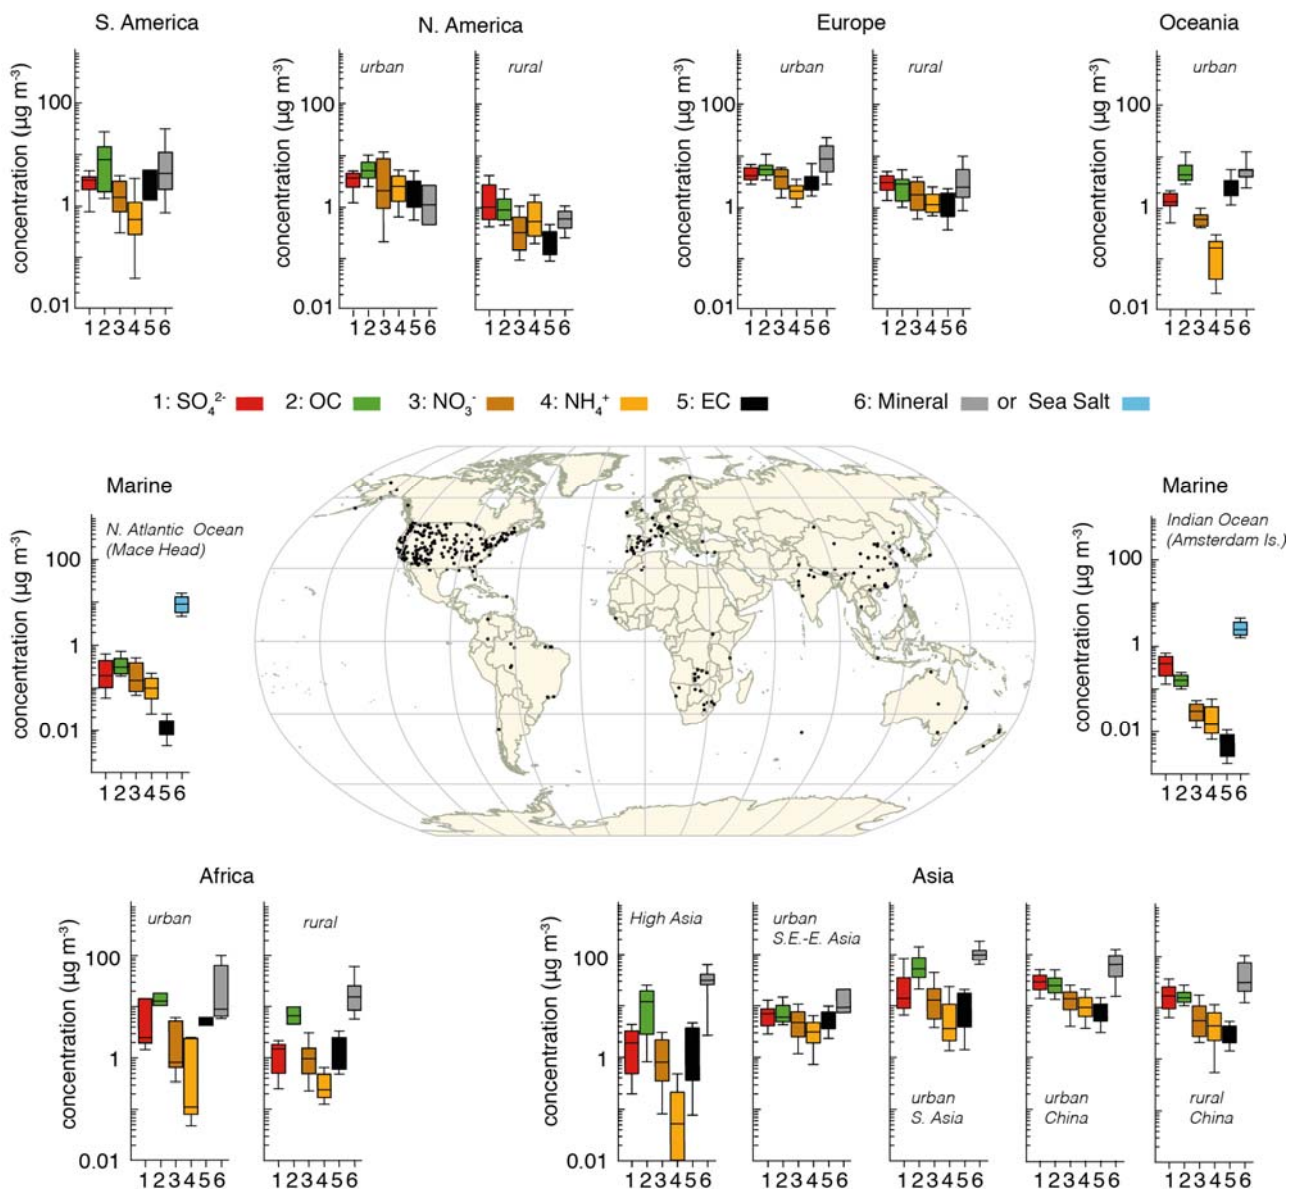

Figure 7.13: Bar chart plots summarizing the mass concentration ($\mu\text{g m}^{-3}$) of seven major aerosol components for particles with diameter smaller than $10 \mu\text{m}$, from various rural and urban sites (dots on the central world map) in six continental areas of the world with at least an entire year of data, and two marine sites. The density of the sites is a qualitative measure of the spatial representativeness of the values for each area. The North Atlantic and Indian Oceans panels correspond to measurements from single sites (Mace Head and Amsterdam Island, respectively) that are not necessarily representative. The relative abundances of different aerosol compounds are considered to reflect the relative importance of emissions of these compounds or their precursors, either anthropogenic or natural, in the different areas. For consistency the mass of OA has been converted to that of organic carbon (OC), according to a conversion factor (typically 1.4–1.6), as provided in each study. For each area, the panels represent the median, the 25th to 75th percentiles (box), and the 10th to 90th percentiles (whiskers) for each aerosol component. These include: 1) **urban United States** (Chow et al., 1993; Kim et al., 2000; Ito et al., 2004; Malm and Schichtel, 2004; Sawant et al., 2004; Liu et al., 2005); **rural United States** (Chow et al., 1993; Malm et al., 1994; Malm and Schichtel, 2004; Liu et al., 2005); 2) **marine northern Atlantic Ocean** (Rinaldi et al., 2009; Ovadnevaite et al., 2011); 3) **urban Europe** (Lenschow et al., 2001; Querol et al., 2001; Roosli et al., 2001; Rodriguez et al., 2002; Putaud et al., 2004; Querol et al., 2004; Rodriguez et al., 2004; Hueglin et al., 2005; Lonati et al., 2005; Querol et al., 2006; Viana et al., 2006; Viana et al., 2007; Perez et al., 2008; Querol et al., 2008; Yin and Harrison, 2008; Lodhi et al., 2009); **rural Europe** (Gullu et al., 2000; Querol et al., 2001; Rodriguez et al., 2002; Putaud et al., 2004; Puxbaum et al., 2004; Querol et al., 2004; Rodriguez et al., 2004; Hueglin et al., 2005; Kocak et al., 2007; Salvador et al., 2007; Yttri, 2007; Viana et al., 2008; Yin and Harrison, 2008; Querol et al., 2009; Theodosi et al., 2010); 4) **high Asia**, with altitude larger than 1680 m (Shresth et al., 2000; Zhang et al., 2001; Carrico et al., 2003; Rastogi and Sarin, 2005; Ming et al., 2007a; Rengarajan et al., 2007; Qu et al., 2008; Zhang et al., 2008; Decesari et al., 2010; Ram et al., 2010; Zhang et al., 2012b); **urban South Asia** (Rastogi and Sarin,

2005; Kumar et al., 2007; Lodhi et al., 2009; Chakraborty and Gupta, 2010; Khare and Baruah, 2010; Raman et al., 2010; Safai et al., 2010; Stone et al., 2010; Sahu et al., 2011); **urban China** (Cheng et al., 2000; Yao et al., 2002; Zhang et al., 2002; Wang et al., 2003; Ye et al., 2003; Xiao and Liu, 2004; Wang et al., 2005b; Hagler et al., 2006; Oanh et al., 2006; Wang et al., 2006; Zhang et al., 2011; Zhang et al., 2012b); **rural China** (Hu et al., 2002; Zhang et al., 2002; Hagler et al., 2006; Zhang et al., 2012b); **South-East and East Asia** (Lee and Kang, 2001; Oanh et al., 2006; Kim et al., 2007; Han et al., 2008; Khan et al., 2010); **5) South America** (Artaxo et al., 1998; Morales et al., 1998; Artaxo et al., 2002; Celis et al., 2004; Bourotte et al., 2007; Fuzzi et al., 2007; Mariani and Mello, 2007; de Souza et al., 2010; Martin et al., 2010a; Gioda et al., 2011); **6) urban Africa** (Favez et al., 2008; Mkoma, 2008; Mkoma et al., 2009a); **rural Africa** (Maenhaut et al., 1996; Nyanganyura et al., 2007; Mkoma, 2008; Mkoma et al., 2009b; Mkoma et al., 2009a; Weinstein et al., 2010); **7) marine Indian Ocean** (Sciare et al., 2009; Rinaldi et al., 2011); **8) urban Oceania** (Chan et al., 1997; Maenhaut et al., 2000; Wang and Shooter, 2001; Wang et al., 2005a; Radhi et al., 2010).

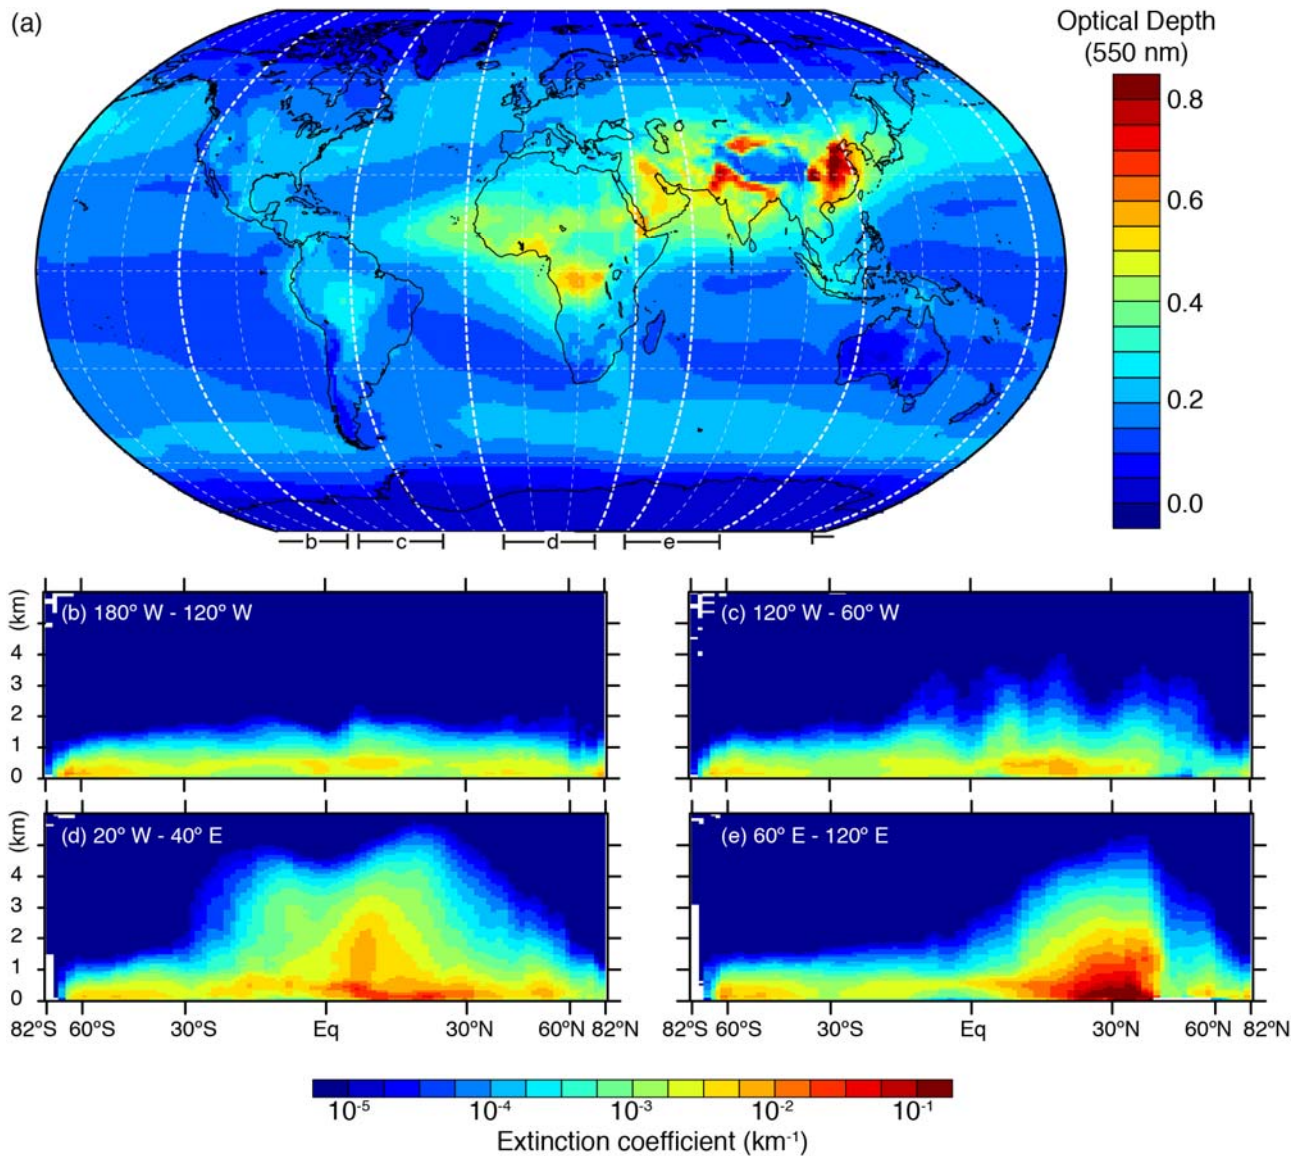

Figure 7.14: a) Spatial distribution of the 550 nm aerosol optical depth (AOD, unitless) from the ECMWF Integrated Forecast System model with assimilation of MODIS aerosol optical depth (Benedetti et al., 2009; Morcrette et al., 2009) averaged over the period 2003–2010; b) to e) latitudinal vertical cross-sections of the 532 nm aerosol extinction coefficient (km^{-1}) for four longitudinal bands (180°W to 120°W, 120°W to 60°W, 20°W to 40°E, and 60°E to 120°E, respectively) from the CALIOP instrument for the year 2010 (nighttime all-sky data, version 3; Winker et al., 2013).

Figure 7.15: Comparison of vertical profiles of BC mass mixing ratios (ng kg^{-1}) as measured by airborne SP2 instruments during the HIPPO1 (Schwarz et al., 2010) and A-FORCE (Oshima et al., 2012) campaigns and simulated by a range of AeroCom II models (Schulz et al., 2009). The black solid lines are averages of a number of vertical profiles in each latitude zone with the horizontal lines representing the standard deviation of the measurements at particular height ranges. Each HIPPO1 profile is the average of about 20 vertical profiles over the mid-Pacific in a two week period in January 2009. The A-FORCE profile is the average of 120 vertical profiles measured over the East China Sea and Yellow Sea downstream of the Asian continent in March-April 2009. The model values (colour lines) are monthly averages corresponding to the measurement location and month, using meteorology and emissions corresponding to the year 2006.

Figure 7.16: Schematic depicting the myriad aerosol-cloud-precipitation related processes occurring within a typical GCM grid box. The schematic conveys the importance of considering aerosol-cloud-precipitation processes as part of an interactive system encompassing a large range of spatiotemporal scales. Cloud types include low-level stratocumulus and cumulus where research focuses on aerosol activation, mixing between cloudy and environmental air, droplet coalescence and scavenging which results in cloud processing of aerosol particles, and new particle production near clouds; cirrus clouds where a key issue is ice nucleation through homogeneous and heterogeneous freezing; and deep convective clouds where some of the key questions relate to aerosol influences on liquid, ice, and liquid-ice pathways for precipitation formation, cold pool formation, and scavenging. These processes influence the shortwave and longwave cloud radiative effect and hence climate. Primary processes that affect aerosol-cloud interactions are labeled in orange while secondary processes that result from and influence aerosol-cloud interactions are in grey.

Figure 7.17: Annual zonal mean top-of-atmosphere RFar (in W m^{-2}) due to all anthropogenic aerosols from the different AeroCom II models. No adjustment for missing species in certain models has been applied. The multi-model mean and 5th to 95th percentile range from AeroCom II models (Myhre et al., 2013) are shown with a black solid line and grey envelope. The estimates from Bellouin et al. (2013) and Su et al. (2013) are shown with dotted lines. The forcings are for the 1850 to 2000 period. See supplementary material for a figure with labelled individual AeroCom II model estimates.

Figure 7.18: Annual mean top-of-atmosphere RFarI (in $W m^{-2}$) due to different anthropogenic aerosol types, for the 1750 to 2010 period. Hatched whisker boxes show median (line), 5th to 95th percentile ranges (box) and min/max values (whiskers) from AeroCom II models (Myhre et al., 2013) corrected for the 1750–2010 period. Solid coloured boxes show the AR5 best estimates and 90% uncertainty ranges. BC FF is for black carbon from fossil fuel and biofuel, POA FF is for primary organic aerosol from fossil fuel and biofuel, BB is for biomass burning aerosols, and SOA is for secondary organic aerosols.

Figure 7.19: (a) GCM studies and studies involving satellite estimates of RFAri (red), ERFAci (green) and ERFAri+aci (blue in grey-shaded box). Each symbol represents the best estimate per model and paper (see Table 7.3 for references). The values for RFAri are obtained from the CMIP5 models. ERFAci and ERFAri+aci studies from GCMs on liquid phase stratiform clouds are divided into those published prior to and included in AR4 (labeled AR4, triangles up), studies published after AR4 (labeled AR5, triangles down) and from the CMIP5/ACCMIP models (filled circles). GCM estimates that include adjustments beyond aerosol-cloud interactions in liquid phase stratiform clouds are divided into those including aerosol-cloud interactions in mixed-phase clouds (stars) and those including aerosol-cloud interactions in convective clouds (diamonds). Studies that take satellite data into account are labeled as "satellites". Studies highlighted in black are considered for our expert judgement of ERFAri+aci. **(b)** Whisker boxes from GCM studies and studies involving satellite data of RFAri, ERFAci and ERFAri+aci. They are grouped into RFAri from CMIP5/ACCMIP GCMs (labeled CMIP5 in red), ERFAci from GCMs (labeled AR4, AR5 in green), all estimates of ERFAri+aci shown in the upper panel (labeled "All" in blue), ERFAri+aci from GCMs highlighted in the upper panel (labeled "highlighted GCMs" in blue), ERFAri+aci from satellites highlighted in the upper panel (labeled "Highlighted Satellites" in blue), and our expert judgement based on estimates of ERFAri+aci from these GCM and satellite studies (labeled "Expert Judgement" in blue). Displayed are the averages (cross sign), median values (middle line), 17th and 83th percentiles (*likely* range shown as box boundaries) and 5th and 95th percentiles (whiskers). References for the individual estimates are provided in Table 7.3. Table 7.4 includes the values of the GCM and satellite studies considered for the expert judgement of ERFAri+aci that are highlighted in black.

Figure 7.20: Illustration of the response of the large-scale atmospheric overturning to warming (adapted from Bony et al., 2013). The overturning intensity is shown on the y -axis and is measured by the difference between the mean motion in upward moving air and the mean motion in downward moving air. The warming is shown on the x -axis and is measured by the change in globally-averaged surface temperature, ΔT_s , after an abrupt quadrupling of atmospheric CO₂. The grey region delineates responses for which ΔT_s is zero by definition. Nearly one half of the final reduction in the intensity of the overturning is evident before any warming is felt, and can be associated with a rapid adjustment of the hydrological cycle to changes in the atmospheric cooling rate accompanying a change in CO₂. With warming the circulation intensity is further reduced. The rapid adjustment, as measured by the change in circulation intensity for zero warming, is different over land and ocean. Over land the increase in CO₂ initially causes an intensification of the circulation. The result is robust in the sense that it is apparent in all of the 15 CMIP5 models analysed, irrespective of the details of their configuration.

Figure 7.21: Estimate (5–95% range) of the increase in precipitation amount per °C of global-mean surface temperature change. At left (blue) are climate model predictions of changes in time-averaged global precipitation; at centre and right (orange) are predictions or estimates of the typical or average increase in local 99.9th percentile extremes, over 24 hours (centre) and over one hour or less (right). Data are adapted from (A) GCM studies (Allen and Ingram, 2002; and Lambert and Webb, 2008, for time-average; O’Gorman and Schneider, 2009 for extremes), (B) long-term trends at many sites globally (Westra et al., 2013), (C) GCMs constrained by present-day observations of extremes (O’Gorman, 2012), (D) LES and CRM studies of radiative convective equilibrium (Muller et al., 2011; Romps, 2011).

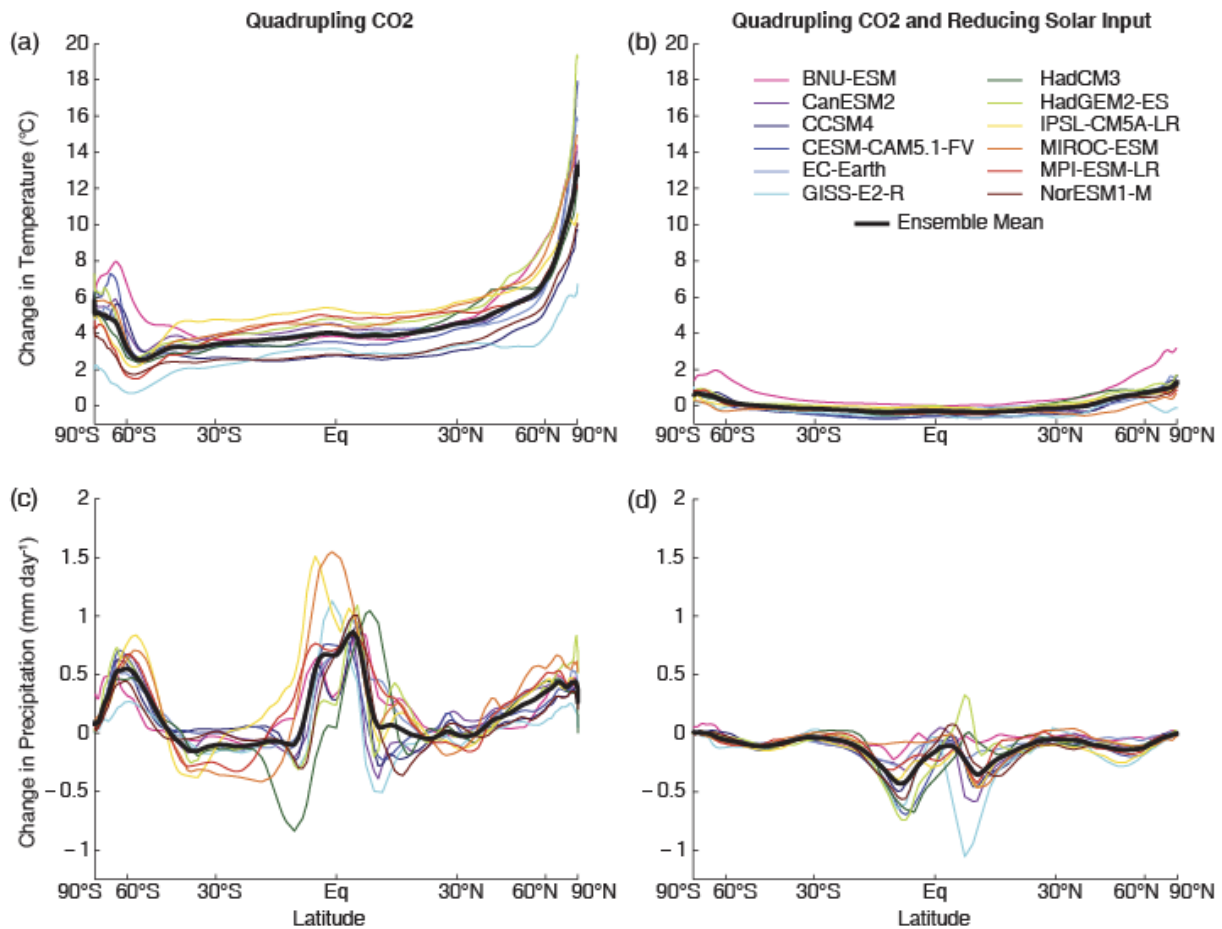

Figure 7.22: Zonally- and annually-averaged change in surface air temperature (°C) for (a) an abrupt $4 \times \text{CO}_2$ experiment and (b) an experiment where the $4 \times \text{CO}_2$ forcing is balanced by a reduction in the total solar irradiance to produce a global top-of-atmosphere flux imbalance of less than $\pm 0.1 \text{ W m}^{-2}$ during the first 10 years of the simulation (GeoMIP G1 experiment; Kravitz et al., 2011). (c) and (d) Same as (a) and (b) but for the change in precipitation (mm day^{-1}). The multi-model ensemble mean is shown with a thick black solid line. All changes are relative to the pre-industrial control experiment and averaged over years 11–50. The figure extends the results from Schmidt et al. (2012b) and shows the results from an ensemble of 12 coupled ocean-atmosphere general circulation models.

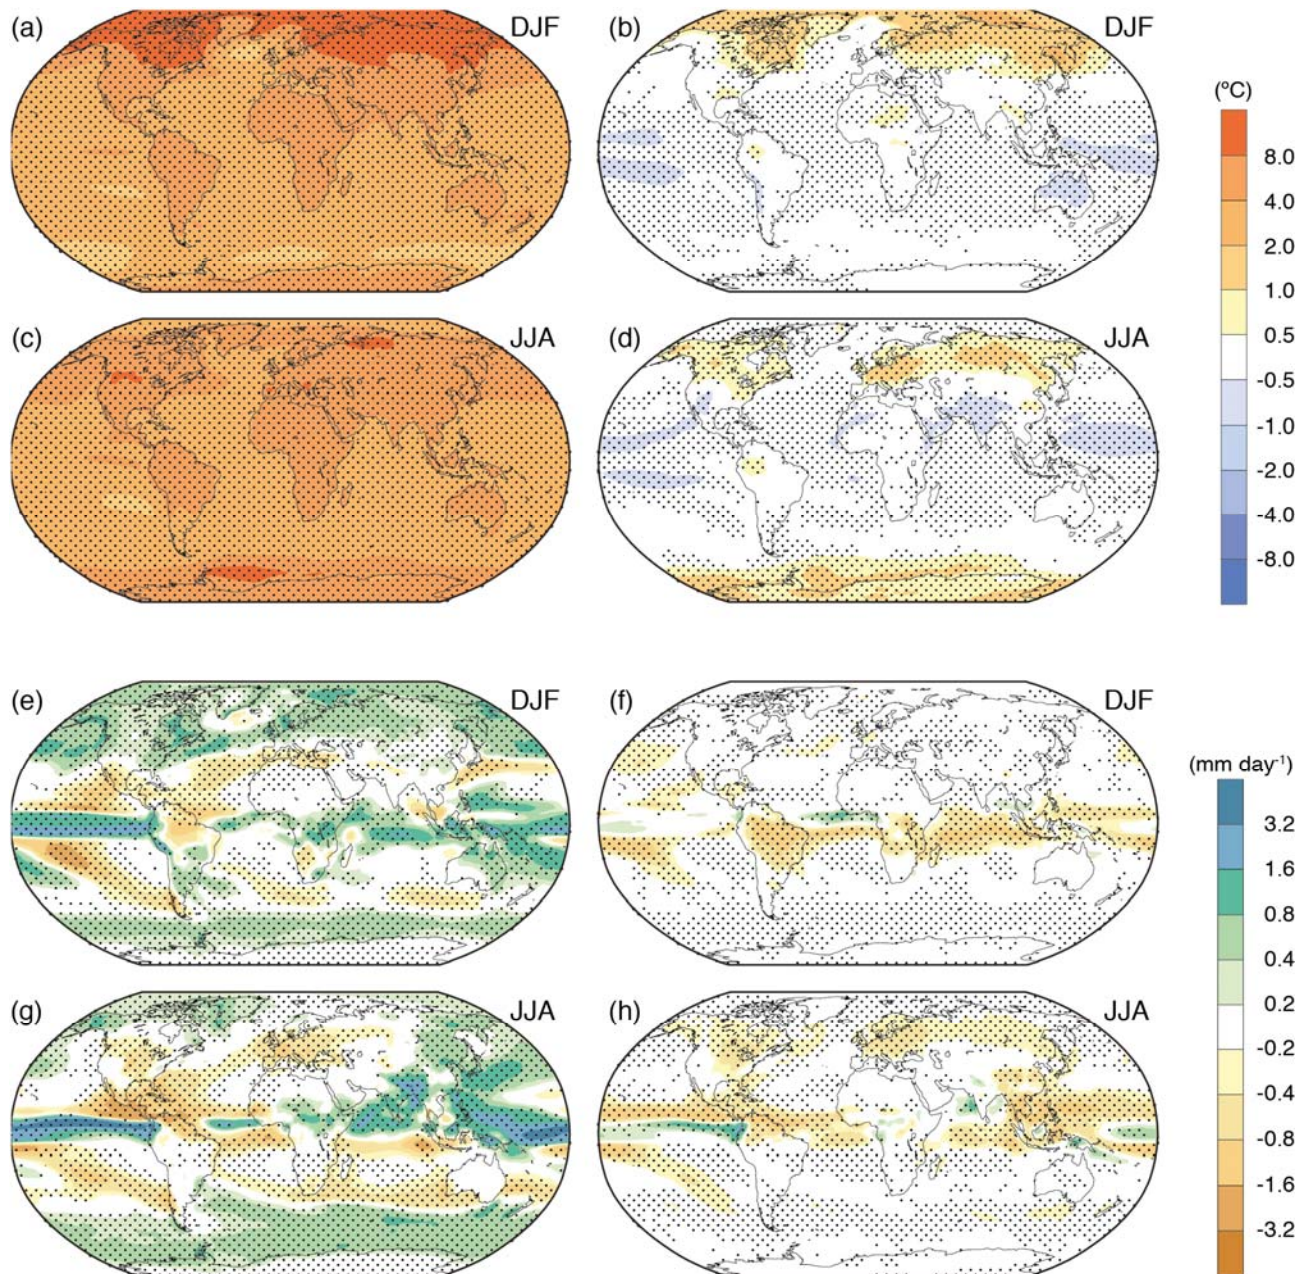

Figure 7.23: Multi-model mean of the change in surface air temperature ($^{\circ}\text{C}$) averaged over December, January and February months for (a) an abrupt $4 \times \text{CO}_2$ simulation and (b) an experiment where the $4 \times \text{CO}_2$ forcing is balanced by a reduction in the total solar irradiance to produce a global top-of-atmosphere flux imbalance of less than $\pm 0.1 \text{ W m}^{-2}$ during the first 10 years of the simulation (GeoMIP G1 experiment; Kravitz et al., 2011). (c-d) same as (a-b) but for the June, July and August months. (e-h) same as (a-d) but for the change in precipitation (mm day^{-1}). All changes are relative to the pre-industrial control experiment and averaged over years 11-50. The figure extends the results from Schmidt et al. (2012b) and shows the results from an ensemble of 12 coupled ocean-atmosphere general circulation models. Stippling denotes agreement on the sign of the temperature anomaly in at least 9 out of the 12 models.

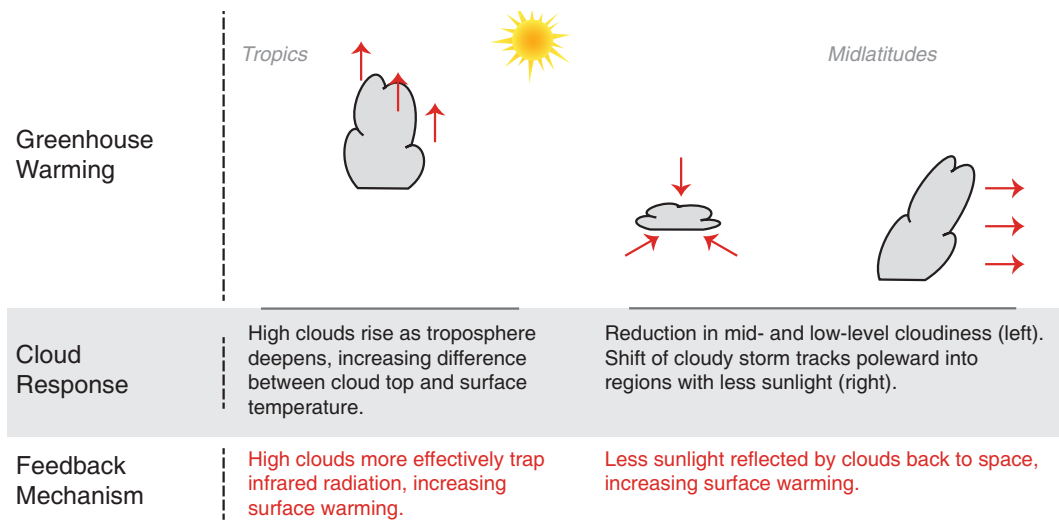

Figure 7.24: Timeseries of globally-averaged (a) surface temperature ($^{\circ}\text{C}$) and (b) precipitation (mm day^{-1}) changes relative to each model's $1 \times \text{CO}_2$ reference simulation. Solid lines are for simulations using SRM through an increasing reduction of the total solar irradiance to balance a $1\% \text{ yr}^{-1}$ increase in CO_2 concentration until year 50 after which SRM is stopped for the next 20 years (GeoMIP G2 experiment; Kravitz et al., 2011). Dashed lines are for $1\% \text{ CO}_2$ increase simulations with no SRM. The multi-model ensemble mean is shown with thick black lines.

FAQ 7.1, Figure 1: Schematic of important cloud feedback mechanisms.

Aerosol-radiation interactions

Scattering aerosols

(a)

Aerosols scatter solar radiation. Less solar radiation reaches the surface, which leads to a localised cooling.

(b)

The atmospheric circulation and mixing processes spread the cooling regionally and in the vertical.

Absorbing aerosols

(c)

Aerosols absorb solar radiation. This heats the aerosol layer but the surface, which receives less solar radiation, can cool locally.

(d)

At the larger scale there is a net warming of the surface and atmosphere because the atmospheric circulation and mixing processes redistribute the thermal energy.

FAQ 7.2, Figure 1: Overview of interactions between aerosols and solar radiation and their impact on climate. The left panels show the instantaneous radiative effects of aerosols, while the right panels show their overall impact after the climate system has responded to their radiative effects.

Aerosol-cloud interactions

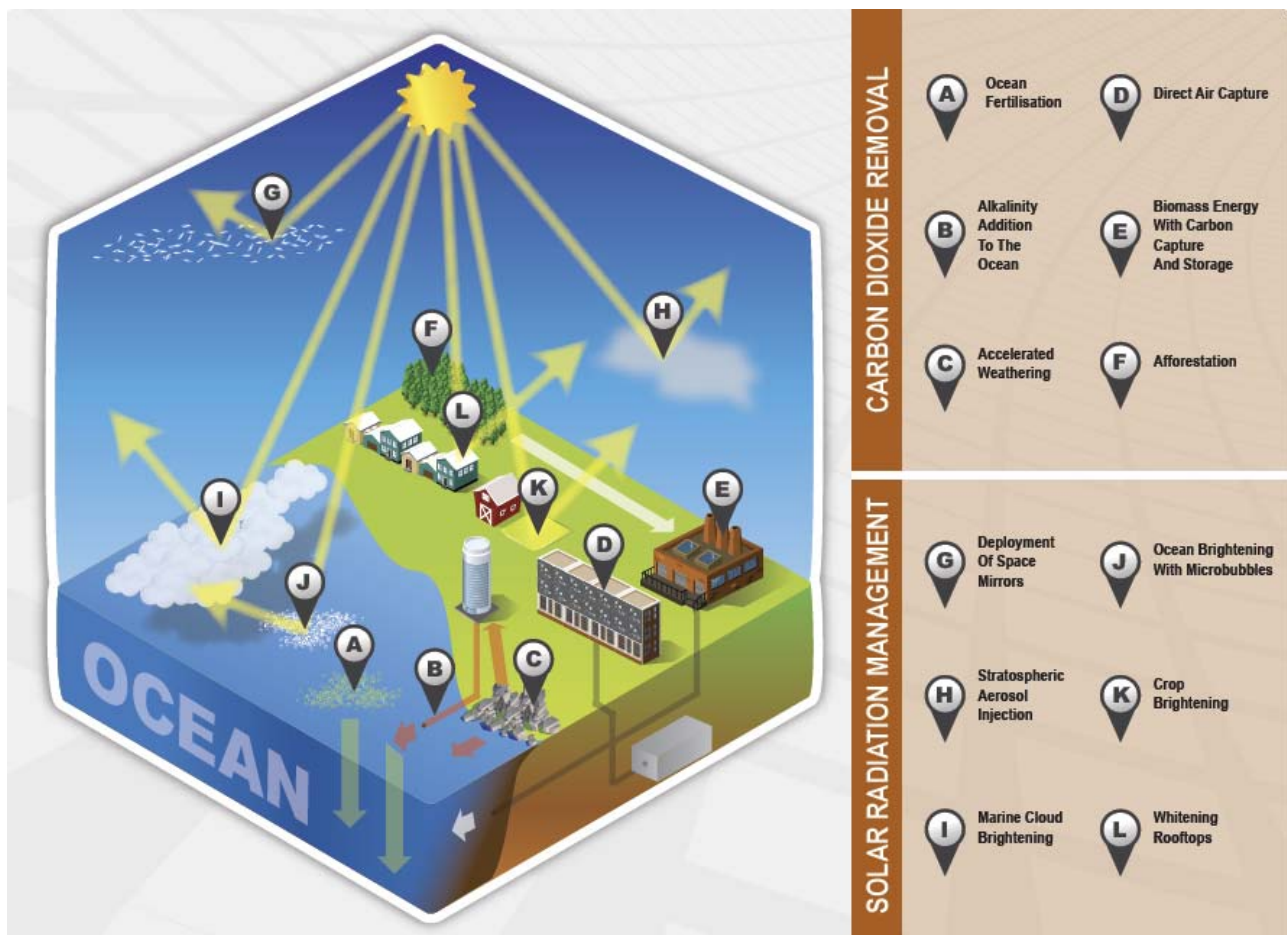

Aerosols serve as cloud condensation nuclei upon which liquid droplets can form.

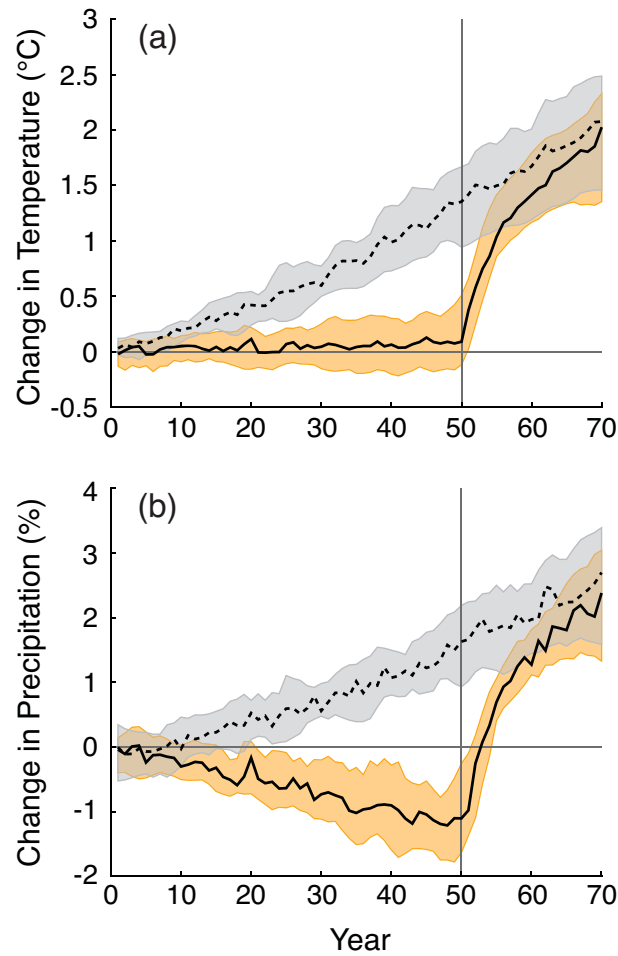

More aerosols result in a larger concentration of smaller droplets, leading to a brighter cloud. However there are many other possible aerosol-cloud-precipitation processes which may amplify or dampen this effect.

FAQ 7.2, Figure 2: Overview of aerosol-cloud interactions and their impact on climate. Panels (a) and (b) represent a clean and a polluted low-level cloud, respectively.

FAQ 7.3, Figure 1: Overview of some proposed geoengineering methods as they have been suggested. Carbon Dioxide Removal methods (see Chapter 6, Section 6.5 for details): (A) nutrients are added to the ocean (ocean fertilization), which increases oceanic productivity in the surface ocean and transports a fraction of the resulting biogenic carbon downward, (B) alkalinity from solid minerals is added to the ocean, which causes more atmospheric CO₂ to dissolve in the ocean, (C) the weathering rate of silicate rocks is increased, and the dissolved carbonate minerals are transported to the ocean, (D) atmospheric CO₂ is captured chemically, and stored either underground or in the ocean, (E) biomass is burned at an electric power plant with carbon capture, and the captured CO₂ is stored either underground or in the ocean and (F) CO₂ is captured through afforestation and reforestation to be stored in land ecosystems. Solar Radiation Management methods (see Chapter 7, Section 7.7 for details): (G) reflectors are placed in space to reflect solar radiation, (H) aerosols are injected in the stratosphere, (I) marine clouds are seeded in order to be made more reflective, (J) microbubbles are produced at the ocean surface to make it more reflective, (K) more reflective crops are grown, and (L) roofs and other built structures are whitened.

FAQ 7.3, Figure 2: Change in globally-averaged (a) surface temperature ($^{\circ}\text{C}$) and (b) precipitation (%) in two idealised experiments. Solid lines are for simulations using Solar Radiation Management (SRM) to balance a $1\% \text{ yr}^{-1}$ increase in CO_2 concentration until year 50, after which SRM is stopped. Dashed lines are for simulations with a $1\% \text{ yr}^{-1}$ increase in CO_2 concentration and no SRM. The pink and blue envelopes show the 25th to 75th percentiles from eight different models.

Executive Summary

It is unequivocal that anthropogenic increases in the well-mixed greenhouse gases (WMGHGs) have substantially enhanced the greenhouse effect, and the resulting forcing continues to increase. Aerosols partially offset the forcing of the WMGHGs and dominate the uncertainty associated with the total anthropogenic driving of climate change.

As in previous IPCC assessments, AR5 uses the radiative forcing¹ (RF) concept, but it also introduces effective radiative forcing² (ERF). The RF concept has been used for many years and in previous IPCC assessments for evaluating and comparing the strength of the various mechanisms affecting Earth's radiation balance and thus causing climate change. Whereas in the RF concept all surface and tropospheric conditions are kept fixed, the ERF calculations presented here allow all physical variables to respond to perturbations except for those concerning the ocean and sea ice. The inclusion of these adjustments makes ERF a better indicator of the eventual temperature response. ERF and RF values are significantly different for anthropogenic aerosols due to their influence on clouds and on snow cover. These changes to clouds are rapid adjustments and occur on a time scale much faster than responses of the ocean (even the upper layer) to forcing. RF and ERF are estimated over the industrial era from 1750 to 2011 if other periods are not explicitly stated. [8.1; Box 8.1; Figure 8.1]

Industrial-Era Anthropogenic Forcing

The total anthropogenic ERF over the industrial era is 2.3 (1.1 to 3.3) W m⁻².³ It is certain that the total anthropogenic ERF is positive. Total anthropogenic ERF has increased more rapidly since 1970 than during prior decades. The total anthropogenic ERF estimate for 2011 is 44% higher compared to the AR4 RF estimate for the year 2005 due to reductions in estimated forcing due to aerosols but also to continued growth in greenhouse gas RF. [8.5.1; Figure 8.15; Figure 8.16]

Due to increased concentrations, RF from WMGHGs has increased by 0.20 (0.18 to 0.22) W m⁻² (8%) since the AR4 estimate for the year 2005. The RF of WMGHG is 2.83 (2.54 to 3.12) W m⁻². The majority of this change since AR4 is due to increases in the CO₂ RF of nearly 10%. The industrial era RF for CO₂ alone is 1.82 (1.63 to 2.01) W m⁻², and CO₂ is the component with the largest global mean RF. Over the last decade RF of CO₂ has an average growth rate of 0.27 (0.24 to 0.30) W m⁻² per decade. The best estimate for ERF of WMGHG is the same as the RF but with a larger uncertainty ($\pm 20\%$). [8.3.2; 8.5.2; Figure 8.18, Figure 8.6]

The net forcing by WMGHGs other than CO₂ shows a small increase since the AR4 estimate for the year 2005. A small growth in the CH₄ concentration has increased its RF by 2% to an AR5 value of 0.48 (0.43 to 0.53) W m⁻². RF of N₂O has increased by 6% since AR4 and is now 0.17 (0.15 to 0.19) W m⁻². N₂O concentrations continue to rise while those of CFC-12, the third largest WMGHG contributor to RF for several decades, is falling due to its phase-out under the Montreal Protocol and amendments. Since 2011 N₂O has become the third largest WMGHG contributor to RF. The RF from all halocarbons (0.36 W m⁻²) is very similar to the value in AR4, with a reduced RF from CFCs but increases from many of their substitutes. Four of the halocarbons (CFC-11, CFC-12, CFC-113, and HCFC-22) account for around 85% of the total halocarbon RF. The first three of these compounds have declining RF over the last five years but their combined decrease is compensated for by the increased RF from HCFC-22. Since AR4, the RF from all

¹ Change in net downward radiative flux at the tropopause after allowing for stratospheric temperatures to readjust to radiative equilibrium, while holding surface and tropospheric temperatures and state variables fixed at the unperturbed values.

² Change in net downward radiative flux at the TOA after allowing for atmospheric temperatures, water vapour, clouds and land albedo to adjust, but with global mean surface temperature or ocean and sea ice conditions unchanged (calculations presented in this chapter use the fixed ocean conditions method).

³ Uncertainties are given associated with best estimates of forcing. The uncertainty values represent the 5–95% (90%) confidence range.

HFCs has nearly doubled but still only amounts to 0.02 W m^{-2} . There is *high confidence*⁴ that the overall growth rate in RF from all WMGHG is smaller over the last decade than in the 1970s and 1980s owing to a reduced rate of increase in the combined non-CO₂ RF. [8.3.2; Figure 8.6]

Ozone and stratospheric water vapour contribute substantially to RF. The total RF estimated from modelled ozone changes is $0.35 (0.15 \text{ to } 0.55) \text{ W m}^{-2}$, with RF due to tropospheric ozone changes of $0.40 (0.20 \text{ to } 0.60) \text{ W m}^{-2}$ and due to stratospheric ozone changes of $-0.05 (-0.15 \text{ to } +0.05) \text{ W m}^{-2}$. Ozone is not emitted directly into the atmosphere but is formed by photochemical reactions. Tropospheric ozone RF is largely attributed to anthropogenic emissions of methane, nitrogen oxides, carbon monoxide, and non-methane volatile organic compounds, while stratospheric ozone RF results primarily from ozone depletion by halocarbons. Estimates are also provided attributing RF to emitted compounds. Ozone depleting substances (ODS) cause ozone RF of $-0.15 (-0.30 \text{ to } 0.0) \text{ W m}^{-2}$, some of which is in the troposphere. Tropospheric ozone precursors cause ozone RF of $0.50 (0.30 \text{ to } 0.70) \text{ W m}^{-2}$, some of which is in stratosphere; this value is larger than that in AR4. There is *robust evidence* that tropospheric ozone also has a detrimental impact on vegetation physiology, and therefore on its CO₂ uptake, but there is a *low confidence* on quantitative estimates of the RF due to this indirect effect. RF for stratospheric water vapour produced by CH₄ oxidation is $0.07 (0.02 \text{ to } 0.12) \text{ W m}^{-2}$. The RF best estimates for ozone and stratospheric water vapour are either identical or consistent with the range in AR4. [8.2; 8.3.3; Figure 8.7]

The magnitude of the aerosol forcing is reduced since AR4. The RF due to aerosol-radiation-interactions, sometimes referred to as *direct aerosol effect*, is given a best estimate of $-0.35 (-0.85 \text{ to } +0.15) \text{ W m}^{-2}$, and black carbon (BC) on snow and ice is $0.04 (0.02 \text{ to } 0.09) \text{ W m}^{-2}$. The ERF due to aerosol-radiation-interactions is $-0.45 (-0.95 \text{ to } +0.05) \text{ W m}^{-2}$. A total aerosol-cloud-interaction⁵ is quantified in terms of the ERF concept with an estimate of $-0.45 (-1.2 \text{ to } 0.0) \text{ W m}^{-2}$. The total aerosol effect is estimated as ERF of $-0.9 (-1.9 \text{ to } -0.1) \text{ W m}^{-2}$. The large uncertainty in aerosol ERF is the dominant contributor to overall net industrial era forcing uncertainty. Since AR4 more aerosol processes have been included in models, and differences between models and observations persist, resulting in similar uncertainty in the aerosol forcing as in AR4. Despite the large uncertainty range, there is a *high confidence* that aerosols have offset a substantial portion of WMGHG global mean forcing. [8.3.4; 8.5.1; Figure 8.15; Figure 8.16]

There is *robust evidence* that anthropogenic land use change has increased the land surface albedo, which leads to a RF of $-0.15 \pm 0.10 \text{ W m}^{-2}$. There is still a large spread of estimates due to different assumptions for the albedo of natural and managed surfaces and the fraction of land use changes before 1750. Land use change causes additional modifications that are not radiative, but impact the surface temperature, in particular through the hydrologic cycle. These are more uncertain and they are difficult to quantify, but tend to offset the impact of albedo changes. As a consequence, there is *low agreement* on the sign of the net change in global mean temperature as a result of land use change. [8.3.5]

Attributing forcing to emissions provides a more direct link from human activities to forcing. The RF attributed to methane emissions is *very likely*⁶ to be much larger ($\sim 1.0 \text{ W m}^{-2}$) than that attributed to methane concentration increases ($\sim 0.5 \text{ W m}^{-2}$) as concentration changes result from the partially offsetting impact of emissions of multiple species and subsequent chemical reactions. In addition, emissions of carbon monoxide are *virtually certain* to have had a positive RF, while emissions of NO_x are *likely* to have had a net negative RF at the global scale. Emissions of ozone-depleting halocarbons are *very likely* to have caused a net positive

⁴ In this Report, the following summary terms are used to describe the available evidence: limited, medium, or robust; and for the degree of agreement: low, medium, or high. A level of confidence is expressed using five qualifiers: very low, low, medium, high, and very high, and typeset in italics, e.g., *medium confidence*. For a given evidence and agreement statement, different confidence levels can be assigned, but increasing levels of evidence and degrees of agreement are correlated with increasing confidence (see Section 1.4 and Box TS.1 for more details).

⁵ The aerosol-cloud-interaction represents the portion of rapid adjustments to aerosols initiated by aerosol-cloud interactions, and is defined here as the total aerosol ERF minus the ERF due to aerosol-radiation-interactions (the latter includes cloud responses to the aerosol-radiation-interaction RF).

⁶ In this Report, the following terms have been used to indicate the assessed likelihood of an outcome or a result: Virtually certain 99-100% probability, Very likely 90-100%, Likely 66-100%, About as likely as not 33-66%, Unlikely 0-33%, Very unlikely 0-10%, Exceptionally unlikely 0-1%. Additional terms (Extremely likely: 95-100%, More likely than not >50-100%, and Extremely unlikely 0-5%) may also be used when appropriate. Assessed likelihood is typeset in italics, e.g., *very likely* (see Section 1.4 and Box TS.1 for more details).

RF as their own positive RF has outweighed the negative RF from the stratospheric ozone depletion that they have induced. [8.3.3; 8.5.1; Figure 8.17; FAQ8.2]

Forcing agents such as aerosols, ozone and land albedo changes are highly heterogeneous spatially and temporally. These patterns generally track economic development; strong negative aerosol forcing appeared in eastern North America and Europe during the early 20th century, extending to Asia, South America and central Africa by 1980. Emission controls have since reduced aerosol pollution in North America and Europe, but not in much of Asia. Ozone forcing increased throughout the 20th century, with peak positive amplitudes around 15°N–30°N due to tropospheric pollution but negative values over Antarctica due to stratospheric loss late in the century. The pattern and spatial gradients of forcing affect global and regional temperature responses as well as other aspects of climate response such as the hydrologic cycle. [8.6.2; Figure 8.25]

Natural Forcing

Satellite observations of total solar irradiance (TSI) changes from 1978 to 2011 show that the most recent solar cycle minimum was lower than the prior two. This *likely* led to a small negative RF of -0.04 (-0.08 to -0.00) W m⁻² between 1986 and 2008. The best estimate of RF due to TSI changes representative for the 1750 to 2011 period is 0.05 (0.00 to 0.10) W m⁻². This is substantially smaller than the AR4 estimate due to the addition of the latest solar cycle and inconsistencies in how solar RF has been estimated in earlier IPCC assessments. There is very low confidence concerning future solar forcing estimates, but there is high confidence that the TSI RF variations will be much smaller than the projected increased forcing due to GHG during the forthcoming decades. [8.4.1; Figure 8.10; Figure 8.11]

The RF of volcanic aerosols is well understood and is greatest for a short period (~2 year) following volcanic eruptions. There have been no major volcanic eruptions since Mt. Pinatubo in 1991, but several smaller eruptions have caused a RF for the years 2008–2011 of -0.10 (-0.13 to -0.07) W m⁻² as compared to 1750 and -0.05 (-0.07 to -0.03) W m⁻² as compared to 1999–2002. Emissions of CO₂ from volcanic eruptions since 1750 have been at least 100 times smaller than anthropogenic emissions. [8.4.2; 8.5.2; Figure 8.12; Figure 8.13; Figure 8.18]

There is very high confidence that industrial-era natural forcing is a small fraction of the anthropogenic forcing except for brief periods following large volcanic eruptions. In particular, *robust evidence* from satellite observations of the solar irradiance and volcanic aerosols demonstrates a near-zero (-0.1 to +0.1 W m⁻²) change in the natural forcing compared to the anthropogenic ERF increase of 1.0 (0.7 to 1.3) W m⁻² from 1980 to 2011. The natural forcing over the last 15 years has *likely* offset a substantial fraction (10 to 95%) of the anthropogenic forcing. [8.5.2; Figure 8.18, Figure 8.19, Figure 8.20]

Future Anthropogenic Forcing and Emission Metrics

Differences in RF between the emission scenarios considered here⁷ are relatively small for year 2030 but become very large by 2100 and are dominated by CO₂. The scenarios show a substantial weakening of the negative total aerosol ERF. Nitrate aerosols are an exception to this reduction with a substantial increase, which is a robust feature among the few available models for these scenarios. The scenarios emphasized in this assessment do not span the range of future emissions in the literature, however, particularly for near-term climate forcings. [8.2.2; Figure 8.2; 8.5.3; Figure 8.21; Figure 8.22]

Emission metrics such as GWP and GTP can be used to quantify and communicate the relative and absolute contributions to climate change of emissions of different substances, and of emissions from regions/countries or sources/sectors. The metric that has been used in policies is the GWP, which integrates the RF of a substance over a chosen time horizon, relative to that of CO₂. The Global Temperature change Potential (GTP) is the ratio of change in global mean surface temperature at a chosen point in time from the substance of interest relative to that from CO₂. There are significant uncertainties related to both GWP and GTP and the relative uncertainties are larger for GTP. There are also limitations and

⁷ Chapter 1 describes the Representative Concentration Pathways (RCPs) that are the primary scenarios discussed in this report.

inconsistencies related to their treatment of indirect effects and feedbacks. The values are very dependent on metric type and time horizon. The choice of metric and time horizon depends on the particular application and which aspects of climate change are considered relevant in a given context. Metrics do not define policies or goals, but facilitate evaluation and implementation of multi-component policies to meet particular goals. All choices of metric contain implicit value-related judgements such as type of effect considered and weighting of effects over time. This assessment provides updated values of both GWP and GTP for many compounds. [8.7.1, 8.7.2, Table 8.7, Table 8.A.1, Supplementary Material Table 8.SM.16]

Forcing and temperature response can also be attributed to sectors. From this perspective and with the GTP metric, a single year's worth of current global emissions from the energy and industrial sectors have the largest contributions to global mean warming over the next ~50–100 years. Household fossil fuel and biofuel, biomass burning and on-road transportation are also relatively large contributors to warming over these timescales, while current emissions from sectors that emit large amounts of methane (animal husbandry, waste/landfills and agriculture) are also important over shorter time horizons (up to 20 years). [8.7.2; Figure 8.34]

8.1 Radiative Forcing

There are a variety of ways to examine how various drivers contribute to climate change. In principle, observations of the climate response to a single factor could directly show the impact of that factor, or climate models could be used to study the impact of any single factor. In practice, however, it is usually difficult to find measurements that are only influenced by a single cause, and it is computationally prohibitive to simulate the response to every individual factor of interest. Hence various metrics intermediate between cause and effect are used to provide estimates of the climate impact of individual factors, with applications both in science and policy. Radiative forcing (RF) is one of the most widely used metrics, with most other metrics based upon RF. In this chapter, we discuss RF from natural and anthropogenic components during the industrial period, presenting values for 2011 relative to 1750 unless otherwise stated, and projected values through 2100 (see also Annex II). In this section, we present the various definitions of RF used in this chapter, and discuss the utility and limitations of RF. These definitions are used in the subsequent sections quantifying the RF due to specific anthropogenic (Section 8.3) and natural (Section 8.4) causes and integrating RF due to all causes (Sections 8.5, 8.6). Atmospheric chemistry relevant for RF is discussed in Section 8.2 and used throughout the chapter. Emission metrics using RF that are designed to facilitate rapid evaluation and comparison of the climate effects of emissions are discussed in Section 8.7.

8.1.1 The Radiative Forcing Concept

RF is the net change in the energy balance of the Earth system due to some imposed perturbation. It is usually expressed in watts per square meter averaged over a particular period of time and quantifies the energy imbalance that occurs when the imposed change takes place. Though usually difficult to observe, calculated RF provides a simple quantitative basis for comparing some aspects of the potential climate response to different imposed agents, especially global mean temperature, and hence is widely used in the scientific community. Forcing is often presented as the value due to changes between two particular times, such as preindustrial to present-day, while its time-evolution provides a more complete picture.

8.1.1.1 Defining Radiative Forcing

Alternative definitions of RF have been developed, each with its own advantages and limitations. The instantaneous RF refers to an instantaneous change in net (down minus up) radiative flux (shortwave plus longwave; in W m^{-2}) due to an imposed change. This forcing is usually defined in terms of flux changes at the top of the atmosphere (TOA) or at the climatological tropopause, with the latter being a better indicator of the global mean surface temperature response in cases when they differ.

Climate change takes place when the system responds in order to counteract the flux changes, and all such responses are explicitly excluded from this definition of forcing. The assumed relation between a sustained RF and the equilibrium global mean surface temperature response (ΔT) is $\Delta T = \lambda \text{RF}$ where λ is the climate sensitivity parameter. The relationship between RF and ΔT is an expression of the energy balance of the climate system and a simple reminder that the steady state global mean climate response to a given forcing is determined both by the forcing and the responses inherent in λ .

Implicit in the concept of RF is the proposition that the change in net irradiance in response to the imposed forcing alone can be separated from all subsequent responses to the forcing. These are not in fact always clearly separable and thus some ambiguity exists in what may be considered a forcing versus what is part of the climate response.

In both the TAR and AR4, the term radiative forcing (RF, also called stratospherically-adjusted RF, as distinct from instantaneous RF) was defined as the change in net irradiance at the tropopause after allowing for stratospheric temperatures to readjust to radiative equilibrium, while holding surface and tropospheric temperatures and state variables such as water vapour and cloud cover fixed at the unperturbed values⁸. RF is generally more indicative of the surface and tropospheric temperature responses than instantaneous RF, especially for agents such as carbon dioxide or ozone change that substantially alter stratospheric

⁸ Tropospheric variables were fixed except for the impact of aerosols on cloud albedo due to changes in droplet size with constant cloud liquid water which was considered an RF in AR4 but is part of ERF in AR5.

temperatures. To be consistent with TAR and AR4, RF is hereafter taken to mean the stratospherically-adjusted radiative forcing.

8.1.1.2 *Defining Effective Radiative Forcing*

For many forcing agents the RF gives a very useful and appropriate way to compare the relative importance of their potential climate effect. Instantaneous RF or RF is not an accurate indicator of the temperature response for all forcing agents, however. Rapid adjustments in the troposphere can either enhance or reduce the flux perturbations, leading to substantial differences in the forcing driving long-term climate change. In much the same way that allowing for the relatively rapid adjustment of stratospheric temperatures provides a more useful characterization of the forcing due to stratospheric constituent changes, inclusion of rapid tropospheric adjustments has the potential to provide more useful characterization for drivers in the troposphere (see also Chapter 7, Section 7.1.3).

Many of the rapid adjustments affect clouds and are not readily included into the RF concept. For example, for aerosols, especially absorbing ones, changes in the temperature distribution above the surface occur due to a variety of effects, including cloud response to changing atmospheric stability (Hansen et al., 2005; Chapter 7, Section 7.3.5.2), and cloud absorption effects (Jacobson, 2012), that affect fluxes but are not strictly part of RF. Similar adjustments take place for many forcings, including CO₂ (Chapter 7, Section 7.2.5.6).

Aerosols also alter cloud properties via microphysical interactions leading to indirect forcings (referred to as aerosol-cloud interactions, Chapter 7, Section 7.4). Although these adjustments are complex and not fully quantified, they occur both on the microphysical scale of the cloud particles as well as on a more macroscopic scale involving whole cloud systems (e.g., Shine et al., 2003; Penner et al., 2006; Quaas et al., 2009). A portion of these adjustments occurs over a short period, on cloud-life cycle time scales, and is not part of a feedback arising from the surface temperature changes. Previously these type of adjustments have sometimes been termed ‘fast feedbacks’ (e.g., Gregory et al., 2004; Hansen et al., 2005), while in AR5 they will be denoted ‘rapid adjustments’ to emphasize their distinction from feedbacks involving surface temperature changes. Atmospheric chemistry responses have typically been included under the RF framework, and hence could also be included in a forcing encompassing rapid adjustments, which is important when evaluating forcing attributable to emissions changes (Section 8.1.2) and in the calculation of emission metrics (Section 8.7).

Studies have demonstrated the utility of including rapid adjustment in comparison of forcing agents, especially in allowing quantification of forcing due to aerosol-induced changes in clouds (e.g., effects previously denoted as cloud lifetime or semi-direct effects; see Figure 7.3) that are not amenable to characterization by RF (e.g., Rotstayn and Penner, 2001; Shine et al., 2003; Hansen et al., 2005; Lohmann et al., 2010; Ban-Weiss et al., 2012). Several measures of forcing have been introduced that include rapid adjustments. We term a forcing that accounts for rapid adjustments the effective radiative forcing (ERF). Conceptually, ERF represents the change in net TOA downward radiative flux after allowing for atmospheric temperatures, water vapour, and clouds to adjust, but with global mean surface temperature or a portion of surface conditions unchanged. The primary methods in use for such calculations are (1) fixing sea surface temperatures (SSTs) and sea ice cover at climatological values while allowing all other parts of the system to respond until reaching steady state (e.g., Hansen et al., 2005) or (2) analyzing the transient global mean surface temperature response to an instantaneous perturbation and using the regression of the response extrapolated back to the start of the simulation to derive the initial ERF (Gregory et al., 2004; Gregory and Webb, 2008). The ERF calculated using the regression technique has an uncertainty of about 10% (for the 5–95% confidence interval) for a single 4 x CO₂ simulation (ERF ~7 W m⁻²) due to internal variability in the transient climate (Andrews et al., 2012a), while given a similar length simulation the uncertainty due to internal variability in ERF calculated using the fixed-SST technique is much smaller and hence the latter may be more suitable for very small forcings. Analysis of both techniques shows that the fixed-SST method yields a smaller spread across models, even in calculations neglecting the uncertainty in the regression fitting procedure (Andrews et al., 2012a). As a portion of land area responses are included in the fixed-SST technique, however, that ERF is slightly less than it would be with surface temperature held fixed everywhere. It is possible to adjust for this in the global mean forcing, though we do not include such a correction here as we examine regional as well as global ERF, but the land response will also introduce

artificial gradients in land-sea temperatures that could cause small local climate responses. In contrast, there is no global mean temperature response included in the regression method. Despite the low bias in fixed-SST ERF due to land responses, results from a multi-model analysis of the forcing due to CO₂ are 7% greater using this method than using the regression technique (Andrews et al., 2012a) though this is within the uncertainty range of the calculations. While each technique has advantages, forcing diagnosed using the fixed-SST method is available for many more forcing agents in the current generation of climate models than forcing diagnosed using the regression method. Hence for practical purposes, ERF is hereafter used for results from the fixed-SST technique unless otherwise stated (see also Box 8.1).

[START BOX 8.1 HERE]

Box 8.1: Definition of Radiative Forcing (RF) and Effective Radiative Forcing (ERF)

The two most commonly used measures of radiative forcing in this chapter are the radiative forcing (RF) and the effective radiative forcing (ERF). RF is defined, as it was in AR4, as the change in net downward radiative flux at the tropopause after allowing for stratospheric temperatures to readjust to radiative equilibrium, while holding surface and tropospheric temperatures and state variables such as water vapor and cloud cover fixed at the unperturbed values.

ERF is the change in net top-of-the-atmosphere downward radiative flux after allowing for atmospheric temperatures, water vapour, and clouds to adjust, but with surface temperature or a portion of surface conditions unchanged. While there are multiple methods to calculate ERF, we take ERF to mean the method in which sea surface temperatures and sea ice cover are fixed at climatological values unless otherwise specified. Land-surface properties (temperature, snow and ice cover and vegetation) are allowed to adjust in this method. Hence ERF includes both the effects of the forcing agent itself and the rapid adjustments to that agent (as does RF, though stratospheric temperature is the only adjustment for the latter). In the case of aerosols, the rapid adjustments of clouds encompass effects that have been referred to as indirect or semi-direct forcings (see Chapter 7, Figure 7.3 and Section 7.5), with some of these same cloud responses also taking place for other forcing agents (see Chapter 7, Section 7.2). Calculation of ERF requires longer simulations with more complex models than calculation of RF, but the inclusion of the additional rapid adjustments makes ERF a better indicator of the eventual global mean temperature response, especially for aerosols. When forcing is attributed to emissions or used for calculation of emission metrics, additional responses including atmospheric chemistry and the carbon cycle are also included in both RF and ERF (see Section 8.1.2). The general term *forcing* is used to refer to both RF and ERF.

[END BOX 8.1 HERE]

The conceptual relation between instantaneous RF, RF and ERF is illustrated in Figure 8.1. It implies the adjustments to the instantaneous RF involve effects of processes that occur more rapidly than the time scale of the response of the global mean surface temperature to the forcing. However, there is no a priori timescale defined for adjustments to be rapid with the fixed-SST method. The majority take place on timescales of seasons or less, but there is a spectrum of adjustment times. Changes in land ice and snow cover, for instance, may take place over many years. The ERF thus represents that part of the instantaneous RF that is maintained over long timescales and more directly contributes to the steady-state climate response. The RF can be considered a more limited version of ERF. Since the atmospheric temperature has been allowed to adjust, ERF would be nearly identical if calculated at the tropopause instead of the TOA for tropospheric forcing agents, as would RF. Recent work has noted likely advantages of the ERF framework for understanding model responses to CO₂ as well as to more complex forcing agents (see Chapter 7, Section 7.2.5.6).

The climate sensitivity parameter λ derived with respect to RF can vary substantially across different forcing agents (Forster et al., 2007). The response to RF from a particular agent relative to the response to RF from CO₂ has been termed the *efficacy* (Hansen et al., 2005). By including many of the rapid adjustments that differ across forcing agents, the ERF concept includes much of their relative efficacy and therefore leads to more uniform climate sensitivity across agents. For example, the influence of clouds on the interaction of aerosols with sunlight and the effect of aerosol heating on cloud formation can lead to very large differences in the response per unit RF from black carbon located at different altitudes, but the response per unit ERF is

nearly uniform with altitude (Hansen et al., 2005; Ming et al., 2010; Ban-Weiss et al., 2012). Hence as we use ERF in this chapter when it differs significantly from RF, efficacy is not used hereinafter. For inhomogeneous forcings, we note that the climate sensitivity parameter may also depend upon the horizontal forcing distribution, especially with latitude (Shindell and Faluvegi, 2009; Section 8.2.2).

A combination of RF and ERF will be used in this chapter with RF provided to keep consistency with TAR and AR4, and ERF used to allow quantification of more complex forcing agents and, in some cases, provide a more useful metric than RF.

8.1.1.3 Limitations of Radiative Forcing

Both the RF and ERF concepts have strengths and weaknesses in addition to those discussed above. Dedicated climate model simulations that are required to diagnose the ERF can be more computationally demanding than those for instantaneous RF or RF since many years are required to reduce the influence of climate variability. The presence of meteorological variability can also make it difficult to isolate the ERF of small forcings that are easily isolated in the pair of radiative transfer calculations performed for RF (Figure 8.1). For RF, on the other hand, a definition of the tropopause is required, which can be ambiguous.

In many cases, however, ERF and RF are nearly equal. Analysis of 11 models from the current CMIP5 generation finds that the rapid adjustments to CO₂ cause fixed-SST-based ERF to be 2% less than RF, with an intermodel standard deviation of 7% (Vial et al., 2013). This is consistent with an earlier study of six GCMs that found a substantial inter-model variation in the rapid tropospheric adjustment to CO₂ using regression analysis in slab ocean models, though the ensemble mean adjustment was less than 5% (Andrews and Forster, 2008). Part of the large uncertainty range arises from the greater noise inherent in regression analyses of single runs in comparison with fixed-SST experiments. Using fixed-SST simulations, Hansen et al. (2005) found that ERF is virtually identical to RF for increased CO₂, tropospheric ozone and solar irradiance, and within 6% for methane, N₂O, stratospheric aerosols, and for the aerosol-radiation interaction of reflective aerosols. Shindell et al. (2013b) also found that RF and ERF are statistically equal for tropospheric ozone. Lohmann et al. (2010) report a small increase in the forcing from CO₂ using ERF instead of RF based on the fixed-SST technique, while finding no substantial difference for methane, RF due to aerosol-radiation interactions or aerosol effects on cloud albedo. In the fixed-SST simulations of Hansen et al. (2005), ERF was ~20% less than RF for the atmospheric effects of black carbon (BC) aerosols (not including microphysical aerosol-cloud interactions), and nearly 300% greater for the forcing due to BC snow albedo forcing (Hansen et al., 2007). ERF was slightly greater than RF for stratospheric ozone in Hansen et al. (2005), but the opposite is true for more recent analyses (Shindell et al., 2013b), and hence it seems most appropriate at present to use RF for this small forcing. The various studies demonstrate that RF provides a good estimate of ERF in most cases, as the differences are very small, with the notable exceptions of BC-related forcings (Bond et al., 2013). ERF provides better characterization of those effects, as well as allowing quantification of a broader range of effects including all aerosol-cloud interactions. Hence while RF and ERF are generally quite similar for well-mixed greenhouse gases, ERF typically provides a more useful indication of climate response for near-term climate forcings (see Box 8.2). As the rapid adjustments included in ERF differ in strength across climate models, the uncertainty range for ERF estimates tends to be larger than the range for RF estimates.

[START BOX 8.2 HERE]

Box 8.2: Grouping Forcing Compounds by Common Properties

As many compounds cause RF when their atmospheric concentration is changed, it can be useful to refer to groups of compounds with similar properties. Here we discuss two primary groupings: well-mixed greenhouse gases (WMGHGs) and near-term climate forcings (NTCFs).

We define as ‘well-mixed’ those greenhouse gases that are sufficiently mixed throughout the troposphere that concentration measurements from a few remote surface sites can characterise the climate-relevant atmospheric burden; although these gases may still have local variation near sources and sinks and even small hemispheric gradients. Global forcing per unit emission and emission metrics for these gases thus do not depend on the geographic location of the emission, and forcing calculations can assume even horizontal

distributions. These gases, or a subset of them, have sometimes been referred to as ‘long-lived greenhouse gases’ as they are well-mixed because their atmospheric lifetimes are much greater than the timescale of a few years for atmospheric mixing, but the physical property that causes the above common characteristics is more directly associated with their mixing within the atmosphere. WMGHGs include CO₂, N₂O, CH₄, SF₆, and many halogenated species. Conversely, ozone is not a WMGHG.

We define ‘Near-term climate forcers’ (NTCF) as those compounds whose impact on climate occurs primarily within the first decade after their emission. This set of compounds is primarily composed of those with short lifetimes in the atmosphere compared to WMGHGs, and has been sometimes referred to as short-lived climate forcers or short-lived climate pollutants. However, the common property that is of greatest interest to a climate assessment is the timescale over which their impact on climate is felt. This set of compounds includes methane, which is also a WMGHG, as well as ozone and aerosols, or their precursors, and some halogenated species that are not WMGHGs. These compounds do not accumulate in the atmosphere at decadal to centennial timescales, and so their effect on climate is predominantly in the near-term following their emission.

[END BOX 8.2 HERE]

Whereas the global mean ERF provides a useful indication of the eventual change in global-mean surface temperature, it does not reflect regional climate changes. This is true for all forcing agents, but is especially the case for the inhomogeneously distributed forcings because they activate climate feedbacks based on their regional distribution. For example, forcings over Northern Hemisphere middle and high latitudes induce snow and ice albedo feedbacks more than forcings at lower latitudes or in the Southern Hemisphere (e.g., Shindell and Faluvegi, 2009).

In the case of agents that strongly absorb incoming solar radiation (such as black carbon (BC), and to a lesser extent organic carbon (OC) and ozone) the TOA forcing provides little indication of the change in solar radiation reaching the surface which can force local changes in evaporation and alter regional and general circulation patterns (e.g., Ramanathan and Carmichael, 2008; Wang et al., 2009). Hence the forcing at the surface, or the atmospheric heating, defined as the difference between surface and tropopause/TOA forcing, might also be useful metrics. Global mean precipitation changes can be related separately to ERF within the atmosphere and to a slower response to global mean temperature changes (Andrews et al., 2010; Ming et al., 2010; Ban-Weiss et al., 2012). Relationships between surface forcing and localized aspects of climate response have not yet been clearly quantified, however.

In general, most widely used definitions of forcing and most forcing-based metrics are intended to be proportional to the eventual temperature response, and most analyses to date have explored the global mean temperature response only. These metrics do not explicitly include impacts such as changes in precipitation, surface sunlight available for photosynthesis, extreme events, etc, or regional temperatures, which can differ greatly from the global mean. Hence although they are quite useful for understanding the factors driving global mean temperature change, they provide only an imperfect and limited perspective on the factors driving broader climate change. Additionally, a metric based solely on radiative perturbations does not allow comparison of non-radiative forcings, such as effects of land cover change on evapotranspiration or physiological impacts of CO₂ and O₃ except where these cause further impacts on radiation such as through cloud cover changes (e.g., Andrews et al., 2012b).

[INSERT FIGURE 8.1 HERE]

Figure 8.1: Cartoon comparing (a) instantaneous RF, (b) RF, which allows stratospheric temperature to adjust, (c) flux change when the surface temperature is fixed over the whole Earth (a method of calculating ERF), (d) the ERF calculated allowing atmospheric and land temperature to adjust while ocean conditions are fixed, and (e) the equilibrium response to the climate forcing agent. The methodology for calculation of each type of forcing is also outlined. ΔT_o represents the land temperature response, while ΔT_s is the full surface temperature response. Updated from Hansen et al. (2005).

8.1.2 Calculation of Radiative Forcing due to Concentration or Emission Changes

Analysis of forcing due to observed or modelled concentration changes between preindustrial, defined here as 1750, and a chosen later year provides an indication of the importance of different forcing agents to

climate change during that period. Such analyses have been a mainstay of climate assessments. This perspective has the advantage that observational data are available to accurately quantify the concentration changes for several of the largest forcing components. Atmospheric concentration changes, however, are the net result of variations in emissions of multiple compounds and any climate changes that have influenced processes such as wet removal, atmospheric chemistry or the carbon cycle. Characterizing forcing according to *concentration* changes thus mixes multiple root causes along with climate feedbacks. Policy decisions are better informed by analysis of forcing attributable to *emissions*, which the IPCC first presented in AR4. These analyses can be applied to historical emissions changes in a ‘backward-looking’ perspective, as done e.g., for major WMGHGs (den Elzen et al., 2005; Hohne et al., 2011) and NTCFs (Shindell et al., 2009), or to current or projected future emissions in a ‘forward-looking’ view (see Section 8.7). Emissions estimates through time typically come from the scientific community, often making use of national reporting for recent decades.

With the greater use of emission-driven models, e.g., in CMIP5, it is becoming more natural to estimate ERF resulting from emissions of a particular species rather than concentration-based forcing. Such calculations typically necessitate model simulations with chemical transport models or chemistry-climate models, however, and require careful consideration of which processes are included, especially when comparing results to concentration-based forcings. In particular, simulation of concentration responses to emissions changes requires incorporating models of the carbon cycle and atmospheric chemistry (gas and aerosol phases). The requisite expansion of the modelling realm for emissions-based forcing or emission metrics should in principle be consistent for all drivers. For example, as the response to aerosol or ozone precursor emissions includes atmospheric chemistry, the response to CO₂ emissions should as well. Additionally, if the CO₂ concentration responses to CO₂ emissions include the impact of CO₂-induced climate changes on carbon uptake, then the effect of climate changes caused by any other emission on carbon uptake should also be included. Similarly, if the effects of atmospheric CO₂ concentration change on carbon uptake are included, the effects of other atmospheric composition or deposition changes on carbon uptake should be included as well (see also Chapter 6, Section 6.4.1). Comparable issues are present for other forcing agents. In practice, the modelling realm used in studies of forcing attributable to emissions has not always been consistent. Furthermore, climate feedbacks have sometimes been included in the calculation of forcing due to ozone or aerosol changes, as when concentrations from a historical transient climate simulation are imposed for an ERF calculation. In this chapter, we endeavour to clarify which processes have been included in the various estimates of forcing attributed to emissions (Sections 8.3 and 8.7).

RF or ERF estimates based on either historical emissions or concentrations provide valuable insight into the relative and absolute contribution of various drivers to historical climate change. Scenarios of changing future emissions and land use are also developed based on various assumptions about socio-economic trends and societal choices. The forcing resulting from such scenarios is used to understand the drivers of potential future climate changes (Sections 8.5.3 and 8.6). As with historical forcings, the actual impact on climate depends on both the temporal and spatial structure of the forcings and the rate of response of various portions of the climate system.

8.2 Atmospheric Chemistry

8.2.1 Introduction

Most radiatively active compounds in the Earth’s atmosphere are chemically active, meaning that atmospheric chemistry plays a large role in determining their burden and residence time. In the atmosphere, a gaseous chemically active compound can be affected by 1) interaction with other species (including aerosols and water) in its immediate vicinity and 2) interaction with solar radiation (photolysis). Physical processes (wet removal and dry deposition) act on some chemical compounds (gas or aerosols) to further define their residence time in the atmosphere. Atmospheric chemistry is characterized by many interactions and patterns of temporal or spatial variability, leading to significant nonlinearities (Kleinman et al., 2001) and a wide range of timescales of importance (Isaksen et al., 2009).

This section will assess updates in understanding of processes, modelling and observations since AR4 (Chapter 2, Section 2.3) on key reactive species contributing to RF. Note that aerosols, including processes responsible for the formation of aerosols, are extensively described in Chapter 7, Section 7.3.

8.2.2 Global Chemistry Modelling in CMIP5

Because the distribution of near-term climate forcers (NTCFs) cannot be estimated from observations alone, coupled chemistry-climate simulations are required to define their evolution and associated radiative forcing. While several CMIP5 modeling groups performed simulations with interactive chemistry (i.e., computed simultaneously within the climate model), many models used as input pre-computed distributions of radiatively active gases and/or aerosols. In order to assess the distributions of chemical species and their respective RF, many research groups participated in the Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP).

The ACCMIP simulations Lamarque et al. (2013) were defined to provide information on the long-term changes in atmospheric composition with a few, well-defined atmospheric simulations. Because of the nature of the simulations (pre-industrial, present-day and future climates), only a limited number of chemistry-transport models (models which require a full definition of the meteorological fields needed to simulate physical processes and transport) participated in the ACCMIP project, which instead drew primarily from the same GCMs as CMIP5 (see Lamarque et al., 2013 for a list of the participating models and their configurations), with extensive model evaluation against observations (Bowman et al., 2013; Lee et al., 2013; Shindell et al., 2013c; Voulgarakis et al., 2013; Young et al., 2013).

In all CMIP5/ACCMIP chemistry simulations, anthropogenic and biomass burning emissions are specified. More specifically, a single set of historical anthropogenic and biomass burning emissions (Lamarque et al., 2010) and one set of emissions for each of the RCPs (van Vuuren et al., 2011) was defined (Figure 8.2). This was designed to increase the comparability of simulations. However, these uniform emission specifications mask the existing uncertainty (e.g., Bond et al., 2007; Lu et al., 2011), so that there is in fact a considerable range in the estimates and time evolution of recent anthropogenic emissions (Granier et al., 2011). Historical reconstructions of biomass burning (wildfires and deforestation) also exhibit quite large uncertainties (Kasischke and Penner, 2004; Ito and Penner, 2005; Schultz et al., 2008; van der Werf et al., 2010). Additionally, the RCP biomass burning projections do not include the feedback between climate change and fires discussed in Bowman et al. (2009), Pechony and Shindell (2010) and Thonicke et al. (2010). Finally, the RCP anthropogenic precursor emissions of NTCFs tend to span a smaller range than available from existing scenarios (van Vuuren et al., 2011). The ACCMIP simulations therefore provide an estimate of the uncertainty due to range of representation of physical and chemical processes in models, but does not incorporate uncertainty in emissions.

[INSERT FIGURE 8.2 HERE]

Figure 8.2: Time evolution of global anthropogenic and biomass burning emissions 1850–2100 used in CMIP5/ACCMIP following each RCP. Historical (1850–2000) values are from Lamarque et al. (2010). RCP values are from van Vuuren et al. (2011). Emissions estimates from SRES are discussed in Annex II; note that Black Carbon and Organic Carbon estimates were not part of the SRES and are only shown here for completeness. The Maximum Feasible Reduction (MFR) and Current Legislation (CLE) are discussed in Cofala et al. (2007); as biomass burning emissions are not included in that publication, a fixed amount, equivalent to the value in 2000 from the RCP estimates, is added (see Annex II for more details; Dentener et al., 2006). The post-SRES scenarios are discussed in Van Vuuren et al. (2008) and Rogelj et al. (2011). For those, only the range (minimum-maximum) is shown. Global emissions from the Asian Modeling Exercise are discussed in Calvin et al. (2012). Regional estimates are shown in Supplementary Material Figure 8.SM.1 and Figure 8.SM.2 for the historical and RCPs.

8.2.3 Chemical Processes and Trace Gas Budgets

8.2.3.1 Tropospheric Ozone

The RF from tropospheric ozone is strongly height- and latitude-dependent through coupling of ozone change with temperature, water vapour and clouds (Lacis and Hansen, 1974; Bernsten et al., 1997; Worden et al., 2008; Worden et al., 2011; Bowman et al., 2013). Consequently, it is necessary to accurately estimate the change in the ozone spatio-temporal structure using global models and observations. It is also well established that surface ozone detrimentally affects plant productivity (Ashmore, 2005; Fishman et al., 2010), albeit estimating this impact on climate, while possible significant, is still limited to a few studies (Sitch et al., 2007; UNEP, 2011).

Tropospheric ozone is a by-product of the oxidation of carbon monoxide, methane and non-methane hydrocarbons in the presence of nitrogen oxides. As emissions of these precursors have increased (Figure 8.2), tropospheric ozone has increased since pre-industrial times (Volz and Kley, 1988; Marenco et al., 1994) and over the last decades (Parrish et al., 2009; Cooper et al., 2010; Logan et al., 2012), but with important regional variations (Section 2.2). Ozone production is usually limited by the supply of HO_x (OH + HO₂) and NO_x (NO + NO₂) (Levy, 1971; Logan et al., 1981). Ozone's major chemical loss pathways in the troposphere are through 1) photolysis (to O¹D, followed by reaction with water vapour) and 2) reaction with HO₂ (Seinfeld and Pandis, 2006). The former pathway leads to couplings between stratospheric ozone (photolysis rate being a function of the overhead ozone column) and climate change (through water vapour). Observed surface ozone abundances typically range from less than 10 ppb over the tropical Pacific Ocean to more than 100 ppb downwind of highly emitting regions. The lifetime of ozone in the troposphere varies strongly with season and location: it may be as little as a few days in the tropical boundary layer, or as much as 1 year in the upper troposphere. Two recent studies give similar global mean lifetime of ozone: 22.3 ± 2 days (Stevenson et al., 2006) and 23.4 ± 2.2 days (Young et al., 2013).

For present (circa 2000) conditions, the various components of the budget of global mean tropospheric ozone are estimated from the ACCMIP simulations and other model simulations since AR4 (Table 8.1). In particular, most recent models define a globally and annually averaged tropospheric ozone burden of (337 ± 23 Tg, one-sigma). Differences in the definition of the tropopause lead to inter-model variations of approximately 10% (Wild, 2007). This multi-model mean estimate of global annual tropospheric ozone burden has not significantly changed since the Stevenson et al. (2006) estimates (344 ± 39 Tg, one-sigma), and is consistent with the most recent satellite-based OMI-MLS (Ziemke et al., 2011) and TES (Osterman et al., 2008) climatologies.

Estimates of the ozone chemical sources and sinks (uncertainty estimates are quoted here as one-sigma) are less robust, with a net chemical production (production *minus* loss) of 618 ± 275 Tg yr⁻¹ (Table 8.1), larger than the ACCENT results (442 ± 309 Tg yr⁻¹; Stevenson et al., 2006). Estimates of ozone deposition (1094 ± 264 Tg yr⁻¹) are slightly increased since ACCENT (1003 ± 200 Tg yr⁻¹) while estimates of the net influx of ozone from the stratosphere to the troposphere (477 ± 96 Tg yr⁻¹) have slightly decreased since ACCENT (552 ± 168 Tg yr⁻¹). Additional model estimates of this influx (Hegglin and Shepherd, 2009; Hsu and Prather, 2009) fall within both ranges, as do estimates based on observations (Murphy and Fahey, 1994; Gettelman et al., 1997; Olsen et al., 2002), all estimates being sensitive to their choice of tropopause definition and interannual variability.

Table 8.1: Summary of tropospheric ozone global budget model and observation estimates for present (circa 2000) conditions. Focus is on modelling studies published since AR4. STE stands for stratosphere-troposphere exchange. All uncertainties quoted as 1 standard deviation (68% confidence interval).

Model simulations for present-day conditions or the recent past are evaluated (Figure 8.3) against frequent ozonesonde measurements (Logan, 1999; Tilmes et al., 2012) and additional surface, aircraft and satellite measurements. The ACCMIP model simulations (Figure 8.3) indicate 10–20% negative bias at 250 hPa in the Southern Hemisphere tropical region, and a slight underestimate in Northern Hemisphere tropical region. Comparison with satellite-based estimates of tropospheric ozone column (Ziemke et al., 2011) indicates an annual mean bias of -4.3 ± 29 Tg (with a spatial correlation of 0.87 ± 0.07 , one-sigma) for the ACCMIP simulations (Young et al., 2013). Overall, our ability to simulate tropospheric ozone burden for present (circa 2000) has not substantially changed since AR4. Evaluation (using a subset of two ACCMIP models) of simulated trends (1960s to present or shorter) in surface ozone against observations at remote surface sites (see Chapter 2, Section 2.2) indicates an underestimation, especially in the Northern Hemisphere (Lamarque et al., 2010). While this limits the ability to represent recent ozone changes, it is unclear how this translates into an uncertainty on changes since pre-industrial times.

[INSERT FIGURE 8.3 HERE]

Figure 8.3: Comparisons between observations and simulations for the monthly mean ozone for ACCMIP results (Young et al., 2013). ACCENT refers to the model results in Stevenson et al. (2006). For each box, the correlation of the seasonal cycle is indicated by the “r” value, while the mean normalized bias estimated is indicated by “mnbe” value.

In most studies ‘pre-industrial’ does not identify a specific year but is usually assumed to correspond to 1850s levels; no observational information on ozone is available for that time period. Using the Lamarque et al. (2010) emissions, the ACCMIP models (Young et al., 2013) are unable to reproduce the low levels of ozone observed at Montsouris 1876–1886 (Volz and Kley, 1988). The other early ozone measurements using Schönbein paper are controversial (Marengo et al., 1994) and assessed to be of qualitative use only. The main uncertainty in estimating the pre-industrial to present-day change in ozone therefore remains the lack of constraint on emission trends because of the very incomplete knowledge of pre-industrial ozone concentrations, of which no new information is available. The uncertainty on pre-industrial conditions is not confined to ozone but applies to aerosols as well (e.g., Schmidt et al., 2012), although ice and lake core records provide some constraint on pre-industrial aerosol concentrations.

The ACCMIP results provide an estimated tropospheric ozone increase (Figure 8.4) from 1850 to 2000 of 98 ± 17 Tg (model range), similar to AR4 estimates. Skeie et al. (2011a) found an additional 5% increase in the anthropogenic contribution to the ozone burden between 2000 and 2010, which translates approximately into a 1.5% increase in tropospheric ozone burden. A best estimate of the change in ozone since 1850 is assessed at 100 ± 25 Tg (one-sigma). Attribution simulations (Stevenson et al., 2013) indicate unequivocally that anthropogenic changes in ozone precursor emissions are responsible for the increase between 1850 and present or into the future.

[INSERT FIGURE 8.4 HERE]

Figure 8.4: Time evolution of global tropospheric ozone burden (in Tg(O₃)) from 1850 to 2100 from ACCMIP results, ACCENT results (2000 only), and observational estimates (see Table 8.1). The box, whiskers, line and dot show the interquartile range, full range, median and mean burdens and differences, respectively. The dashed line indicates the 2000 ACCMIP mean. Adapted from Young et al. (2013).

8.2.3.2 Stratospheric Ozone and Water Vapour

Stratospheric ozone has experienced significant depletion since the 1960s due to bromine and chlorine-containing compounds (Solomon, 1999), leading to an estimated global decrease of stratospheric ozone of 5% between the 1970s and the mid-1990s, the decrease being largest over Antarctica (Fioletov et al., 2002). Most of the ozone loss is associated with the long-lived bromine and chlorine containing compounds (chlorofluorocarbons and substitutes) released by human activities, in addition to nitrous oxide. This is in addition to a background level of natural emissions of short-lived halogens from oceanic and volcanic sources.

With the advent of the Montreal Protocol and its amendments, emissions of CFCs and replacements have strongly declined (Montzka et al., 2011) and signs of ozone stabilization and even possibly recovery have already occurred (Mader et al., 2010; Salby et al., 2012). A further consequence is that N₂O emissions (Section 8.2.3.4) likely dominate all other emissions in terms of ozone depleting potential (Ravishankara et al., 2009). Chemistry-climate models with resolved stratospheric chemistry and dynamics recently predicted an estimated global mean total ozone column recovery to 1980 levels to occur in 2032 (multi-model mean value, with a range of 2024 to 2042) under the A1B scenario (Eyring et al., 2010a). Increases in the stratospheric burden and acceleration of the stratospheric circulation leads to an increase in the stratosphere-troposphere flux of ozone (Shindell et al., 2006c; Grewe, 2007; Hegglin and Shepherd, 2009; Zeng et al., 2010). This is also seen in recent RCP8.5 simulations, with the impact of increasing tropospheric burden (Kawase et al., 2011; Lamarque et al., 2011). However, observationally-based estimates of recent trends in age of air (Engel et al., 2009; Stiller et al., 2012) do not appear to be consistent with the acceleration of the stratospheric circulation found in model simulations, possibly due to inherent difficulties with extracting trends from SF₆ observations (Garcia et al., 2011).

Oxidation of methane in the stratosphere (see Section 8.2.3.3) is a significant source of water vapour and hence the long-term increase in methane leads to an anthropogenic forcing (see Section 8.3) in the stratosphere. Stratospheric water vapour abundance increased by an average of 1.0 ± 0.2 (one-sigma) ppm during 1980–2010, with methane oxidation explaining approximately 25% of this increase (Hurst et al., 2011). Other factors contributing to the long-term change in water vapour include changes in tropical tropopause temperatures (see Section 2.2.2.1).

8.2.3.3 Methane

The surface mixing ratio of CH₄ has increased by 150% since pre-industrial times (Sections 2.2.1.1.2 and 8.3.2.2) with some projections indicating a further doubling by 2100 (Figure 8.5). Bottom-up estimates of present CH₄ emissions range from 479 to 706 TgCH₄ yr⁻¹ (see Table 6.7), while a recent top-down estimate with uncertainty analysis is 554 ± 56 TgCH₄ yr⁻¹ (Prather et al., 2012). All quoted uncertainties in Section 8.2.3.3 are defined as one-sigma.

[INSERT FIGURE 8.5 HERE]

Figure 8.5: Time evolution of global-averaged mixing ratio of long-lived species 1850–2100 following each RCP; blue (RCP2.6), light blue (RCP4.5), orange (RCP6.0) and red (RCP8.5). Based on Meinshausen et al. (2011b).

The main sink of CH₄ is through its reaction with the hydroxyl radical OH in the troposphere (Ehhalt and Heidt, 1973). A primary source of tropospheric OH is initiated by the photodissociation of O₃, followed by reaction with water vapour (creating sensitivity to humidity, cloud cover and solar radiation) (Levy, 1971; Crutzen, 1973). The other main source of OH is through secondary reactions (Lelieveld et al., 2008), although some of those reactions are still poorly understood (Paulot et al., 2009; Peeters et al., 2009; Taraborrelli et al., 2012). A recent estimate of the CH₄ tropospheric chemical lifetime with respect to OH constrained by methyl chloroform surface observations is 11.2 ± 1.3 years (Prather et al., 2012). In addition, bacterial uptake in soils provides an additional small, less constrained loss (Fung et al., 1991); estimated lifetime = 120 ± 24 years (Prather et al., 2012), with another small loss in the stratosphere (Ehhalt and Heidt, 1973); estimated lifetime = 150 ± 50 years (Prather et al., 2012). Halogen chemistry in the troposphere also contributes to some tropospheric methane loss (Allan et al., 2007), estimated lifetime = 200 ± 100 years (Prather et al., 2012).

The ACCMIP estimate for present CH₄ lifetime with respect to tropospheric OH varies quite widely (9.8 ± 1.6 years (Voulgarakis et al., 2013)), slightly shorter than ((Fiore et al., 2009); 10.2 ± 1.7 years), but quite shorter than the methylchloroform-based estimate of 11.2 ± 1.3 years (Prather et al., 2012). A partial explanation for the range in CH₄ lifetime changes can be found in the degree of representation of chemistry in chemistry-climate models. Indeed, Archibald et al. (2010) showed that the response of OH to increasing nitrogen oxides strongly depends on the treatment of hydrocarbon chemistry in a model. The impact on methane distribution in the ACCMIP simulations is however rather limited since most models prescribed methane as a time-varying lower-boundary mixing ratio (Lamarque et al., 2013).

The chemical coupling between OH and CH₄ leads to a significant amplification of an emission impact; i.e., increasing CH₄ emissions decreases tropospheric OH which in turn increases the CH₄ lifetime and therefore its burden. The OH-lifetime sensitivity for CH₄, $s_{OH} = -\delta \ln(OH)/\delta \ln(CH_4)$ was estimated in Chapter 4 of TAR to be 0.32, implying a 0.32% decrease in tropospheric mean OH (as weighted by CH₄ loss) for a 1% increase in CH₄. The Fiore et al. (2009) multi-model (12 models) study provides a slightly smaller value (0.28 ± 0.03). Holmes et al. (2013) gives a range 0.31 ± 0.04 by combining Fiore et al. (2009), Holmes et al. (2011) and three new model results (0.36, 0.31, 0.27). Only two ACCMIP models reported values (0.19 and 0.26; Voulgarakis et al., 2013). The projections of future CH₄ in Chapter 11 use the Holmes et al. (2013) range and uncertainty, which at the two-sigma level covers all but one model result. The feedback factor f , the ratio of the lifetime of a CH₄ perturbation to the lifetime of the total CH₄ burden, is calculated as $f = 1/(1-s)$. Other CH₄ losses, which are relatively insensitive to CH₄ burden, must be included so that $f = 1.34 \pm 0.06$, (slightly larger but within the range of the Stevenson et al. (2006) estimate of 1.29 ± 0.04 , based on 6 models), leading to an overall perturbation lifetime of 12.4 ± 1.4 years, which is used in calculations of metrics in Section 8.7. Additional details are provided in the Supplementary Material Section 8.SM.2.

8.2.3.4 Nitrous Oxide

Nitrous oxide (N₂O) in 2011 has a surface concentration 19% above its 1750 level (Sections 2.2.1.1.3 and 8.3.2.3). Increases in N₂O lead to depletion of mid- to upper-stratospheric ozone and increase in mid-latitude lower stratospheric ozone (as a result of increased photolysis rate from decreased ozone above). This impacts tropospheric chemistry through increase in stratosphere-troposphere exchange of ozone and odd nitrogen species and increase in tropospheric photolysis rates and OH formation (Prather and Hsu, 2010). Anthropogenic emissions represent around 30–45% of the present-day global total, and are mostly from agricultural and soil sources (Fowler et al., 2009) and fossil-fuel activities. Natural emissions come mostly from microbial activity in the soil. The main sink for N₂O is through photolysis and oxidation reactions in the stratosphere, leading to an estimated lifetime of 131 ± 10 years (Prather et al., 2012), slightly larger than previous estimates (Prather and Hsu, 2010; Montzka et al., 2011). The addition of N₂O to the atmosphere changes its own lifetime through feedbacks that couple N₂O to stratospheric NO_y and O₃ depletion (Prather, 1998; Ravishankara et al., 2009; Prather and Hsu, 2010); so that the lifetime of a perturbation is less than that of the total burden, 121 ± 10 years (one-sigma; Prather et al., 2012) and is used in calculations of metrics (Section 8.7).

8.2.3.5 Halogenated Species

Halogenated species can be powerful greenhouse gases. Those containing chlorine and bromine also deplete stratospheric ozone and are referred to as ozone depleting substances (ODSs). Most of those compounds do not have natural emissions and, because of the implementation of the Montreal Protocol and its amendments, total emissions of ODSs have sharply decreased since the 1990s (Montzka et al., 2011). For CFCs, PFCs and SF₆ the main loss is through photolysis in the stratosphere. The CFC substitutes (hydrochlorofluorocarbons, HCFCs, and hydrofluorocarbons, HFCs) are destroyed by OH oxidation in the troposphere. Their global concentration has steadily risen over the recent past (see Chapter 2, Section 2.2.1.1.4).

8.2.3.6 Aerosols

Aerosol particles are present in the atmosphere with size ranges from a few nanometres to tens of micrometres. They are the results of direct emission (primary aerosols: black carbon, organic carbon, sea salt, dust) into the atmosphere or as products of chemical reactions (secondary inorganic aerosols: sulphate, nitrate, ammonium; and secondary organic aerosols, SOA) occurring in the atmosphere. Secondary inorganic

aerosols are the products of reactions involving sulphur dioxide, ammonia and nitric oxide emissions. SOA are the result of chemical reactions of non-methane hydrocarbons (and their products) with the hydroxyl radical (OH), ozone, nitrate (NO₃) or photolysis (Hallquist et al., 2009). Thus although many hydrocarbons in the atmosphere are of biogenic origin, anthropogenic pollutants can have impacts on their conversion to SOA. There is tremendous complexity and still much uncertainty in the processes involved in the formation of secondary-organic aerosols (Hallquist et al., 2009; Carslaw et al., 2010). Additional information can be found in Section 7.3.2.

Once generated, the size and composition of aerosol particles can be modified by additional chemical reactions, condensation or evaporation of gaseous species and coagulation (Seinfeld and Pandis, 2006). It is this set of processes that defines their physical, chemical and optical properties, and hence their impact on radiation and clouds, with large regional and global differences (Section 7.3.3). Furthermore, their distribution is affected by transport and deposition, defining a residence time in the troposphere of usually a few days (Textor et al., 2006).

8.3 Present-Day Anthropogenic Radiative Forcing

Human activity has caused a variety of changes in different forcing agents in the atmosphere or land surface. A large number of greenhouse gases have had a substantial increase over the industrial era and some of these gases are entirely of anthropogenic origin. Atmospheric aerosols have diverse and complex influences on the climate. Human activity has modified the land cover and changed the surface albedo. Some of the gases and aerosols are directly emitted to the atmosphere whereas others are secondary products from chemical reactions of emitted species. The lifetime of these different forcing agents vary substantially. This section discusses all known anthropogenic forcing agents of non-negligible importance and their quantification in terms of RF or ERF based on changes in abundance over the 1750–2011 period.

In this section we determine the RFs for WMGHGs and heterogeneously distributed species in fundamentally different ways. As described in Box 8.2 the concentrations of WMGHGs can be determined from observations at a few surface sites. For the pre-industrial concentrations these are typically from trapped air in polar ice or firn (Chapter 2, Section 2.2.1). Thus the RFs from WMGHGs are determined entirely from observations (Section 8.3.2). In contrast we do not have sufficient pre-industrial or present day observations of heterogeneously distributed forcing agents (e.g., ozone and aerosols) to be able to characterise their RF; therefore we instead have to rely on chemistry-climate models (Sections 8.3.3 and 8.3.4).

8.3.1 Updated Understanding of the Spectral Properties of GHGs and Radiative Transfer Codes

RF estimates are performed with a combination of radiative transfer codes typical for GCMs as well as more detailed radiative transfer codes. Physical properties are needed in the radiative transfer codes such as spectral properties for gases. The HITRAN (High Resolution TRANsmission molecular absorption) database (Rothman, 2010) is widely used in radiative transfer models. Some researchers studied the difference among different editions of HITRAN databases for diverse uses (Feng et al., 2007; Kratz, 2008; Feng and Zhao, 2009; Fomin and Falaleeva, 2009; Lu et al., 2012). Model calculations have shown that modifications of the spectroscopic characteristics tend to have a modest effect on the determination of RF estimates of order 2–3% of the calculated RF attributed to the combined doubling of CO₂, N₂O and CH₄. These results showed that even the largest overall RF induced by differences among the HITRAN databases is considerably smaller than the range reported for the modelled RF estimates, thus, the line parameter updates to the HITRAN database are not a significant source for discrepancies in the RF calculations appearing in the IPCC reports. However, the more recent HITRAN dataset is still recommended as the HITRAN process offers internal verification and tends to progress closer to the best laboratory measurements. It is found that the differences among the water vapour, CO₂, O₃ etc. continuum absorption formulations tend to be comparable to the differences among the various HITRAN databases (Paynter and Ramaswamy, 2011); but use of the older Robert continuum formula produces significantly larger flux differences, thus, replacement of the older continuum is warranted (Kratz, 2008) and there are still numerous unresolved issues left in the continuum expression, especially related to shortwave radiative transfer (Shine et al., 2012). Differences in absorption data from various HITRAN versions are *very likely* a small contributor to the uncertainty in RF of GHGs.

Line-by-line (LBL) models using the HITRAN dataset as an input are the benchmark of radiative transfer models for GHGs. Some researchers compared different LBL models (Zhang et al., 2005; Collins et al., 2006) and line-wing cutoff, line-shape function and gas continuum absorption treatment effects on LBL calculations (Zhang et al., 2008; Fomin and Falaleeva, 2009). The agreement between LBL codes has been investigated in many studies and found to generally be within a few percent (e.g., Collins et al., 2006; Iacono et al., 2008; Forster et al., 2011a) and to compare well to observed radiative fluxes under controlled situations (Oreopoulos et al., 2012). Forster et al. (2011a) evaluated global mean radiatively important properties of chemistry climate models (CCMs) and found that the combined WMGHG global annual mean instantaneous RF at the tropopause is within 30% of LBL models for all CCM radiation codes tested. The accuracies of the LW RF due to CO₂ and tropospheric ozone increase are generally very good and within 10% for most of the participation models, but problems remained in simulating RF for stratospheric water vapour and ozone changes with errors between 3% and 200% compared to LBL models. Whereas the differences in the results from CCM radiation codes were large, the agreement among the LW LBL codes was within 5%, except for stratospheric water vapour changes.

Most intercomparison studies of the RF of greenhouse gases are for clear-sky and aerosol free conditions; the introduction of clouds would greatly complicate the targets of research and are usually omitted in the intercomparison exercises of GCM radiation codes and LBL codes (e.g., Collins et al., 2006; Iacono et al., 2008). It is shown that clouds can reduce the magnitude of radiative forcing due to greenhouse gases by about 25% (Forster et al., 2005; Worden et al., 2011; Zhang et al., 2011); but the influence of clouds on the diversity in RF is found to be within 5% in four detailed radiative transfer schemes with realistic cloud distributions (Forster et al., 2005). Estimates of GHG RF are based on the LBL codes or the radiative transfer codes compared and validated against LBL models and the uncertainty range from AR4 in the RF of GHG of 10% is retained. We underscore that uncertainty in RF calculations in many GCMs is substantially higher both due to radiative transfer codes and meteorological data such as clouds adopted in the simulations.

8.3.2 Well-mixed Greenhouse Gases

AR4 assessed the RF from 1750 to 2005 of the WMGHGs to be 2.63 W m⁻². The four most important gases were CO₂, CH₄, CFC-12 and N₂O in that order. Halocarbons, comprising chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons /HFCs), perfluorocarbons (PFCs) and SF₆, contributed 0.337 W m⁻² to the total. Uncertainties (90% confidence ranges) were assessed to be approximately 10% for the WMGHGs. The major changes to the science since AR4 are the updating of the atmospheric concentrations, the inclusion of new species (NF₃ and SO₂F₂) and discussion of ERF for CO₂. Since AR4 N₂O has overtaken CFC-12 as the third largest contributor to RF. The total WMGHG RF is now 2.83 (2.54–3.12) W m⁻².

The RFs in this section are derived from the observed differences in concentrations of the WMGHGs between 1750 and 2011. The concentrations of CO₂, CH₄ and N₂O vary throughout the pre-industrial era, mostly due to varying climate, with a possible small contribution from anthropogenic emissions (MacFarling Meure et al., 2006). These variations do not contribute to uncertainty in the RF as strictly defined here, but do affect the RF attribution to anthropogenic emissions. On centennial timescales, variations in late Holocene concentrations of CO₂ are around 10 ppm (see note to Chapter 2, Table 2.1), much larger than the uncertainty in the 1750 concentration. This would equate to a variation in the RF by 10%. For CH₄ and N₂O the centennial variations are comparable to the uncertainties in the 1750 concentrations and so do not significantly affect the estimate of the 1750 value used in calculating RF.

8.3.2.1 CO₂

The tropospheric mixing ratio of CO₂ has increased globally from 278 (276–280) ppm in 1750 to 390.5 (390.3–390.7) ppm in 2011 (Chapter 2, Section 2.2.1.1.1). Here we assess the RF due to changes in atmospheric concentration rather than attributing it to anthropogenic emissions. Chapter 6, Section 6.3.2.6 describes how only a fraction of the historical CO₂ emissions have remained in the atmosphere. The impact of land use change on CO₂ from 1850 to 2000 was assessed in AR4 to be 12–35 ppm (0.17–0.51 W m⁻²).

Using the formula from Table 3 of Myhre et al. (1998), and see Supplementary Material Table 8.SM.1, the CO₂ RF (as defined in Section 8.1) from 1750 to 2011 is 1.82 (1.63–2.01) W m⁻². The uncertainty is dominated by the radiative transfer modelling which is assessed to be 10% (Section 8.3.1). The uncertainty in the knowledge of 1750 concentrations contributes only 2% (see Supplementary Material Table 8.SM.2)

Table 8.2 shows the concentrations and RF in AR4 (2005) and 2011 for the most important WMGHGs. Figure 8.6 shows the time evolution of RF and its rate of change. Since AR4 the RF of CO₂ has increased by 0.16 W m⁻² and continues the rate noted in AR4 of almost 0.3 W m⁻² per decade. As shown in Figure 8.6(d) the rate of increase in the RF from the WMGHGs over the last 15 years has been dominated by CO₂. Since AR4 CO₂ has accounted for over 80% of the WMGHG RF increase. The interannual variability in the rate of increase in the CO₂ RF is largely due to variation in the natural land uptake whereas the trend is driven by increasing anthropogenic emissions (see Chapter 6, Figure 6.8 in Section 6.3.1).

[INSERT FIGURE 8.6 HERE]

Figure 8.6: (a) Radiative forcing from the major well-mixed greenhouse gases and groups of halocarbons from 1850 to 2011 (data from Table A.II.1.1 and Table A.II.4.16), (b) as (a) but with a logarithmic scale, (c) Radiative forcing from the minor well-mixed greenhouse gases from 1850 to 2011 (logarithmic scale). (d) Rate of change in forcing from the major well-mixed greenhouse gases and groups of halocarbons from 1850 to 2011.

As described in Section 8.1.1.3 CO₂ can also affect climate through physical effects on lapse rates and clouds, leading to an ERF that will be different from the RF. Analysis of CMIP5 models (Vial et al., 2013) found a large negative contribution to the ERF (20%) from the increase in land surface temperatures which was compensated for by positive contributions from the combined effects on water vapour, lapse rate, albedo and clouds. It is therefore not possible to conclude with the current information whether the ERF for CO₂ is higher or lower than the RF. Therefore we assess the ratio ERF/RF to be 1.0 and assess our uncertainty in the CO₂ ERF to be (–20% to 20%). We have medium confidence in this based on our understanding that the physical processes responsible for the differences between ERF and RF are small enough to be covered within the 20% uncertainty.

There are additional effects mediated through plant physiology, reducing the conductance of the plant stomata and hence the transpiration of water. Andrews et al. (2012b) find a physiological enhancement of the adjusted forcing by 3.5% due mainly to reductions in low cloud. This is smaller than a study with an earlier model by Doutriaux-Boucher et al. (2009) which found a 10% effect. Longer-term impacts of CO₂ on vegetation distributions also affect climate (O'ishi et al., 2009; Andrews et al., 2012b) but because of the longer timescale we choose to class these as feedbacks rather than rapid adjustments.

8.3.2.2 CH₄

Globally-averaged surface methane concentrations have risen from 722 ± 25 ppb in 1750 to 1803 ± 2 ppb by 2011 (Chapter 2, Section 2.2.1.1.2). Over that timescale the rise has been predominantly due to changes in anthropogenic-related methane. Anthropogenic emissions of other compounds have also affected methane concentrations by changing its removal rate (Section 8.2.3.3). Using the formula from Myhre et al. (1998) (see Supplementary Material Table 8.SM.1) the RF for methane from 1750 to 2011 is 0.48 ± 0.05 W m⁻², with an uncertainty dominated by the radiative transfer calculation. This increase of 0.01 W m⁻² since AR4 is due to the 29 ppb increase in the methane mixing ratio. This is much larger than the 11 ppb increase between TAR and AR4, and has been driven by increases in net natural and anthropogenic emissions, but the relative contributions are not well quantified. Recent trends in methane and their causes are discussed in Chapter 2, Sections 2.2.1.1.2 and Chapter 6, 6.3.3.1. Methane concentrations do vary with latitude and decrease above the tropopause, however this variation only contributes 2% to the uncertainty in RF (Freckleton et al., 1998).

In this section only the direct forcing from changing methane concentrations is addressed. Methane emissions can also have indirect effects on climate through impacts on CO₂, stratospheric water vapour, ozone, sulphate aerosol, and lifetimes of HFCs and HCFCs (Boucher et al., 2009; Shindell et al., 2009; Collins et al., 2010). Some of these are discussed further in Sections 8.3.3, 8.5.1 and 8.7.2.

8.3.2.3 N₂O

Concentrations of nitrous oxide have risen from 270 ± 7 ppb in 1750 to 324.2 ± 0.1 ppb in 2011, an increase of 5 ppb since 2005 (Chapter 2, Section 2.2.1.1.3). N_2O now has the third largest forcing of the anthropogenic gases, at 0.17 ± 0.03 $W m^{-2}$ where the uncertainty is due approximately equally to the pre-industrial concentration and radiative transfer. Only the direct RF from changing nitrous oxide concentrations is included. Indirect effects of N_2O emissions on stratospheric ozone are not taken into account here but are discussed briefly in Section 8.7.2.

8.3.2.4 Other WMGHGs

RFs of the other WMGHG are shown in Figure 8.6 (b and c) and Table 8.2. The contribution of groups of halocarbons to the rate of change of WMGHG RF is shown in Figure 8.6 (d). Between 1970 and 1990 halocarbons made a significant contribution to the rate of change of RF. Since the Montreal Protocol and its amendments, the rate of change of RF from halocarbons and related compounds has been much less, but still just positive (total RF of 0.360 $W m^{-2}$ in 2011 compared to 0.351 $W m^{-2}$ in 2005) as the growth of HCFCs, HFCs, PFCs, and other halogens (SF_6 , SO_2F_2 , NF_3) RFs (total 0.022 $W m^{-2}$ since 2005) more than compensates for the decline in the CFCs, CH_3CCl_3 and CCl_4 RFs (-0.013 $W m^{-2}$ since 2005). The total halocarbon RF is dominated by four gases, namely CFC-12, CFC-11, HCFC-22 and CFC-113 in that order. The indirect RF from the impacts of ODSs is discussed in 8.3.3.2.

8.3.2.4.1 CFCs and HCFCs

The CFCs and HCFCs contribute approximately 11% of the WMGHG RF. Although emissions have been drastically reduced for CFCs, their long lifetimes mean that reductions take substantial time to affect their concentrations. The RF from CFCs has declined since 2005 (mainly due to a reduction in the concentrations of CFC-11 and CFC-12), whereas the RF from HCFCs is still rising (mainly due to HCFC-22).

8.3.2.4.2 HFCs

The RF of HFCs is 0.02 $W m^{-2}$ and has close to doubled since AR4 (2005 concentrations). HFC-134a is the dominant contributor to RF of the HFCs with a RF of 0.01 $W m^{-2}$.

8.3.2.4.3 PFCs and SF_6

These gases have lifetimes of thousands to tens of thousands of years (Table 8.A.1); therefore emissions essentially accumulate in the atmosphere on the timescales considered here. CF_4 has a natural source and a 1750 concentration of 35 ppt (Chapter 2, Section 2.2.1.1.4). These gases currently contribute 0.01 $W m^{-2}$ of the total WMGHG RF.

8.3.2.4.4 New species

Nitrogen trifluoride (NF_3) is used in the electronics industry and sulfur hexafluoride (SF_6) is used as a fumigant. Both have rapidly increasing emissions and high GWPs, but currently contribute only around 0.0001 $W m^{-2}$ and 0.0003 $W m^{-2}$ to anthropogenic RF, respectively (Weiss et al., 2008; Andersen et al., 2009; Muhle et al., 2009).

Table 8.2: Present-day mole fractions (in ppt($pmol mol^{-1}$) except where specified) and RF (in $W m^{-2}$) for the WMGHGs. Concentration data are averages of NOAA and AGAGE observations where available. CO_2 concentrations are the average of NOAA and SIO. See Chapter 2, Table 2.1 for more details of the data sources. The data for 2005 (the time of the AR4 estimates) are also shown. Some of the concentrations vary slightly from those reported in AR4 due to averaging different data sources. Radiative efficiencies for the minor gases are given in Table 8.A.1. Uncertainties in the RF for all gases are dominated by the uncertainties in the radiative efficiencies. We assume the uncertainties in the radiative efficiencies to be perfectly correlated between the gases, and the uncertainties in the present day and 1750 concentrations to be uncorrelated.

Species	Concentrations (ppt)		Radiative forcing ^a ($W m^{-2}$)	
	2011	2005	2011	2005
CO_2 (ppm)	391 ± 0.2	379	1.82 ± 0.19	1.66
CH_4 (ppb)	1803 ± 2	1774	0.48 ± 0.05	0.47^c
N_2O (ppb)	324 ± 0.1	319	0.17 ± 0.03	0.16
CFC-11	238 ± 0.8	251	0.062	0.065
CFC-12	528 ± 1	542	0.17	0.17

CFC-13	2.7		0.0007	
CFC-113	74.3±0.1	78.6	0.022	0.024
CFC-115	8.37	8.36	0.0017	0.0017
HCFC-22	213±0.1	169	0.0447	0.0355
HCFC-141b	21.4±0.1	17.7	0.0034	0.0028
HCFC-142b	21.2±0.2	15.5	0.0040	0.0029
HFC-23	24.0±0.3	18.8	0.0043	0.0034
HFC-32	4.92	1.15	0.0005	0.0001
HFC-125	9.58±0.04	3.69	0.0022	0.0008
HFC-134a	62.7±0.3	34.3	0.0100	0.0055
HFC-143a	12.0±0.1	5.6	0.0019	0.0009
HFC-152a	6.4±0.1	3.4	0.0006	0.0003
SF ₆	7.28±0.03	5.64	0.0041	0.0032
SO ₂ F ₂	1.71	1.35	0.0003	0.0003
NF ₃	0.6	0.3	0.0001	0.0001
CF ₄	79.0±0.1	75.0	0.0040	0.0036
C ₂ F ₆	4.16±0.02	3.66	0.0010	0.0009
CH ₃ CCl ₃	6.32±0.07	18.32	0.0004	0.0013
CCl ₄	85.8±0.8	93.1	0.0146	0.0158
CFCs			0.263±0.026 ^b	0.273 ^c
HCFCs			0.052±0.005	0.041
Montreal Gases ^d			0.330±0.033	0.331
Total halogens			0.360±0.036	0.351 ^f
Total			2.83±0.029	2.64

Notes:

(a) Pre-industrial values are zero except for CO₂ (278 ppm), CH₄ (722 ppb), N₂O (270 ppb), and CF₄ (40 ppt).

(b) Total includes 0.007 W m⁻² to account for CFC-114, Halon-1211 and Halon-1301.

(c) Total includes 0.009 W m⁻² forcing (as in AR4) to account for CFC-13, CFC-114, CFC-115, Halon-1211 and Halon-1301.

(d) Defined here as CFCs+HCFCs+CH₃CCl₃+CCl₄.

(e) The value for the 1750 methane concentrations has been updated from AR4 in this report, thus the 2005 methane RF is slightly lower than reported in AR4.

(f) Estimates for halocarbons given in the table may have changed from estimates reported in AR4 due to updates in radiative efficiencies and concentrations.

8.3.3 Ozone and Stratospheric Water Vapour

Unlike for the WMGHGs, the estimate of the tropospheric and stratospheric ozone concentration changes are almost entirely model based for the full pre-industrial to present-day interval (though, especially for the stratosphere, more robust observational evidence on changes is available for recent decades, see Chapter 2, Section 2.2).

AR4 assessed the RF (for 1750 to 2005) from tropospheric ozone to be 0.35 W m⁻² from multi-model studies with a high 95th percentile of 0.65 W m⁻² to allow for the possibility of model overestimates of the pre-industrial tropospheric ozone levels. The stratospheric ozone RF was assessed from observational trends from 1979 to 1998 to be -0.05 ± 0.1 W m⁻² with the 90% confidence range increased to reflect uncertainty in the trend prior to 1979 and since 1998. In AR4 the RF from stratospheric water vapour generated by methane oxidation was assessed to be $+0.07 \pm 0.05$ W m⁻² based on Hansen et al. (2005).

Since AR4 there have been a few individual studies of tropospheric or stratospheric ozone forcing (Shindell et al., 2006a; Shindell et al., 2006c; Skeie et al., 2011a; Sovde et al., 2011; Shindell et al., 2013a), a multi-model study of stratospheric ozone radiative forcing in the 2010 WMO stratospheric ozone assessment (Forster et al., 2011b), and the ACCMIP multi-model study of tropospheric and tropospheric + stratospheric chemistry models (Conley et al., 2013; Stevenson et al., 2013). There is now greater understanding of how

tropospheric ozone precursors can affect stratospheric ozone, and how ODSs can affect tropospheric ozone (Shindell et al., 2013a). We assess the total ozone RF to be $+0.35$ (0.15 – 0.55) W m^{-2} . This can be split according to altitude or by emitted species (Shindell et al., 2013a). We assess these contributions to be 0.40 (0.20 – 0.60) W m^{-2} for ozone in the troposphere and -0.05 ± 0.10 W m^{-2} for ozone in the stratosphere based on the studies presented in Table 8.3. Alternatively the contributions to the total ozone forcing can be attributed as 0.50 (0.30 – 0.70) W m^{-2} from ozone precursors and -0.15 (-0.3 to 0.0) W m^{-2} from the effect of ODSs. The value attributed to ODSs is assessed to be slightly smaller in magnitude than in the two studies quoted in Table 8.3 (Sovde et al., 2011; Shindell et al., 2013a) since the models used for these had stratospheric ozone RFs with higher magnitudes than the ACCMIP mean (Conley et al., 2013). Differences between the ERFs and RFs for tropospheric and stratospheric ozone are likely to be small compared to the uncertainties in the RFs (Shindell et al., 2013b), so the assessed values for the ERFs are the same as those for the RFs.

The influence of climate change is typically included in ozone RF estimates as those are based on modelled concentration changes, but the available literature provides insufficient evidence for the sign and magnitude of the impact and we therefore refrain from giving an estimate except to assess that it is very likely to be smaller than the overall uncertainty in the total RF. Unlike the WMGHGs, there are significant latitudinal variations in the RFs from changes in tropospheric and stratospheric ozone. The implications of inhomogeneous RFs are explored in more detail in Section 8.6.

There has been one study since AR4 (Myhre et al., 2007) on the radiative forcing from water vapour formed from the stratospheric oxidation of methane (Section 8.3.3.3). This is consistent with the AR4 value and so has not led to any change in the recommended value of 0.07 (0.02 – 0.12) W m^{-2} since AR4.

8.3.3.1 Tropospheric Ozone

Ozone is formed in the troposphere by photochemical reactions of natural and anthropogenic precursor species (Section 8.2.3.1). Changes in ozone above the tropopause due to emissions of stratospheric ozone depleting substances (ODSs) can also affect ozone in the troposphere either by transport across the tropopause or modification of photolysis rates. Changes in climate have also affected tropospheric ozone concentrations (medium evidence, low agreement) through changes in chemistry, natural emissions and transport from the stratosphere (Isaksen et al., 2009).

The most recent estimates of tropospheric ozone radiative forcing come from multi-model studies under ACCMIP (Conley et al., 2013; Lamarque et al., 2013; Stevenson et al., 2013). The model ensemble only reported 1850–2000 RFs (0.34 W m^{-2}) so the single model results from Skeie et al. (2011a) were used to expand the timespan to 1750–2010, adding 0.04 W m^{-2} , and 0.02 W m^{-2} to account for the periods 1750–1850 and 2000–2010 respectively. The best estimate of tropospheric ozone RF taking into account the ACCMIP models and the Sovde et al. (2011) results (the Skeie et al. (2011a) and Shindell et al. (2013a) models are included in ACCMIP) is 0.40 (0.20 – 0.60) W m^{-2} . The quantifiable uncertainties come from the inter-model spread, (-0.11 to 0.11 W m^{-2}) and the differences between radiative transfer models (-0.07 to 0.07 W m^{-2}); all 5–95% confidence interval. Additional uncertainties arise from the lack of knowledge of pre-industrial emissions, and the representation of chemical and physical processes beyond those included in the current models. The tropospheric ozone RF is sensitive to the assumed ‘pre-industrial’ levels. As described in Section 8.2.3.1 very limited late 19th and early 20th century observations of surface ozone concentrations are lower than the ACCMIP models for the same period, however we assess that those observations are very uncertain. Skeie et al. (2011a) and Stevenson et al. (2013) increase their uncertainty ranges to 30% for 1 standard deviation which is equivalent to (-50% to $+50\%$) for the 5–95% confidence range and we adopt this for AR5. The overall *confidence* in the tropospheric ozone RF is assessed as *high*.

Because we have low confidence in the pre-industrial ozone observations, and these were extremely limited in spatial coverage, it is not possible to calculate a purely observationally-based ozone RF. However, modern observations can be used to assess the performance of the chemistry models. Bowman et al. (2013) used satellite retrievals from the TES instrument to constrain the RF from the ACCMIP models. This reduced the inter-model uncertainty by 30%, however we still maintain overall the (-50% to $+50\%$) 5–95% confidence range for AR5.

The time evolution of the tropospheric ozone forcing is shown in Figure 8.7. There is a noticeable acceleration in the forcing after 1950 and a deceleration in the 1990s reflecting the time evolution of anthropogenic precursor emissions. Observational evidence for trends in ozone concentrations is discussed in Chapter 2, Section 2.2.2.3.

It can be useful to calculate a normalised radiative forcing (NRF) which is a radiative forcing per change in ozone column in $\text{W m}^{-2} \text{DU}^{-1}$ or W mol^{-1} . This is only an approximation as the NRF is sensitive to the vertical profile of the ozone change and to the latitudinal profile to a smaller extent. From Table 8.3 we assess the NRF to be 0.042 (0.037 – 0.047) $\text{W m}^{-2} \text{DU}^{-1}$ (94 (83 – 105) W mol^{-1}) similar to the value of 0.042 $\text{W m}^{-2} \text{DU}^{-1}$ (94 W mol^{-1}) in TAR (Ramaswamy et al., 2001).

A small number of studies have looked at attributing the ozone changes among the anthropogenically emitted species. Søvde et al. (2011) report a tropospheric ozone RF of 0.38 W m^{-2} , 0.44 W m^{-2} from ozone precursors and -0.06 W m^{-2} from the impact of stratospheric ozone depletion on the troposphere. Shindell et al. (2013a) also calculate that ODSs are responsible for about -0.06 W m^{-2} of the tropospheric ozone RF, and ozone precursors for about 0.41 W m^{-2} . Six of the models in Stevenson et al. (2013) and Shindell et al. (2009) performed experiments to attribute the ozone RF to the individual precursor emissions. An average of these seven model results leads to attributions of 0.24 ± 0.13 W m^{-2} due to methane emissions, 0.14 ± 0.09 W m^{-2} from NO_x emissions, 0.07 ± 0.03 W m^{-2} from CO, and 0.04 ± 0.03 W m^{-2} from VOCs. These results were calculated by reducing the precursor emissions individually from 2000 to pre-industrial levels. The results were scaled by the total ozone RFs attributed to ozone precursors (0.50 W m^{-2}) to give the contributions to the full 1750–2010 RF. Due to the non-linearity of the chemistry an alternative method of starting from pre-industrial conditions and increasing precursor emissions singly may give a different result. Note that as well as inducing an ozone RF, these ozone precursor species can also strongly affect the concentrations of methane and aerosols, adding extra terms (both positive and negative) to their total indirect forcings. The contributions to the 1750–2010 methane RF are again based on Stevenson et al. (2013) and Shindell et al. (2009). The Stevenson et al. (2013) values are for 1850–2000 rather than 1750 to 2011 so for these we distribute the methane RF for 1750–1850 and 2000–2011 (0.06 W m^{-2}) by scaling the methane and CO contributions (assuming these were the most significant contributors over those time periods). This gives contributions of 0.58 ± 0.08 , -0.29 ± 0.18 , 0.07 ± 0.02 and 0.02 ± 0.02 W m^{-2} for changes from historical to present day emissions of methane (inferred emissions), NO_x , CO and VOCs respectively (uncertainties are 5–95% confidence intervals). The difference between the total methane RF attributed to ozone precursors here (0.38 W m^{-2}) and the value calculated from methane concentration changes in Table 8.2 (0.48 W m^{-2}) is due to non-linearities in the methane chemistry because large single-step changes were used. To allow an easier comparison between the concentration-based and emission-based approaches in Section 8.5.1 the non-linear term ($+0.1$ W m^{-2}) is distributed between the 4 emitted species according to their absolute magnitude so that they total 0.48 W m^{-2} . The scaled results still lie within the uncertainty bounds of the values quoted above. The impact of climate change over the historical period on methane oxidation is not accounted for in these calculations.

Tropospheric ozone can also affect the natural uptake of carbon dioxide by decreasing plant productivity (see Chapter 6, Sections 6.4.8.3 and 8.2.3.1) and it is found that this indirect effect could have contributed to the total CO_2 RF (Section 8.3.2.1; Sitch et al., 2007), roughly doubling the overall RF attributed to ozone precursors. While we assess there to be robust evidence of an affect we make no assessment of the magnitude due to lack of further corroborating studies.

[INSERT FIGURE 8.7 HERE]

Figure 8.7: Time evolution of the radiative forcing from tropospheric and stratospheric ozone from 1750 to 2010. Tropospheric ozone data are from Stevenson et al. (2013) scaled to give 0.40 W m^{-2} at 2010. The stratospheric ozone RF follow the functional shape of the Effective Equivalent Stratospheric Chlorine assuming a 3 year age of air (Daniel et al., 2010) scaled to give -0.05 W m^{-2} at 2010.

Table 8.3: Contributions of tropospheric and stratospheric ozone changes to radiative forcing from 1750 to 2010.

Troposphere			NRF $\text{m W m}^{-2} \text{DU}^{-1}$	Stratosphere		
LW	SW	Total		LW	SW	Total

AR4 (Forster et al., (2007)			0.35 (0.25 to 0.65)				-0.05 (-0.15 to 0.05)
Shindell et al. (2013a) ^f			0.33 (0.31 to 0.35)				-0.08 (-0.10 to -0.06)
WMO (Forster et al., 2011b)							-0.03 ^a (-0.23 to +0.17) +0.03 ^b
Søvde et al. (2011)			0.45 ^c 0.38 ^d	40 39			-0.12 -0.12
Skeie et al. (2011a)			0.41 (0.21 to 0.61)	38			
ACCMIP ^e	0.33 (0.24 to 0.42)	0.08 (0.06 to 0.10)	0.41 (0.21 to 0.61)	42 (37 to 47)	-0.13 (-0.26 to 0)	0.11 (0.03 to 0.19)	-0.02 (-0.09 to 0.05)

Notes:

(a) From multi-model results.

(b) From Randel and Wu (2007) observation-based data set.

(c) Using the REF chemistry.

(d) Using the R2 chemistry.

(e) The ACCMIP tropospheric ozone RFs are from Stevenson et al. (2013). The stratospheric ozone values are from Conley et al. (2013) calculations for 1850–2005 disregarding the MOCAGE model which showed excessive ozone depletion.

(f) Only the GISS-E2-R results (including bias correction) from the Shindell et al. (2013a) study are shown here rather than the multi-model result presented in that paper.

8.3.3.2 Stratospheric Ozone

The decreases in stratospheric ozone due to anthropogenic emissions of ODSs have a positive RF in the short wave (increasing the flux into the troposphere) and a negative radiative forcing in the long-wave. This leaves a residual forcing that is the difference of two larger terms. In the lower stratosphere the long wave effect tends to be larger, whereas in the upper stratosphere the short wave dominates. Thus whether stratospheric ozone depletion has contributed an overall net positive or negative forcing depends on the vertical profile of the change (Forster and Shine, 1997). WMO (2011) assessed the RF from 1979 to 2005 from observed ozone changes (Randel and Wu, 2007) and results from 16 models for the 1970s average to 2004. The observed and modelled mean ozone changes gave RF values of different signs (see Table 8.3). Negative net RFs arise from models with ozone decline in the lowermost stratosphere, particularly at or near the tropopause.

The ACCMIP study also included some models with stratospheric chemistry (Conley et al., 2013). One model in that study stood out as having excessive ozone depletion. Removing that model leaves a stratospheric ozone RF of -0.02 (-0.09 to 0.05) W m^{-2} . These results are in good agreement with the model studies from WMO (2011). Forster et al. (2007) in AR4 calculated a forcing of -0.05 W m^{-2} from observations over the period 1979–1998 and increased the uncertainty to 0.10 W m^{-2} to encompass changes between the pre-industrial period and 2005. The RF from stratospheric ozone due to changes in emissions of ozone precursors and ODSs is here assessed to be -0.05 (-0.15 to 0.05) taking into account all the studies listed in Table 8.3. This is in agreement with AR4 although derived from different data. The timeline of stratospheric ozone forcing is shown in Figure 8.7, making the assumption that it follows the trajectory of the changes in EESC. It reaches a minimum in the late 1990s and starts to recover after that.

The net global RF from ODSs taking into account the compensating effects on ozone and their direct effects as WMGHGs is 0.18 (0.03 – 0.33) W m^{-2} . The patterns of RF for these two effects are different so the small net global RF comprises areas of positive and negative RF.

8.3.3.3 Stratospheric Water Vapour

Stratospheric water vapour is dependent upon the amount entering from the tropical troposphere and from direct injection by volcanic plumes (Joshi and Jones, 2009) and aircraft, and the *in situ* chemical production

from the oxidation of methane and hydrogen. This contrasts with tropospheric water vapour which is almost entirely controlled by the balance between evaporation and precipitation (see FAQ 8.1). We consider trends in the transport (for instance due to the Brewer-Dobson circulation or tropopause temperature changes) to be climate feedback rather than a forcing so the anthropogenic RFs come from oxidation of methane and hydrogen, and emissions from stratospheric aircraft.

Myhre et al. (2007) used observations of the vertical profile of methane to deduce a contribution from oxidation of anthropogenic methane of 0.083 W m^{-2} which compares with the value of 0.07 W m^{-2} from calculations in a 2D model in Hansen et al. (2005). Both these values are consistent with AR4 which obtained the stratospheric water vapour forcing by scaling the methane direct forcing by 15%. Thus the time evolution of this forcing is also obtained by scaling the methane forcing by 15%. The best estimate and uncertainty range from AR4 of $0.07 (0.02\text{--}0.12) \text{ W m}^{-2}$ remain unchanged and the large uncertainty range is due to large differences found in the intercomparison studies of radiative transfer modelling for changes in stratospheric water vapour (see Section 8.3.1).

RF from the current aircraft fleet through stratospheric water vapour emissions is very small. Wilcox et al. (2012) estimate a contribution from civilian aircraft in 2005 of $0.0009 (0.0003\text{--}0.0013) \text{ W m}^{-2}$ with high confidence in the upper limit. Water vapour emissions from aircraft in the troposphere also contribute to contrails which are discussed in Section 8.3.4.5.

8.3.4 Aerosols and Cloud Effects

8.3.4.1 Introduction and Summary of AR4

In AR4 (Forster et al., 2007), RF estimates were provided for three aerosol effects. These were the RF of aerosol-radiation interaction (previously denoted as direct aerosol effect), RF of the aerosol-cloud interaction (previously denoted as the cloud albedo effect), and the impact of BC on snow and ice surface albedo. See Chapter 7 and Figure 7.3 for an explanation of the change in terminology between AR4 and AR5. The RF due to aerosol-radiation interaction is scattering and absorption of shortwave and longwave radiation by atmospheric aerosols. Several different aerosol types from various sources are present in the atmosphere (see Section 8.2). Most of the aerosols primarily scatter solar radiation, but some components absorb solar radiation to various extents with black carbon as the most absorbing component. RF of aerosols in the troposphere is often calculated at the TOA since it is similar to tropopause values (Forster et al., 2007). A best estimate RF of $-0.5 \pm 0.4 \text{ W m}^{-2}$ was given in AR4 for the change in the net aerosol-radiation interaction between 1750 and 2005 and a medium to low level of scientific understanding (LOSU).

An increase in the hygroscopic aerosol abundance may enhance the concentration of cloud condensation nuclei (CCN). This may increase the cloud albedo and under the assumption of fixed cloud water content this effect was given a best estimate of -0.7 W m^{-2} (range from -1.8 to -0.3) in AR4 and a low LOSU.

Black carbon in the snow or ice can lead to a decrease of the surface albedo. This leads to a positive RF. In AR4 this mechanism was given a best RF estimate of $0.1 \pm 0.1 \text{ W m}^{-2}$ and a low LOSU.

Impacts on clouds from the ERF of aerosol-cloud interaction (including both effects previously denoted as cloud lifetime and cloud albedo effect) and the ERF of aerosol-radiation interaction (including both effects previously denoted as direct aerosol effect and semi-direct effect) were not strictly in accordance with the RF concept, because they involve tropospheric changes in variables other than the forcing agent at least in the available model estimates, so no best RF estimates were provided in AR4 (see Section 8.1). However, the ERF of aerosol-cloud and aerosol-radiation interactions were included in the discussion of total aerosol effect in Chapter 7 in AR4 (Denman et al., 2007). The mechanisms influenced by anthropogenic aerosol including the aerosol cloud interactions are discussed in detail in this assessment in Chapter 7, Section 7.5 and summarized in the subsections below.

8.3.4.2 RF of the Aerosol-Radiation Interaction by Component

Based on a combination of global aerosol models and observation-based methods, the best RF estimate of the aerosol-radiation interaction in AR5 is $-0.35 (-0.85 \text{ to } +0.15) \text{ W m}^{-2}$ (see Chapter 7, Section 7.5). This

estimate is thus smaller in magnitude than in AR4, however; with larger uncertainty range. Overall, the estimate compared to AR4 is more robust since the agreement between estimates from models and observation-based methods is much greater (see Chapter 7, Section 7.5). The larger range arises primarily from analysis by observational based methods (see Chapter 7, Section 7.5).

The main source of the model estimate is based on updated simulations in AeroCom (Myhre et al., 2013), which is an intercomparison exercise of a large set of global aerosol models that includes extensive evaluation against measurements. The assessment in Chapter 7 relies to a large extent on this study for the separation in the various aerosol components, except for BC where the assessment in Chapter 7 relies in addition on Bond et al. (2013). The RF of aerosol-radiation interaction is separated into 7 components in this report; namely sulphate, BC from fossil fuel and biofuel, OA from fossil fuel and biofuel, BC and OA combined from biomass burning (BB), nitrate, SOA, and mineral dust. BC and OA from biomass burning are combined due to the joint sources, whereas treated separately for fossil fuel and biofuel since there is larger variability in the ratio of BC to OA in the fossil fuel and biofuel emissions. This approach is consistent with TAR and AR4. Table 8.4 compares the best estimates of RF due to aerosol-radiation interaction for various components in this report with values in SAR, TAR and AR4. In magnitude the sulphate and BC from use of fossil fuel and biofuel dominate. It is important to note that the BB RF is small in magnitude but consists of larger, offsetting terms in magnitude from OA and BC (see Chapter 7, Section 7.5.2). Changes in the estimates of RF due to aerosol-radiation interaction of the various components have been rather modest compared to AR4, except for BC from fossil fuel and biofuel (see Chapter 7, Section 7.5). SOA is a new component compared to AR4. Anthropogenic SOA precursors contribute only modestly to the anthropogenic change in SOA. The increase in SOA is mostly from biogenic precursors and enhanced partitioning of SOA into existing particles from anthropogenic sources and changes in the atmospheric oxidation (Carlton et al., 2010). This change in SOA is therefore of anthropogenic origin, but natural emission of SOA precursors are important (Hoyle et al., 2011).

Note that the best estimate and the uncertainty for the total is not equal to the sum of the aerosol components since the total is estimated based on combination of methods (models and observation-based methods), whereas the estimates for the components rely mostly on model estimates.

Table 8.4: Global and annual mean RF due to aerosol-radiation interaction between 1750 and 2011 of 7 aerosol components for AR5. Values and uncertainties from SAR, TAR, AR4 and AR5 are provided when available. Note that for SAR, TAR and AR4 the end year is somewhat different than for AR5 with 1993, 1998 and 2005, respectively.

	Global Mean Radiative Forcing (W m^{-2})			
	SAR	TAR	AR4	AR5
Sulphate aerosol	-0.40 (-0.80 to -0.20)	-0.40 (-0.80 to -0.20)	-0.40 (-0.60 to -0.20)	-0.40 (-0.60 to -0.20)
BC aerosol from fossil fuel and biofuel	+0.10 (+0.03 to +0.30)	+0.20 (+0.10 to +0.40)	+0.20 (+0.05 to +0.35)	+0.40 (+0.05 to +0.80)
Primary OA aerosol from fossil fuel and biofuel	Not estimated	-0.10 (-0.30 to -0.03)	-0.05 (0.00 to -0.10)	-0.09 (-0.16 to -0.03)
Biomass burning	-0.20 (-0.60 to -0.07)	-0.20 (-0.60 to -0.07)	+0.03(-0.09 to +0.15)	-0.0 (-0.20 to +0.20)
Secondary organic aerosols	Not estimated	Not estimated	Not estimated	-0.03 (-0.27 to +0.20)
Nitrate	Not estimated	Not estimated	-0.10 (-0.20 to 0.00)	-0.11 (-0.30 to -0.03)
Dust	Not estimated	-0.60 to +0.40	-0.10 (-0.30 to +0.10)	-0.10 (-0.30 to +0.10)
Total	Not estimated	Not estimated	-0.50 (-0.90 to -0.10)	-0.35 (-0.85 to +0.15)

The RF due to aerosol-radiation interaction during some time periods is more uncertain than the current RF. Improvements in the observations of aerosols have been substantial with availability of remote sensing from the ground-based optical observational network AERONET and the launch of the MODIS and MISR instruments (starting in 2000) as well as other satellite data. This has contributed to constraining the current RF using aerosol observations. The aerosol observations are very limited backward in time, although there is growing constraint coming from new ice and lake core records, and uncertainties in the historical emission of aerosols and their precursors used in the global aerosol modeling are larger than for current conditions.

Emissions of carbonaceous aerosols are particularly uncertain in the 1800s due to a significant biofuel source in this period, in contrast to the SO₂ emissions that were very small until the end of the 1800s. The uncertainty in the biomass burning emissions also increases backward in time. Note that, for 1850, the biomass burning emissions from Lamarque et al. (2010) are quite different from the previous estimates, but RF due to aerosol-radiation interaction is close to zero for this component. Figure 8.8 shows an example of the time evolution of the RF due to aerosol-radiation interaction as a total and separated into six aerosol components. From 1950 to 1990 there was a strengthening of the total RF due to aerosol-radiation interaction, mainly due to a strong enhancement of the sulphate RF. After 1990 the change has been small with even a weakening of the RF due to aerosol-radiation interaction, mainly due to a stronger BC RF as a result of increased emissions in East and South East Asia.

[INSERT FIGURE 8.8 HERE]

Figure 8.8: Time evolution of RF due to aerosol-radiation interaction and BC on snow and ice. Multi-model results for 1850, 1930, 1980, and 2000 from ACCMIP for aerosol-radiation interaction (Shindell et al., 2013c) and BC on snow and ice (Lee et al., 2013) are combined with higher temporal-resolution results from the GISS-E2 and Oslo-CTM2 models (aerosol-radiation interaction) and Oslo-CTM2 (BC on snow and ice). Uncertainty ranges (5–95%) for year 2010 are shown with vertical lines. Values next to the uncertainty lines are for cases where uncertainties go beyond the scale. The total includes the RF due to aerosol-radiation interaction for six aerosol components and RF due to BC on snow and ice. All values have been scaled to the best estimates for 2011 given in Table 8.4. Note that time evolution for mineral dust is not included and the total RF due to aerosol-radiation interaction is estimated based on simulations of the six other aerosol components.

8.3.4.3 *Aerosol Cloud Interactions*

The radiative forcing by aerosol effects on cloud albedo was previously referred to as the Twomey or cloud albedo effect (see Chapter 7, Section 7.1). Although this RF can be calculated, no estimate of this forcing is given since it has heuristic value only and does not simply translate to the ERF due to aerosol-cloud interaction. The total aerosol ERF, namely ERF due to aerosol-radiation and aerosol-cloud interactions (excluding BC on snow and ice) provided in Chapter 7 is estimated with a 5–95% uncertainty between -0.1 and -1.9 W m^{-2} with a most likely value of -0.9 W m^{-2} [medium confidence]. The likely range of this forcing is between -0.4 and -1.5 W m^{-2} . The estimate of ERF due to aerosol-radiation and aerosol-cloud interaction is lower (i.e., less negative) than the corresponding AR4 RF estimate of -1.2 W m^{-2} because the latter was mainly based on GCM studies that did not take secondary processes (such as aerosol effects on mixed-phase and/or convective clouds and effects on longwave radiation) into account. This new best estimate of ERF due to aerosol-radiation and aerosol-cloud interaction is also consistent with the studies allowing cloud-scale processes and related responses and with the lower estimates of this forcing inferred from satellite observations.

One reason an expert judgment estimate of ERF due to aerosol-radiation and aerosol-cloud interaction is provided rather than ERF due to aerosol-cloud interaction specifically is that the individual contributions are very difficult to disentangle. These contributions are the response of processes that are the outputs from a system that is constantly readjusting to multiple non-linear forcings. Assumptions of independence and linearity are required to deduce ERF due to aerosol-radiation interaction and ERF due to aerosol-cloud interaction (although there is no a priori reason why the individual ERFs should be simply additive). Under these assumptions, ERF due to aerosol-cloud interaction is deduced as the difference between ERF due to aerosol-radiation and aerosol-cloud interaction and ERF due to aerosol-radiation interaction alone. This yields an ERF due to aerosol-cloud interaction estimate of -0.45 W m^{-2} which is much smaller in magnitude than the -1.4 W m^{-2} median forcing value of the models summarized in Chapter 7, Figure 7.19 and is also smaller in magnitude than the AR4 estimates of -0.7 W m^{-2} for RF due to aerosol-cloud interaction.

8.3.4.4 *Black Carbon Deposition in Snow and Ice*

Because absorption by ice is very weak at visible and UV wavelengths, black carbon in snow makes the snow darker and increases absorption. This is not enough darkening to be seen by eye, but it is enough to be important for climate (WARREN and WISCOMBE, 1980; Clarke and Noone, 1985). Several studies since AR4 have re-examined this issue and find that the RF may be weaker than the estimates of Hansen and Nazarenko (2004) in AR4 (Flanner et al., 2007; Koch et al., 2009a; Rypdal et al., 2009; Lee et al., 2013). The anthropogenic BC on snow/ice is assessed to have a positive global and annual mean RF of $+0.04 \text{ W m}^{-2}$

m^{-2} , with a 0.02–0.09 W m^{-2} 5–95% uncertainty range (see further description in Chapter 7, Section 7.5.2.3). This RF has a 2–4 times larger global mean surface temperature change per unit forcing than a change in CO_2 .

In Figure 8.8, the time evolution of global mean RF due to BC on snow and ice is shown based on multi-model simulations in ACCMIP (Lee et al., 2013) for 1850, 1930, 1980 and 2000. The results show a maximum in the RF in 1980 with a small increase since 1850 and a 20% lower RF in 2000 compared to 1980. Those results are supported by observations. The BC concentration in the Arctic atmosphere is observed to be declining since 1990, at least in the Western Hemisphere portion (Sharma et al., 2004), which should lead to less deposition of BC on the snow surface. Surveys across Arctic during 1998 and 2005 to 2009 showed that the BC content of Arctic snow appears to be lower than in 1984 (Doherty et al., 2010) and found BC concentrations in Canada, Alaska, and the Arctic Ocean (e.g., Hegg et al., 2009), about a factor of 2 lower than measured in the 1980s (e.g., Clarke and Noone, 1985). Large-area field campaigns (Huang et al., 2011; Ye et al., 2012) found that the BC content of snow in northeast China is comparable to values found in Europe. The steep drop off in BC content of snow with latitude in northeast China may indicate that there is not much BC in the Arctic coming from China (Huang et al., 2011; Ye et al., 2012; Wang et al., 2013). The change in the spatial pattern of emission of BC is a main cause for the difference in RF due to BC on snow and ice compared to the BC from RF due to aerosol-radiation interaction over the last decades.

8.3.4.5 *Contrails and Contrail-Induced Cirrus*

AR4 assessed the RF of contrails (persistent linear contrails) as +0.01 (–0.007 to +0.02) W m^{-2} and provided no estimate for contrail induced cirrus. In AR5, Chapter 7 gives a best estimate of RF due to contrails of +0.01 (+0.005 to +0.03) W m^{-2} and an ERF estimate of the combined contrails and contrail induced cirrus of +0.05 (+0.02 to +0.15) W m^{-2} . Since AR4, the evidence for contrail induced cirrus has increased due to observational studies (see further details Chapter 7, Section 7.2.5).

8.3.5 *Land Surface Changes*

8.3.5.1 *Introduction*

Anthropogenic land cover change has a direct impact on the Earth radiation budget through a change in the surface albedo. It also impacts the climate through modifications in the surface roughness, latent heat flux, and river runoff. In addition, human activity may change the water cycle through irrigation and power plant cooling, and also generate direct input of heat to the atmosphere by consuming energy. Land use change, and in particular deforestation, also has significant impacts on WMGHG concentration, which are discussed in Chapter 6, Section 6.3.2.2. Potential geo-engineering techniques that aim at increasing the surface albedo are discussed in Chapter 7, Section 7.7.2.3.

AR4 referenced a large number of RF estimates resulting from a change in land cover albedo. It discussed the uncertainties due to the reconstruction of historical vegetation, the characterization of present day vegetation and the surface radiation processes. On this basis, AR4 gave a best estimate of RF relative to 1750 due to land use related surface albedo at $-0.2 \pm 0.2 \text{ W m}^{-2}$ with a level of scientific understanding at medium-low.

8.3.5.2 *Land Cover Changes*

Hurt et al. (2006) estimates that 42–68% of the global land surface was impacted by land use activities (crop, pasture, wood harvest) during the 1700–2000 period. Until the mid-20th century most land use change took place over the temperate regions of the Northern hemisphere. Since then, reforestation is observed in Western Europe, North America and China as a result of land abandonment and afforestation efforts, while deforestation is concentrated in the tropics. After a rapid increase of the rate of deforestation during the 1980s and 1990s, satellite data indicate a slowdown in the past decade (FAO, 2012).

Since AR4, Pongratz et al. (2008) and Kaplan et al. (2011) extended existing reconstructions on land use back in time to the past millennium, accounting for the progress of agriculture technique, historical events such as the black death or war invasions. As agriculture was already widespread over Europe and South-Asia

by 1750, the RF, that is defined with respect to this date, is weaker than the radiative flux change from the state of natural vegetation cover (see Figure 8.9). Deforestation in Europe and Asia during the last millennium led to a significant regional negative forcing. Betts et al. (2007) and Goosse et al. (2006) argue that it probably contributed to the ‘Little Ice Age’, together with natural solar and volcanic activity components, before the increase in greenhouse gas concentration led to temperatures similar to those experienced in the early part of the second millennium. There is still significant uncertainty in the anthropogenic land cover change, and in particular its time evolution (Gaillard et al., 2010).

8.3.5.3 Surface Albedo and Radiative Forcing

Surface albedo is the ratio between reflected and incident solar flux at the surface. It varies with the surface cover. Most forests are darker (i.e., lower albedo) than grasses and croplands, which are darker than barren land and desert. As a consequence, deforestation tends to increase the Earth albedo (negative RF) while cultivation of some bright surfaces may have the opposite effect. Deforestation also leads to a large increase in surface albedo in case of snow cover as low vegetation accumulates continuous snow cover more readily in early winter allowing it to persist longer in spring. This causes average winter albedo in deforested areas to be generally much higher than that of a tree-covered landscape (Bernier et al., 2011).

The pre-industrial impact of the Earth albedo increase due to land use change, including the reduced snow masking by tall vegetation, is estimated to be on the order of -0.05 W m^{-2} (Pongratz et al., 2009). Since then, the increase in world population and agriculture development led to additional forcing. Based on reconstruction of land use since the beginning of the industrial era, Betts et al. (2007) and Pongratz et al. (2009) computed spatially and temporally distributed estimates of the land use radiative forcing. They estimate that the shortwave flux change induced by the albedo variation, from fully natural vegetation state to 1992, is on the order of -0.2 W m^{-2} (range -0.24 to -0.21 W m^{-2}). The RF, defined with respect to 1750, is in the range -0.17 to -0.18 W m^{-2} . A slightly stronger value (-0.22 W m^{-2}) was found by Davin et al. (2007) for the period 1860–1992.

[INSERT FIGURE 8.9 HERE]

Figure 8.9: Change in TOA SW flux [W m^{-2}] following the change in albedo as a result of anthropogenic Land Use Change for three periods (1750, 1900 and 1992 from top to bottom). By definition, the RF is with respect to 1750, but some anthropogenic changes had already occurred in 1750. The lower right inset shows the globally averaged impact of the surface albedo change to the TOA SW flux (left scale) as well as the corresponding RF (right scale) after normalization to the 1750 value. Based on simulations by Pongratz et al. (2009).

In recent years, the availability of global scale MODIS data (Schaaf et al., 2002) has improved surface albedo estimates (Rechid et al., 2009). These data have been used by Myhre et al (2005a) and Kvalevag et al. (2010). They argue that the observed albedo difference between natural vegetation and croplands is less than usually assumed in climate simulations, so that the RF due to land use change is weaker than in estimates that do not use the satellite data. On the other hand, Nair et al. (2007) show observational evidence of an underestimate of the surface albedo change in land use analysis in southwest Australia. Overall, there is still a significant range of RF estimates for the albedo component of land use forcing. This is mostly due to the range of albedo change as a result of land use change, as shown in an inter-comparison of 7 atmosphere-land models (de Noblet-Ducoudre et al., 2012).

Deforestation has a direct impact on the atmospheric CO_2 concentration, and therefore contributes to the WMGHG RF as quantified in Section 8.3.2. Conversely, afforestation is a climate mitigation strategy to limit the CO_2 concentration increase. Several authors have compared the radiative impact of deforestation/afforestation that results from the albedo change with the greenhouse effect of CO_2 released/sequestered. Pongratz et al. (2010) shows that the historic land use change has had a warming impact (i.e., greenhouse effect dominates) at the global scale and over most regions with the exception of Europe and India. Bala et al. (2007) results show latitudinal contrast where the greenhouse effect dominates for low latitude deforestation while the combined effect of albedo and evapotranspiration impact does at high-latitude. These results are also supported by Bathiany et al. (2010). Similarly, Lohila et al. (2010) shows that the afforestation of boreal peatlands results in a balanced RF between the albedo and greenhouse effect. Overall, because of the opposite impacts, the potential of afforestation to mitigate climate change is limited (Arora and Montenegro, 2011) while it may have undesired impacts on the atmospheric circulation, shifting precipitation patterns (Swann et al., 2012).

8.3.5.4 *Other Impacts of Land Cover Change on the Earth's Albedo*

Burn scars resulting from agriculture practices, uncontrolled fires or deforestation (Bowman et al., 2009) have a lower albedo than unperturbed vegetation (Jin and Roy, 2005). On the other hand, at high latitude, burnt areas are more easily covered by snow, which may result in an overall increase of the surface albedo. Surface blackening of natural vegetation due to fire is relatively short-lived and typically disappears within one to a few years (Jin et al., 2012). Myhre et al. (2005b) estimates a global albedo-related radiative effect due to African fires of 0.015 W m^{-2} .

Over semi-arid areas, the development of agriculture favours the generation of dust. Mulitza et al. (2010) demonstrates a very large increase of dust emission and deposition in the Sahel concomitant with the development of agriculture in this area. This, together with the analysis of dust sources (Ginoux et al., 2010), suggests that a significant fraction of the dust that is transported over the Atlantic has an anthropogenic origin and impacts the Earth albedo. There is no full estimate of the resulting RF, however. The dust RF estimate in Section 8.3.4.2 includes both land use contributions and change in wind-driven emissions. Both dust and biomass burning aerosol may impact the Earth surface albedo as these particles can be deposited on snow, which has a large impact on its absorption, in particular for soot. This is discussed in Section 8.3.4.4.

Urban areas have an albedo that is 0.01–0.02 smaller than adjacent croplands (Jin et al., 2005). There is the potential for a strong increase through white roof coating with the objective of mitigating the heat island effect (Oleson et al., 2010). Although the global scale impact is small, local effects can be very large, as shown by Campra et al. (2008) that reports a regional (260 km^2) 0.09 increase in albedo and -20 W m^{-2} RF as a consequence of greenhouse horticulture development.

8.3.5.5 *Impacts of Surface Change on Climate*

Davin et al. (2007) argues that the climate sensitivity to land use forcing is lower than that for other forcings, due to its spatial distribution but also the role of non-radiative processes. Indeed, in addition to the impact on the surface albedo, land use change also modifies the evaporation and surface roughness, with counterbalancing consequences on the lower atmosphere temperature. There is increasing evidence that the impact of land use on evapotranspiration — a non RF on climate — is comparable to, but of opposite sign than, the albedo effect, so that RF is not as useful a metric as it is for gases and aerosols. For instance, Findell et al. (2007) climate simulations show a negligible impact of land use change on the global mean temperature, although there are some significant regional changes.

Numerical climate experiments demonstrate that the impact of land use on climate is much more complex than just the RF. This is due in part to the very heterogeneous nature of land use change (Barnes and Roy, 2008), but mostly due to the impact on the hydrological cycle through evapotranspiration, root depth, and cloudiness (van der Molen et al., 2011). As a consequence, the forcing on climate is not purely radiative and the net impact on the surface temperature may be either positive or negative depending on the latitude (Bala et al., 2007). Davin and de Noblet-Ducoudre (2010) analyses the impact on climate of large-scale deforestation; the albedo cooling effect dominates for high latitude whereas reduced evapotranspiration dominates in the tropics. This latitudinal trend is confirmed by observations of the temperature difference between open land and nearby forested land (Lee et al., 2011).

Irrigated areas have continuously increased during the 20th century although a slowdown has been observed in recent decades (Bonfils and Lobell, 2007). There is clear evidence that irrigation leads to local cooling of several degrees (Kueppers et al., 2007). Irrigation also affects cloudiness and precipitation (Puma and Cook, 2010). In the United States, DeAngelis et al. (2010) found that irrigation in the Great Plains in the summer produced enhanced precipitation in the Midwest 1,000 km to the northeast.

8.3.5.6 *Conclusions*

There is still a rather wide range of estimates of the albedo change due to anthropogenic land use change, and its RF. Although most published studies provide an estimate close to -0.2 W m^{-2} , there is convincing evidence that it may be somewhat weaker as the albedo difference between natural and anthropogenic land

cover may have been overestimated. In addition, non-radiative impact of land use have a similar magnitude, and may be of opposite sign, as the albedo effect (though these are not part of RF). A comparison of the impact of land use change according to seven climate models showed a wide range of results (Pitman et al., 2009), partly due to difference in the implementation of land cover change, but mostly due to different assumptions on ecosystem albedo, plant phenology and evapotranspiration. There is no agreement on the sign of the temperature change induced by anthropogenic land use change. It is very likely that land use change led to an increase of the Earth albedo with a RF of $-0.15 \pm 0.10 \text{ W m}^{-2}$, but a net cooling of the surface — accounting for processes that are not limited to the albedo — is about as likely as not.

8.4 Natural Radiative Forcing Changes: Solar and Volcanic

Several natural drivers of climate change operate on multiple timescales. Solar variability takes place at many timescales that include centennial and millennial scales (Helama et al., 2010), as the radiant energy output of the Sun changes. Also, variations in the astronomical alignment of the Sun and Earth (Milankovitch cycles) induce cyclical changes in RF, but this is substantial only at millennial and longer timescales (see Chapter 5, Section 5.2.1.1). Volcanic forcing is highly episodic, but can have dramatic, rapid impacts on climate. No major asteroid impacts occurred during the reference period (1750–2012) and thus this effect is not considered here. This section discusses solar and volcanic forcings, the two dominant natural contributors of climate change since the preindustrial time.

8.4.1 Solar Irradiance

In earlier IPCC reports the forcing was estimated as the instantaneous RF at TOA. However, due to wavelength-albedo dependence, solar radiation-wavelength dependence and absorption within the stratosphere and the resulting stratospheric adjustment, the RF is reduced to ~78% of the TOA instantaneous RF (Gray et al., 2009). There is *low confidence* in the exact value of this number, which can be model and timescale dependent (Gregory et al., 2004; Hansen et al., 2005). AR4 gives an 11-year running mean instantaneous TOA RF between 1750 and the present of 0.12 W m^{-2} with a range of estimates of $0.06\text{--}0.30 \text{ W m}^{-2}$, equivalent to a RF of 0.09 W m^{-2} with a range of $0.05\text{--}0.23 \text{ W m}^{-2}$. For a consistent treatment of all forcing agents, hereafter we use RF while numbers quoted from AR4 will be provided both as RF and instantaneous RF at TOA.

8.4.1.1 Satellite Measurements of Total Solar Irradiance (TSI)

TSI measured by the Total Irradiance Monitor (TIM) on the spaceborne Solar Radiation and Climate Experiment (SORCE) is $1360.8 \pm 0.5 \text{ W m}^{-2}$ during 2008 (Kopp and Lean, 2011) which is $\sim 4.5 \text{ W m}^{-2}$ lower than the Physikalisch-Meteorologisches Observatorium Davos (PMOD) TSI composite during 2008 (Frohlich, 2009). The difference is probably due to instrumental biases in measurements prior to TIM. Measurements with the PREcision MONitor Sensor (PREMOS) instrument support the TIM absolute values (Kopp and Lean, 2011). The TIM calibration is also better linked to national standards which provides further support that it is the most accurate (see Supplementary Material Section 8.SM.6). Given the lower TIM TSI values relative to currently used standards, most general circulation models are calibrated to incorrectly high values. However, the few tenths of a percent bias in the absolute TSI value has minimal consequences for climate simulations because the larger uncertainties in cloud properties have a greater effect on the radiative balance. As the maximum-to-minimum TSI relative change is well-constrained from observations, and historical variations are calculated as changes relative to modern values, a revision of the absolute value of TSI affects RF by the same fraction as it affects TSI. The downward revision of TIM TSI with respect to PMOD, being 0.3%, thus has a negligible impact on RF, which is given with a relative uncertainty of several tens of percent.

Since 1978, several independent space-based instruments have directly measured the TSI. Three main composite series were constructed, referred to as the Active Cavity Radiometer Irradiance Monitor (ACRIM) (Willson and Mordvinov, 2003), the Royal Meteorological Institute of Belgium (RMIB) (Dewitte et al., 2004) and the PMOD (Frohlich, 2006) series. There are two major differences between ACRIM and PMOD. The first is the rapid drift in calibration between PMOD and ACRIM before 1981. This arises because both composites employ the Hickey-Frieden (HF) radiometer data for this interval, while a re-evaluation of the early HF degradation has been implemented by PMOD but not by ACRIM. The second one, involving also

RMIB, is the bridging of the gap between the end of ACRIM I (mid-1989) and the beginning of ACRIM II (late 1991) observations, as it is possible that a change in HF data occurred during this gap. This possibility is neglected in ACRIM and thus its TSI increases by more than 0.5 W m^{-2} during solar cycle (SC 22). These differences lead to different long-term TSI trends in the three composites (see Figure 8.10): ACRIM rises until 1996 and subsequently declines, RMIB has an upward trend through 2008 and PMOD shows a decline since 1986 which unlike the other two composites, follows the solar-cycle-averaged sunspot number (Lockwood, 2010). Moreover, the ACRIM trend implies that the TSI on time scales longer than the SC is positively correlated with the cosmic ray variation indicating a decline in TSI throughout most of the 20th century (the opposite to most TSI reconstructions produced to date, see 8.4.1.2). Furthermore, extrapolating the ACRIM TSI long-term drift would imply a brighter Sun in the Maunder minimum (MM) than now, again opposite to most TSI reconstructions (Lockwood and Frohlich, 2008). Finally, analysis of instrument degradation and pointing issues (Lee et al., 1995) and independent modeling based on solar magnetograms (Wenzler et al., 2009; Ball et al., 2012), confirm the need for correction of HF data, and we conclude that PMOD is more accurate than the other composites.

TSI variations of $\sim 0.1\%$ were observed between the maximum and minimum of the 11-year SC in the three composites mentioned above (Kopp and Lean, 2011). This variation is mainly due to an interplay between relatively dark sunspots, bright faculae and bright network elements (Foukal and Lean, 1988; see Section 5.2.1.2). A declining trend since 1986 in PMOD solar minima is evidenced in Figure 8.10. Considering the PMOD solar minima values of 1986 and 2008, the RF is -0.04 W m^{-2} . Our assessment of the uncertainty range of changes in TSI between 1986 and 2008 is -0.08 to 0.0 W m^{-2} and includes the uncertainty in the PMOD data (Frohlich, 2009; see Supplementary Material Section 8.SM.6) but is extended to also take into account the uncertainty of combining the satellite data.

For incorporation of TIM data with the previous and overlapping data, in Figure 8.10 we have standardized the composite time series to the TIM series (over 2003–2012, the procedure is explained in Supplementary Material Section 8.SM.6. Moreover as we consider annual averages, ACRIM and PMOD start at 1979 because for 1978 both composites have only two months data.

[INSERT FIGURE 8.10 HERE]

Figure 8.10: Annual average composites of measured Total Solar Irradiance: The Active Cavity Radiometer Irradiance Monitor (ACRIM) (Willson and Mordvinov, 2003), the Physikalisch-Meteorologisches Observatorium Davos (PMOD) (Frohlich, 2006) and the Royal Meteorological Institute of Belgium (RMIB) (Dewitte et al., 2004). These composites are standardized to the annual average (2003–2012) Total Solar Irradiance Monitor (TIM) (Kopp and Lean, 2011) measurements that are also shown.

8.4.1.2 TSI Variations since Preindustrial Time

The year 1750, which is used as the preindustrial reference for estimating RF, corresponds to a maximum of the 11-year SC. Trend analysis are usually performed over the minima of the solar cycles that are more stable. For such trend estimates, it is then better to use the closest SC minimum, which is in 1745. To avoid trends caused by comparing different portions of the solar cycle, we analyze TSI changes using multi-year running means. For the best estimate we use a recent TSI reconstruction by Krivova et al. (2010) between 1745 and 1973 and from 1974 to 2012 by Ball et al. (2012). The reconstruction is based on physical modeling of the evolution of solar surface magnetic flux, and its relationship with sunspot group number (before 1974) and sunspot umbra and penumbra and faculae afterwards. This provides a more detailed reconstruction than other models (see the time series in Supplementary Material Table 8.SM.3). The best estimate from our assessment of the most reliable TSI reconstruction gives a 7-year running mean RF between the minima of 1745 and 2008 of 0.05 W m^{-2} . Our assessment of the range of RF from TSI changes is 0.0 – 0.10 W m^{-2} which covers several updated reconstructions using the same 7-year running mean past-to-present minima years (Wang et al., 2005; Steinhilber et al., 2009; Delaygue and Bard, 2011), see Supplementary Material Table 8.SM.4. All reconstructions rely on indirect proxies that inherently do not give consistent results. There are relatively large discrepancies among the models (see Figure 8.11). With these considerations, we adopt this value and range for AR5. This RF is almost half of that in AR4, in part because the AR4 estimate was based on the previous solar cycle minimum while the AR5 estimate includes the drop of TSI in 2008 compared to the previous two SC minima (see 8.4.1). Concerning the uncertainty range, in AR4 the upper limit corresponded to the reconstruction of Lean (2000), based on the reduced

brightness of non-cycling Sun-like stars assumed typical of a Maunder minimum (MM) state. The use of such stellar analogues was based on the work of Baliunas and Jastrow (1990), but more recent surveys have not reproduced their results and suggest that the selection of the original set was flawed (Hall and Lockwood, 2004; Wright, 2004); the lower limit from 1750 to present in AR4 was due to the assumed increase in the amplitude of the 11-year cycle only. Thus the RF and uncertainty range have been obtained in a different way in AR5 compared to AR4. Maxima to maxima RF give a higher estimate than minima to minima RF, but the latter is more relevant for changes in solar activity. Given the *medium agreement* and *medium evidence*, this RF value has a *medium confidence level* (although *confidence* is higher for the last three decades). Figure 8.11 shows several TSI reconstructions modelled using sunspot group numbers (Wang et al., 2005; Krivova et al., 2010; Ball et al., 2012) and sunspot umbra and penumbra and faculae (Ball et al., 2012), or cosmogenic isotopes (Steinhilber et al., 2009; Delaygue and Bard, 2011). These reconstructions are standardized to PMOD solar cycle 23 (1996–2008) (see also Supplementary Material Section 8.SM.6).

For the MM-to-present AR4 gives a TOA instantaneous RF range of 0.1–0.28 W m⁻², equivalent to 0.08–0.22 W m⁻² with the RF definition used here. The reconstructions in Schmidt et al. (2011) indicate a MM-to-present RF range of 0.08–0.18 W m⁻², which is within the AR4 range although narrower. As discussed above, the estimates based on irradiance changes in Sun-like stars are not included in this range because the methodology has been shown to be flawed. A more detailed explanation of this is found in Supplementary Material Section 8.SM.6. For details about TSI reconstructions on millennia time scales see Chapter 5, Section 5.2.1.1.

[INSERT FIGURE 8.11 HERE]

Figure 8.11: Reconstructions of Total Solar Irradiance since 1745, annual resolution series from Wang et al. (2005) with and without an independent change in the background level of irradiance, Krivova et al. (2010) combined with Ball et al. (2012), and 5-year time resolution series from Steinhilber et al. (2009) and Delaygue and Bard (2011). The series are standardized to the PMOD measurements of solar cycle 23 (1996–2008) (PMOD is already standardized to TIM).

8.4.1.3 Attempts to Estimate Future Centennial Trends of TSI

Cosmogenic isotope and sunspot data (Rigozo et al., 2001; Solanki and Krivova, 2004; Abreu et al., 2008) reveal that currently the Sun is in a grand activity maximum that began ~1920 (20th century grand maximum). However, SC 23 showed an activity decline not previously seen in the satellite era (McComas et al., 2008; Smith and Balogh, 2008; Russell et al., 2010). Most current estimations suggest that the forthcoming solar cycles will have lower TSI than those for the past 30 years (Abreu et al., 2008; Lockwood et al., 2009; Rigozo et al., 2010; Russell et al., 2010). Also there are indications that the mean magnetic field in sunspots may be diminishing on decadal level. A linear expansion of the current trend may indicate that of the order of half the sunspot activity may disappear by about 2015 (Penn and Livingston, 2006). These studies only suggest that the Sun may have left the 20th century grand maximum and not that it is entering another grand minimum. But other works propose a grand minimum during the 21st century, estimating a RF within a range of -0.16 to 0.12 W m⁻² between this future minimum and the present day TSI (Jones et al., 2012). However, much more evidence is needed and at present there is *very low confidence* concerning future solar forcing estimates.

Nevertheless, even if there is such decrease in the solar activity, there is a *high confidence* that the TSI RF variations will be much smaller in magnitude than the projected increased forcing due to GHG (see Chapter 12, Section 12.3.1).

8.4.1.4 Variations in Spectral Irradiance

8.4.1.4.1 Impacts of UV variations on the stratosphere

Ozone is the main gas involved in stratospheric radiative heating. Ozone production rate variations are largely due to solar UV irradiance changes (HAIGH, 1994), with observations showing statistically significant variations in the upper stratosphere of 2–4% along the SC (Soukharev and Hood, 2006). UV variations may also produce transport-induced ozone changes due to indirect effects on circulation (Shindell et al., 2006b). Additionally, statistically significant evidence for an 11-year variation in stratospheric temperature and zonal winds is attributed to UV radiation (Frame and Gray, 2010). The direct UV heating of the background ozone is dominant and over twice as large as the ozone heating in the upper stratosphere and

above, while indirect solar and terrestrial radiation through the SC-induced ozone change is dominant below about 5 hPa (Shibata and Kodera, 2005). The RF due to solar-induced ozone changes is a small fraction of the solar RF discussed in 8.4.1.1 (Gray et al., 2009).

8.4.1.4.2 *Measurements of spectral irradiance*

Solar spectral irradiance (SSI) variations in the far (120–200 nm) and middle (200–300 nm) ultraviolet (UV) are the primary driver for heating, composition, and dynamic changes of the stratosphere, and although these wavelengths compose a small portion of the incoming radiation they show large relative variations between the maximum and minimum of the SC compared to the corresponding TSI changes. As UV heating of the stratosphere over a SC has the potential to influence the troposphere indirectly, through dynamic coupling, and therefore climate (Haigh, 1996; Gray et al., 2010), the UV may have a more significant impact on climate than changes in TSI alone would suggest. Although this indicates that metrics based only on TSI are not appropriate, UV measurements present several controversial issues and modelling is not yet robust.

Multiple space-based measurements made in the past 30 years indicated that UV variations account for ~30% of the SC TSI variations, while ~70% were produced within the visible and infrared (Rottman, 2006). However, current models and data provide the range of 30–90% for the contribution of the UV variability below 400 nm to TSI changes (Ermolli et al., 2012), with a more probable value of ~60% (Morrill et al., 2011; Ermolli et al., 2012). The Spectral Irradiance Monitor (SIM) on board SORCE (Harder et al., 2009) shows, over the SC 23 declining phase, measurements that are rather inconsistent with prior understanding, indicating that additional validation and uncertainty estimates are needed (DeLand and Cebula, 2012; Lean and Deland, 2012). A wider exposition can be found in Supplementary Material Section 8.SM.6.

8.4.1.4.3 *Reconstructions of preindustrial UV variations*

The Krivova et al. (2010) reconstruction is based on what is known about spectral contrasts of different surface magnetic features and the relationship between TSI and magnetic fields. The authors interpolated backwards to the year 1610 based on sunspot group numbers and magnetic information. The Lean (2000) model is based on historical sunspot number and area and is scaled in the UV using measurements from the Solar Stellar Irradiance Comparison Experiment (SOLSTICE) on board the Upper Atmosphere Research Satellite (UARS). The results show smoothed 11-year UV SSI changes between 1750 and the present of ~25% at ~120 nm, ~8% at 130–175 nm, ~4% at 175–200 nm, and ~0.5% at 200–350 nm. Thus, the UV SSI appears to have generally increased over the past four centuries with larger trends at shorter wavelengths. As few reconstructions are available, and recent measurements suggest a poor understanding of UV variations and their relationship with solar activity, there is *very low confidence* in these values.

8.4.1.5 *The Effects of Cosmic Rays on Clouds*

Changing cloud amount or properties modify the Earth's albedo and therefore affect climate. It has been hypothesized that cosmic ray flux create atmospheric ions which facilitates aerosol nucleation and new particle formation with a further impact on cloud formation (Dickinson, 1975; Kirkby, 2007). High solar activity means a stronger heliospheric magnetic field and thus a more efficient screen against cosmic rays. Under the hypothesis underlined above, the reduced cosmic ray flux would promote fewer clouds amplifying the warming effect expected from high solar activity. There is evidence from laboratory, field and modelling studies that ionization from cosmic ray flux may enhance aerosol nucleation in the free troposphere (Merikanto et al., 2009; Mirme et al., 2010; Kirkby et al., 2011). However there is *high confidence (medium evidence and high agreement)* that the cosmic ray-ionization mechanism is too weak to influence global concentrations of cloud condensation nuclei or their change over the last century or during a SC in a climatically-significant way (Harrison and Ambaum, 2010; Erlykin and Wolfendale, 2011; Snow-Kropla et al., 2011). A detailed exposition is found in Chapter 7, Section 7.4.6.

8.4.2 *Volcanic Radiative Forcing*

8.4.2.1 *Introduction*

Volcanic eruptions that inject substantial amounts of SO₂ gas into the stratosphere are the dominant natural cause of externally-forced climate change on the annual and multi-decadal time scales, both because of the multi-decadal variability of eruptions and the time scale of the climate system response, and can explain

much of the preindustrial climate change of the last millennium (Schneider et al., 2009; Brovkin et al., 2010; Legras et al., 2010; Miller et al., 2012). While volcanic eruptions inject both mineral particles (called ash or tephra) and sulphate aerosol precursor gases (predominantly SO₂) into the atmosphere, it is the sulphate aerosols, which because of their small size are effective scatterers of sunlight and have long lifetimes, that are responsible for RF important for climate. Global annually-averaged emissions of CO₂ from volcanic eruptions since 1750 have been at least 100 times smaller than anthropogenic emissions, and inconsequential for climate on millennial and shorter time scales (Gerlach, 2011). To be important for climate change, sulphur must be injected into the stratosphere, as the lifetime of aerosols in the troposphere is only about one week, while sulphate aerosols in the stratosphere from tropical eruptions have a lifetime of about one year, and those from high-latitude eruptions last several months. Most stratospheric aerosols are from explosive eruptions that directly put sulphur into the stratosphere, but Bourassa et al. (2012; 2013) showed that sulphur injected into the upper troposphere can then be lifted into the stratosphere over the next month or two by deep convection and large scale Asian summer monsoon circulation, although Vernier et al. (2013) and Fromm et al. (2013) suggested that direct injection was also important. Robock (2000), AR4 (Forster et al., 2007) and Timmreck (2012) provide summaries of this relatively well understood forcing agent.

There have been no major volcanic eruptions since Mt. Pinatubo in 1991 (Figure 8.12), but several smaller eruptions have caused a RF for the years 2008–2011 of -0.10 (-0.13 to -0.07) W m⁻² approximately twice the magnitude of the 1999–2002 RF of -0.05 (-0.07 to -0.03) W m⁻², consistent with the trends noted in Solomon et al. (2011). However, the CMIP5 simulations discussed elsewhere in this report did not include the recent small volcanic forcing in their calculations. New work has also produced a better understanding of high latitude eruptions, the hydrological response to volcanic eruptions (Trenberth and Dai, 2007; Anchukaitis et al., 2010), better long-term records of past volcanism, and better understanding of the effects of very large eruptions.

There are several ways to measure both the SO₂ precursor and sulphate aerosols in the stratosphere, using balloons, airplanes, and both ground- and satellite-based remote sensing. Both the infrared and ultraviolet signals sensed by satellite instruments can measure SO₂, and stratospheric aerosol measurements by space-based sensors have been made on a continuous basis since 1978 by a number of instruments employing solar and stellar occultation, limb scattering, limb emission, and lidar strategies (Thomason and Peter, 2006; Kravitz et al., 2011; Solomon et al., 2011).

Forster et al. (2007) described four mechanisms by which volcanic forcing influences climate: RF due to aerosol-radiation interaction; differential (vertical or horizontal) heating, producing gradients and changes in circulation; interactions with other modes of circulation, such as El Niño/Southern Oscillation (ENSO); and ozone depletion with its effects on stratospheric heating, which depends on anthropogenic chlorine (stratospheric ozone would increase with a volcanic eruption under low-chlorine conditions). In addition, the enhanced diffuse light from volcanic aerosol clouds impacts vegetation and hence the carbon cycle (Mercado et al., 2009) and aerosol-cloud interaction of sulphate aerosols on clouds in the troposphere can also be important (Schmidt et al., 2010), though Frolicher et al. (2011) showed that the impacts of the 1991 Pinatubo eruption on the carbon cycle were small.

8.4.2.2 Recent Eruptions

The background stratospheric aerosol concentration was affected by several small eruptions in the first decade of the 21st century (Nagai et al., 2010; Vernier et al., 2011; Neely et al., 2013; see also Figure 8.13), with a very small contribution from tropospheric pollution (Siddaway and Petelina, 2011; Vernier et al., 2011), and had a small impact on RF (Solomon et al., 2011). Two recent high-latitude eruptions, of Kasatochi Volcano (52.1°N, 175.3°W) on August 8, 2008 and of Sarychev Volcano (48.1°N, 153.2°E) on June 12–16, 2009, each injected ~1.5 Tg SO₂ into the stratosphere, but did not produce detectable climate response. Their eruptions, however, led to better understanding of the dependence of the amount of material and time of year of high-latitude injections to produce climate impacts (Haywood et al., 2010; Kravitz et al., 2010; Kravitz et al., 2011). The RF from high-latitude eruptions is a function of seasonal distribution of insolation and the 3–4 month lifetime of high-latitude volcanic aerosols. Kravitz and Robock (2011) showed that high-latitude eruptions must inject at least 5 Tg SO₂ into the lower stratosphere in the spring or summer, and much more in fall or winter, to have a detectable climatic response.

On April 14, 2010 the Eyjafjallajökull volcano in Iceland (63.6°N, 19.6°W) began an explosive eruption phase that shut down air traffic in Europe for 6 days and continued to disrupt it for another month. The climatic impact of Eyjafjallajökull was about 10,000 times less than that of Pinatubo, however, because it emitted less than 50 kt SO₂ and its lifetime in the troposphere was 50 times less than if it had been injected into the stratosphere, and was therefore undetectable amidst the chaotic weather noise in the atmosphere (Robock, 2010). 2011 saw the continuation of a number of small eruptions with significant tropospheric SO₂ and ash injections, including Puyehue-Cordón Caulle in Chile, Nabro in Eritrea, and Grimsvötn in Iceland. None have been shown to have produced an important RF, but the June 13, 2011 Nabro eruption resulted in the largest stratospheric aerosol cloud since the 1991 Pinatubo eruption (Bourassa et al., 2012), more than 1.5 Tg SO₂.

Figure 8.12 shows reconstructions of volcanic aerosol optical depth since 1750. Figure 8.13 shows details of the vertical distribution of stratospheric aerosols in the tropics since 1985. The numerous small eruptions in the past decade are evident, but some of them were at higher latitudes and their full extent is not captured in this plot.

[INSERT FIGURE 8.12 HERE]

Figure 8.12: Volcanic reconstructions of global mean aerosol optical depth (at 550 nm). Gao et al. (2008) and Crowley and Unterman (2013) are from ice core data, and end in 2000 for Gao et al. (2008) and 1996 for Crowley and Unterman (2013). Sato et al. (1993) includes data from surface and satellite observations, and has been updated through 2011. Updated from Schmidt et al. (2011).

[INSERT FIGURE 8.13 HERE]

Figure 8.13: (Top) Monthly mean extinction ratio (525 nm) profile evolution in the tropics [20°N–20°S] from January 1985 through December 2012 derived from Stratospheric Aerosol and Gas Experiment (SAGE) II extinction in 1985–2005 and Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO) scattering ratio in 2006–2012, after removing clouds below 18 km based on their wavelength dependence (SAGE II) and depolarization properties (CALIPSO) compared to aerosols. Black contours represent the extinction ratio in log-scale from 0.1 to 100. The position of each volcanic eruption occurring during the period is displayed with its first two letters on the horizontal axis, where tropical eruptions are noted in red. The eruptions were Nevado del Ruiz (Ne), Augustine (Au), Chikurachki (Ch), Kliuchevskoi (Kl), Kelut (Ke), Pinatubo (Pi), Cerro Hudson (Ce), Spur (Sp), Lascar (La), Rabaul (Ra), Ulawun (Ul), Shiveluch (Sh), Ruang (Ru), Reventador (Ra), Manam (Ma), Soufrière Hills (So), Tavurvur (Ta), Chaiten (Ch), Okmok (Ok), Kasatochi (Ka), Victoria (Vi* - forest fires with stratospheric aerosol injection), Sarychev (Sa), Merapi (Me), Nabro (Na). Updated from Figure 1 from Vernier et al. (2011). (Bottom) Mean stratospheric aerosol optical depth (AOD) in the tropics [20°N–20°S] between the tropopause and 40 km since 1985 from the SAGE II (black line), the Global Ozone Monitoring by Occultation of Stars (GOMOS) (red line), and CALIPSO (blue line). Updated from Figure 5 from Vernier et al. (2011).

8.4.2.3 Records of Past Volcanism and Effects of Very Large Eruptions

While the effects of volcanic eruptions on climate are largest in the two years following a large stratospheric injection, and the winter warming effect in the Northern Hemisphere has been supported by long-term records (Fischer et al., 2007), there is new work indicating extended volcanic impacts via long-term memory in the ocean heat content and sea level (Stenchikov et al., 2009; Gregory, 2010; Ottera et al., 2010). Zanchettin et al. (2012) found changes in the North Atlantic Ocean circulation that imply strengthened northward oceanic heat transport a decade after major eruptions, which contributes to the emergence of extensive winter warming over the continental Northern Hemisphere along with persistent cooling over Arctic regions on decadal time scales, in agreement with Zhong et al. (2011) and Miller et al. (2012).

New work on the mechanisms by which a supereruption (Self and Blake, 2008) could force climate has focused on the 74,000 BP eruption of the Toba volcano (2.5°N, 99.0°E). Robock et al. (2009) used simulations of up to 900 times the 1991 Pinatubo sulphate injection to show that the forcing is weaker than that predicted based on a linear relationship with the sulphate aerosol injection. The results agreed with a previous simulation by Jones et al. (2005). They also showed that chemical interactions with ozone had small impacts on the forcing and that the idea of Bekki et al. (1996) that water vapour would limit and prolong the growth of aerosols was not supported. Timmreck et al. (2010) however, incorporating the idea of Pinto et al. (1989) that aerosols would grow and therefore both have less RF per unit mass and fall out of the atmosphere more quickly, found much less of a radiative impact from such a large stratospheric input.

8.4.2.4 *Future Effects*

We expect large eruptions over the next century but cannot predict when. Ammann and Naveau (2003) and Stothers (2007) suggested an 80-year periodicity in past eruptions, but the data record is quite short and imperfect, and there is no mechanism proposed that would cause this. While the period 1912–1963 CE was unusual for the past 500 years in having no large volcanic eruptions, and the period 1250–1300 CE had the most globally climatically-significant eruptions in the past 1500 years (Gao et al., 2008), current knowledge only allows us to predict such periods on a statistical basis, assuming that the recent past distributions are stationary. Ammann and Naveau (2003), Gusev (2008), and Deligne et al. (2010) studied these statistical properties and Ammann and Naveau (2010) showed how they could be used to produce a statistical distribution for future simulations. Although the future forcing from volcanic eruptions will only depend on the stratospheric aerosol loading for most forcing mechanisms, the future effects on reducing ozone will diminish as ozone depleting substances diminish in the future (Eyring et al., 2010b).

[START BOX 8.3 HERE]

Box 8.3 Volcanic Eruptions as Analogues

Volcanic eruptions provide a natural experiment of a stratospheric aerosol cloud that can serve to inform us of the impacts of the proposed production of such a cloud as a means to control the climate, which is one method of geoengineering (Rasch et al., 2008); see Chapter 7, Section 7.7. For example, Trenberth and Dai (2007) showed that the Asian and African summer monsoon, as well as the global hydrological cycle, was weaker for the year following the 1991 Pinatubo eruption, which is consistent with climate model simulations (Robock et al., 2008). MacMynowski et al. (2011) showed that because the climate system response of the hydrological cycle is rapid, forcing from volcanic eruptions, which typically last about a year, can serve as good analogues for longer-lived forcing. The formation of sulphate aerosols, their transport and removal, their impacts on ozone chemistry, their RF, and the impacts on whitening skies all also serve as good analogues for geoengineering proposals. Volcanic impacts on the carbon cycle because of more diffuse radiation (Mercado et al., 2009) and on remote sensing can also be useful analogues, and the volcanic impacts on contrail-generated sub-visual cirrus (Long et al., 2009) can be used to test the long-term impacts of a permanent stratospheric cloud.

Smoke from fires generated by nuclear explosions on cities and industrial areas, which could be lofted into the stratosphere, would cause surface cooling and a reduction of stratospheric ozone (Mills et al., 2008). Volcanic eruptions that produce substantial stratospheric aerosol clouds also serve as an analogue that supports climate model simulations of the transport and removal of stratospheric aerosols, their impacts on ozone chemistry, their RF, and the climate response. The use of the current global nuclear arsenal still has the potential to produce nuclear winter, with continental temperatures below freezing in summer (Robock et al., 2007a; Toon et al., 2008), and the use of only 100 nuclear weapons could produce climate change unprecedented in recorded human history (Robock et al., 2007b), with significant impacts on global agriculture (Ozdogan et al., 2013; Xia and Robock, 2013).

[END BOX 8.3 HERE]

8.5 Synthesis of Global Mean Radiative Forcing, Past and Future

The RF can be used to quantify the various agents that drive climate change over the industrial era or the various contributions to future climate change. There are multiple ways in which RF can be attributed to underlying causes, each providing various perspectives on the importance of the different factors driving climate change. This section evaluates the RF with respect to emitted component and with respect to the ultimate atmospheric concentrations. The uncertainties in the RF agents vary and the confidence levels for these are presented in this section. Finally, this section shows historical and scenarios of future time evolution of RF.

8.5.1 Summary of Radiative Forcing by Species and Uncertainties

Table 8.5 has an overview of the RF agents considered here and each of them is given a confidence level for the change in RF over the industrial era to the present day. The confidence level is based on the evidence (robust, medium, and limited) and the agreement (high, medium, and low; see further description in Chapter 1). The confidence level of the forcing agents goes beyond the numerical values available in estimates and is an assessment for a particular forcing agent to have a real value within the estimated range. Some of the RF agents have robust evidence such as WMGHG with well documented increases based on high precision measurements as well as contrails as additional clouds which can be seen by direct observations. However, for some RF agents the evidence is more limited regarding their existence such as aerosol influence on cloud cover. The consistency in the findings for a particular forcing agent determines the evaluation of the evidence. A combination of different methods, e.g., observations and modeling, and thus the understanding of the processes causing the forcing is important for this evaluation. The agreement is a qualitative judgment of the difference between the various estimates for a particular RF agent. Chapter 1, Figure 1.11 shows how the combined evidence and agreement results in five levels for the confidence level. The colour codes used in Figure 1.11 for the confidence level are adopted in Table 8.5.

Table 8.5: Confidence level for the forcing estimate associated with each forcing agent for the 1750–2011 period. The confidence level is based on the evidence and the agreement as given in the table. The basis for the confidence level and change since AR4 is provided. See Chapter 1, Figure 1.11 for further description of the evidence, agreement and confidence level. Note, that the confidence levels given in Table 8.5 are for 2011 relative to 1750 and for some of the agents the confidence level may be different for certain portions of the industrial era.

	Evidence	Agreement	Confidence Level	Basis for Uncertainty Estimates (more certain / less certain)	Change in Understanding Since AR4
WMGHG	Robust	High	Very high	Measured trends from different observed data sets and differences between radiative transfer models	No major change
Tropospheric Ozone	Robust	Medium	High	Observed trends of ozone in the troposphere and model results for the industrial era / Differences between model estimates of RF	No major change
Stratospheric Ozone	Robust	Medium	High	Observed trends in stratospheric and total ozone and modelling of ozone depletion / Differences between estimates of RF	No major change
Stratospheric Water Vapour from CH ₄	Robust	Low	Medium	Similarities in results of independent methods to estimate the RF / Known uncertainty in RF calculations	Elevated due to more studies
Aerosol-Radiation Interactions	Robust	Medium	High	A large set of observations and converging independent estimates of RF / Differences between model estimates of RF	Elevated due to more robust estimates from independent methods
Aerosol-Cloud Interactions	Medium	Low	Low	Variety of different observational evidence and modelling activities / Spread in model estimates of ERF and differences between observations and model results	ERF in AR5 has a similar confidence level to RF in AR4
Rapid adjustment Aerosol-Radiation Interactions	Medium	Low	Low	Observational evidence combined with results from different types of models / Large spread in model estimates	Elevated due to increased evidence
Total aerosol effect	Medium	Medium	Medium	A large set of observations and model results, independent methods to derive ERF estimates / Aerosol-cloud interaction processes and	Not provided previously

				anthropogenic fraction of CCN still fairly uncertain	
Surface Albedo (Land Use)	Robust	Medium	High	Estimates of deforestation for agricultural purposes and well known physical processes / Spread in model estimates of RF	Elevated due to the availability of high quality satellite data
Surface Albedo (BC Aerosol on Snow and Ice)	Medium	Low	Low	Observations of snow samples and the link between BC content in snow and albedo / Large spread in model estimates of RF	No major change
Contrails	Robust	Low	Medium	Contrails observations , large number of model estimates / Spread in model estimates of RF and uncertainties in contrail optical properties	No major change
Contrail Induced Cirrus	Medium	Low	Low	Observations of a few events of contrail induced cirrus / Extent of events uncertain and large spread in estimates of ERF	Elevated due to additional studies increasing the evidence
Solar Irradiance	Medium	Medium	Medium	Satellite information over recent decades and small uncertainty in radiative transfer calculations / Large relative spread in reconstructions based on proxy data	Elevated due to better agreement of a weak RF
Volcanic Aerosol	Robust	Medium	High	Observations of recent volcanic eruptions / reconstructions of past eruptions	Elevated due to improved understanding

Notes:

The confidence level for aerosol-cloud interactions includes rapid adjustments (which include what was previously denoted as cloud lifetime effect or second indirect aerosol effect). The separate confidence level for the rapid adjustment for aerosol-cloud interactions is very low. For aerosol-radiation interaction the table provides separate confidence levels for RF due to aerosol-radiation interaction and rapid adjustment associated with aerosol-radiation interaction.

Evidence is robust for several of the RF agents because of long term observations of trends over the industrial era and well defined links between atmospheric or land surfaced changes and their radiative effects. Evidence is medium for a few agents where the anthropogenic changes or the link between the forcing agent and its radiative effect are less certain. Medium evidence can be assigned in cases where observations or modelling provide a diversity of information and thus not a consistent picture for a given forcing agent. We assess the evidence to be limited only for rapid adjustment associated with aerosol-cloud interaction where model studies in some cases indicate changes but direct observations of clouds alterations are scarce. High agreement is only given for the WMGHG where the relative uncertainties in the RF estimates are much smaller than for the other RF agents. Low agreement can either be due to large diversity in estimates of the magnitude of the forcing or from the fact that the method to estimate the forcing has a large uncertainty. Stratospheric water vapour is an example of the latter with modest difference in the few available estimates but a known large uncertainty in the radiative transfer calculations (see further description in Section 8.3.1).

Figure 8.14 shows the development of the confidence level over the last 4 IPCC assessments for the various RF mechanisms. In the previous IPCC reports level of scientific understanding (LOSU) has been used instead of confidence level. For comparison with previous IPCC assessments the LOSU is converted approximately to confidence level. Note that LOSU and confidence level use different terms for their rankings. The figure shows generally increasing confidence levels but also that more RF mechanisms have been included over time. The confidence level for the RF due to aerosol-radiation interactions, surface albedo due to land use, and volcanic aerosols have been raised and are now at the same ranking as those for change in stratospheric and tropospheric ozone. This is due to an increased understanding of key parameters and their uncertainties for the elevated RF agents. For tropospheric and stratospheric ozone changes research

has shown further complexities with changes primarily influencing the troposphere or the stratosphere being linked to some extent (see Section 8.3.3). The rapid adjustment associated with aerosol-cloud interactions is given the confidence level *very low* and had a similar level in AR4. For rapid adjustment associated with aerosol-radiation interactions (previously denoted as semi-direct effect) the confidence level is *low* and is raised compared to AR4, since the evidence is improved and is now medium (see Chapter 7, Section 7.5.2).

[INSERT FIGURE 8.14 HERE]

Figure 8.14: Confidence level of the forcing mechanisms in the 4 last IPCC assessments. In the previous IPCC assessments the level of scientific understanding (LOSU) has been adopted instead of confidence level, but for comparison with previous IPCC assessments the LOSU is converted approximately to confidence level. The thickness of the bars represents the relative magnitude of the current forcing (with a minimum value for clarity of presentation). LOSU for the RF mechanisms was not available in the first IPCC Assessment (Houghton et al., 1990). Rapid adjustments associated with aerosol-cloud interactions (shown as RA aero.-cloud interac.) which include what was previously referred to as the second indirect aerosol effect or cloud lifetime effect whereas rapid adjustments associated with aerosol-radiation interactions (shown as RA aero.-rad. interac.) were previously referred to as the semi-direct effect (see Chapter 7, Figure 7.3). In AR4 the confidence level for aerosol-cloud interaction was given both for RF due to aerosol-cloud interaction and rapid adjustment associated with aerosol-cloud interaction. Generally the aerosol-cloud interaction is not separated into various components in AR5, hence the confidence levels for ERF due to aerosol-cloud interaction in AR5 and for RF due to aerosol-cloud interaction from previous IPCC reports are compared. The confidence level for the rapid adjustment associated with aerosol-cloud interaction is comparable for AR4 and AR5.

Table 8.6 shows the best estimate of the RF and ERF (for AR5 only) for the various RF agents from the various IPCC assessments. The RF due to WMGHG has increased by 16% and 8% since TAR and AR4, respectively. This is mainly due to increased concentrations (see Section 8.3.2), whereas the other changes for the anthropogenic RF agents compared to AR4 are due to re-evaluations and in some cases from improved understanding. An increased number of studies, additional observational data, and better agreement between models and observations can be the causes for such re-evaluations. The best estimates for RF due to aerosol-radiation interactions, BC on snow, and solar irradiance are all substantially decreased in magnitude compared to AR4, otherwise the modifications to the best estimates are rather small. For the RF due to aerosol-radiation interaction and BC on snow the changes in the estimates are based on additional new studies since AR4 (see Section 8.3.4 and Chapter 7, Section 7.5). For the change in the estimate of the solar irradiance it is a combination on how the RF is calculated, new evidence showing some larger earlier estimates were incorrect, and a downward trend observed during recent years in the solar activity that has been taken into account (see Section 8.4.1). The estimate for ERF due to aerosol-cloud interaction includes rapid adjustment but still this ERF is smaller in magnitude than the AR4 RF estimate due to aerosol-cloud interactions without rapid adjustments (a theoretical construct not quantified in AR5). The uncertainties for ERF due to CO₂ increase when compared to RF (see Section 8.3.2). We assume the relative ERF uncertainties for CO₂ apply to all WMGHG. For the short-lived GHG we do not have sufficient information to include separate ERF uncertainty to each of these forcing agents (see Section 8.1.1.3). However, for these forcing mechanisms the RF uncertainties are larger than for the WMGHG and thus it is unlikely that rapid adjustments change the uncertainties substantially.

Figure 8.15 shows the RF for agents listed in Table 8.6 over the 1750–2011 period. The methods for calculation of forcing estimates are described in Section 8.3 and 8.4. For some of the components the forcing estimates are based on observed abundance whereas some are estimated from a combination of model simulations and observations whereas for others are purely model based. Solid bars are given for ERF, whereas RF values are given as (additional) hatched bars. Similarly the uncertainties are given for ERF in solid lines and dotted lines for RF. An important assumption is that different forcing mechanisms can be treated additively to calculate the total forcing (see Boucher and Haywood, 2001; Forster et al., 2007; Haywood and Schulz, 2007). Total ERF over the industrial era calculated from Monte Carlo simulations are shown in Figure 8.16, with a best estimate of 2.29 W m⁻². For each of the forcing agents a PDF is generated based on uncertainties provided in Table 8.6. The combination of the individual RF agents to derive total forcing follows the same approach as in AR4 (Forster et al., 2007) which is based on the method in Boucher and Haywood (2001). The PDF of the GHGs (sum of WMGHG, ozone, and stratospheric water vapour) has a more narrow shape than the PDF for the aerosols due to the much lower relative uncertainty. Therefore, the large uncertainty in the aerosol forcing is the main cause of the large uncertainty in the total anthropogenic ERF. The total anthropogenic forcing is *virtually certain* to be positive with the probability for a negative value less than 0.1%. Compared to AR4 the total anthropogenic ERF is more strongly positive with an

increase of 44%. This is caused by a combination of growth in GHG concentration, and thus strengthening in forcing of WMGHG, and weaker ERF estimates of aerosols (aerosol-radiation and aerosol-cloud interaction) as a result of new assessments of these effects.

Table 8.6: Summary table of RF estimates for AR5 and comparison with the 3 previous IPCC assessment reports. ERF values for AR5 are included. For AR5 the values are given for the period 1750–2011, whereas earlier final years have been adopted in the previous IPCC assessment reports.

	Global Mean Radiative Forcing ($W m^{-2}$)				Comment	ERF ($W m^{-2}$)
	SAR (1750–1993)	TAR (1750–1998)	AR4 (1750–2005)	AR5 (1750–2011)		AR5
Well-mixed Greenhouse Gases (CO ₂ , CH ₄ , N ₂ O, and Halocarbons)	2.45 (2.08 to 2.82)	2.43 (2.19 to 2.67)	2.63 (2.37 to 2.89)	2.83 (2.54 to 3.12)	Change due to increase in concentrations	2.83 (2.26 to 3.40)
Tropospheric Ozone	+0.40 (0.20 to 0.60)	+0.35 (0.20 to 0.50)	+0.35 (0.25 to 0.65)	+0.40 (0.20 to 0.60)	Slightly modified estimate	
Stratospheric Ozone	–0.1 (–0.2 to –0.05)	–0.15 (–0.25 to –0.05)	–0.05 (–0.15 to +0.05)	–0.05 (–0.15 to +0.05)	Estimate unchanged	
Stratospheric Water Vapour from CH ₄	Not estimated	+0.01 to +0.03	+0.07 (+0.02, +0.12)	+0.07 (+0.02 to +0.12)	Estimate unchanged	
Aerosol-Radiation Interactions	Not estimated	Not estimated	–0.50 (–0.90 to –0.10)	–0.35 (–0.85 to +0.15)	Re-evaluated to be smaller in magnitude	–0.45 (–0.95 to +0.05)
Aerosol-Cloud Interactions	0 to –1.5 (sulphate only)	0 to –2.0 (all aerosols)	–0.70 (–1.80 to –0.30) (all aerosols)	Not estimated	Replaced by ERF and re-evaluated to be smaller in magnitude	–0.45 (–1.2 to 0.0)
Surface Albedo (Land Use)	Not estimated	–0.20 (–0.40 to 0.0)	–0.20 (–0.40 to 0.0)	–0.15 (–0.25 to –0.05)	Re-evaluated to be slightly smaller in magnitude	
Surface Albedo (BC aerosol on Snow and Ice)	Not estimated	Not estimated	+0.10 (0.0 to +0.20)	+0.04 (+0.02 to +0.09)	Re-evaluated to be weaker	
Contrails	Not estimated	+0.02 (+0.006 to +0.07)	+0.01 (+0.003 to +0.03)	+0.01 (+0.005 to +0.03)	No major change	
Combined Contrails and Contrail Induced Cirrus	Not estimated	0 to +0.04	Not estimated	Not estimated		0.05 (0.02 to 0.15)
Total Anthropogenic	Not estimated	Not estimated	1.6 (0.6 to 2.4)		Stronger positive due to changes in various forcing agents	2.3 (1.1 to 3.3)
Solar Irradiance	+0.30 (+0.10 to +0.50)	+0.30 (+0.10 to +0.50)	+0.12 (+0.06 to +0.30)	+0.05 (0.0 to +0.10)	Re-evaluated to be weaker	

Notes:

Volcanic RF is not added to the table due to the periodic nature of volcanic eruptions which makes it difficult to compare to the other forcing mechanisms.

[INSERT FIGURE 8.15 HERE]

Figure 8.15: Bar chart for RF (hatched) and ERF (solid) for the period 1750–2011, where the total ERF is derived from Figure 8.16. Uncertainties (5–95% confidence range) are given for RF (dotted lines) and ERF (solid lines).

[INSERT FIGURE 8.16 HERE]

Figure 8.16: Probability density function (PDF) of ERF due to total GHG, aerosol forcing, and total anthropogenic forcing. The GHG consists of WMGHG, ozone, and stratospheric water vapour. The PDFs are generated based on uncertainties provided in Table 8.6. The combination of the individual RF agents to derive total forcing over the industrial era are done by Monte Carlo simulations and based on the method in Boucher and Haywood (2001). PDF of the ERF from surface albedo changes and combined contrails and contrail induced cirrus are included in the total anthropogenic forcing, but not shown as a separate PDF. We currently do not have ERF estimates for some forcing mechanisms: ozone, land use, solar etc. For these forcings we assume that the RF is representative of the ERF and for the ERF uncertainty an additional uncertainty of 17% has been included in quadrature to the RF uncertainty. See Supplementary Material Section 8.SM.7 and Table 8.SM.4 for further description on method and values used in the calculations. Lines at the top of the figure compare the best estimates and uncertainty ranges (5–95% confidence range) with RF estimates from AR4.

Figure 8.17 shows the forcing over the industrial era by emitted compounds (see Supplementary Material Tables 8.SM.6 and 8.SM.7 actual numbers and references). It is more complex to view the RF by emitted species than by change in atmospheric abundance (Figure 8.15) since the number of emitted compounds and changes leading to RF is larger than the number of compounds causing RF directly (see Section 8.3.3). The main reason for this is the indirect effect of several compounds and in particular components involved in atmospheric chemistry (see Section 8.2). To estimate the RF by the emitted compounds in some cases the emission over the entire industrial era is needed (e.g., for CO₂) whereas for other compounds (such as ozone and CH₄) quite complex simulations are required (see Section 8.3.3). CO₂ is the dominant positive forcing both by abundance and by emitted compound. Emissions of CH₄, CO, and NMVOC all lead to excess CO₂ as one end product if the carbon is of fossil origin and is the reason why the RF of direct CO₂ emissions is slightly lower than the RF of abundance change of CO₂. For CH₄ the contribution from emission is estimated to be almost twice as large as that from the CH₄ concentration change, 0.97 W m⁻² versus 0.48 W m⁻², respectively. This is because emission of CH₄ leads to ozone production, stratospheric water vapour, CO₂ (as mentioned above), and importantly affects its own lifetime (Section 8.2). Actually, emissions of CH₄ would lead to a stronger RF via the direct methane greenhouse effect (0.64 W m⁻²) than the RF from abundance change of CH₄ (0.48 W m⁻²). This is because other compounds have influenced the lifetime of CH₄ and reduced the abundance of CH₄, most notably NO_x. Emissions of CO (0.23 W m⁻²) and NMVOC (0.10 W m⁻²) have only indirect effects on RF through ozone production, CH₄ and CO₂ and thus contribute an overall positive RF. Emissions of NO_x on the other hand have indirect effects that lead to positive RF through ozone production and also effects that lead to negative RF through reduction of CH₄ lifetime and thus its concentration, and through contributions to nitrate aerosol formation. The overall effect of anthropogenic emissions of NO_x is a negative RF. Emissions of ammonia also contribute to nitrate aerosol formation, with a small offset due to compensating changes in sulphate aerosols. Additionally indirect effects from sulphate on atmospheric compounds are not included here as models typically simulate a small effect, but there are large relative differences in the response between models. Impacts of emissions other than CO₂ on the carbon cycle via changes in atmospheric composition (ozone or aerosols) are also not shown due to the limited amount of available information.

Emissions of BC have a positive RF through aerosol-radiation interactions and BC on snow (0.64 W m⁻², see Section 8.3.4 and Chapter 7, Section 7.5). The emissions from the various compounds are co-emitted; this is in particular the case for BC and OC from biomass burning aerosols. The net RF of biomass burning emissions for aerosol-radiation interactions is close to zero, but with rather strong positive RF from BC and negative RF from OC (see Sections 8.3.4 and Chapter 7, Section 7.5). The ERF due to aerosol-cloud interactions is caused by primary anthropogenic emissions of BC, OC, and dust as well as secondary aerosol from anthropogenic emissions of SO₂, NO_x and NH₃. However, quantification of the contribution from the various components to the ERF due to aerosol-cloud interactions has not been attempted in this assessment.

[INSERT FIGURE 8.17 HERE]

Figure 8.17: RF bar chart for the period 1750–2011 based on emitted compounds (gases, aerosols or aerosol precursors) or other changes. Numerical values and their uncertainties are shown in Supplementary Material Tables 8.SM.6 and 8.SM.7. Note, that a certain part of CH₄ attribution is not straightforward and discussed further in Section 8.3.3. Red (positive RF) and blue (negative forcing) are used for emitted components which affect few forcing agents, whereas for emitted components affecting many compounds several colours are used as indicated in the inset at the upper part the figure. The vertical bars indicate the relative uncertainty of the radiative forcing induced by each component. Their length is proportional to the thickness of the bar, i.e., the full length is equal to the bar thickness for a ±50% uncertainty. The net impact of the individual contributions is shown by a diamond symbol and its uncertainty (5–95% confidence range) is given by the horizontal error bar. ERF_{aci} is ERF due to aerosol-cloud interaction. BC and OC

are co-emitted, especially for biomass burning emissions (given as Biomass Burning in the figure) and to a large extent also for fossil and biofuel emissions (given as Fossil and Biofuel in the figure). SOA has not been included since the formation depends on a variety of factors not currently sufficiently quantified.

8.5.2 Time Evolution of Historical Forcing

The time evolution of global mean forcing is shown in Figure 8.18 for the industrial era. Over all time periods during the industrial era CO₂ and other WMGHG have been the dominant term, except for shorter periods with strong volcanic eruptions. The time evolution shows an almost continuous increase in the magnitude of anthropogenic ERF. This is the case both for CO₂ and other WMGHG as well as several individual aerosol components. The forcing from CO₂ and other WMGHG has increased somewhat faster since the 1960s. The total aerosol ERF (aerosol-radiation interaction and aerosol-cloud interaction) has the strongest negative forcing (except for brief periods with large volcanic forcing), with a strengthening in the magnitude similar to many of the other anthropogenic forcing mechanisms with time. The global mean forcing of aerosol-radiation interactions was rather weak until 1950 but strengthened in the latter half of the last century and in particular in the period between 1950 and 1980. The RF due to aerosol-radiation interaction by aerosol component is shown in Section 8.3.4 (Figure 8.8).

While there is *high confidence level* for a substantial enhancement in the negative aerosol forcing in the period 1950–1980, there is much more uncertainty in the relative change in global mean aerosol forcing over the last two decades (1990–2010). Over the last two decades there has been a strong geographic shift in aerosol and aerosol precursor emissions (see Chapter 2, Section 2.2.3), and there are some uncertainties in these emissions (Granier et al., 2011). In addition to the regional changes in the aerosol forcing there is also likely a competition between various aerosol effects. Emission data indicate a small increase in the BC emissions (Granier et al., 2011) but model studies also indicate a weak enhancement of other aerosol types. Therefore, the net aerosol forcing depends on the balance between absorbing and scattering aerosols for aerosol-radiation interaction as well as balance between the changes in aerosol-radiation and aerosol-cloud interactions. In the ACCMIP models, for example, the RF due to aerosol-radiation interaction becomes less negative during 1980 to 2000, but total aerosol ERF becomes more negative (Shindell et al., 2013c). There is a *very low confidence level* for the trend in the total aerosol forcing during the past 2–3 decades, even the sign; however, there is *high confidence* that the offset from aerosol forcing to WMGHG forcing during this period was much smaller than over the 1950–1980 period.

The volcanic RF has a very irregular temporal pattern and for certain years has a strongly negative RF. There has not been a major volcanic eruption in the past decade, but some weaker eruptions give a current RF that is slightly negative relative to 1750 and slightly stronger in magnitude compared to 1999–2002 (see Section 8.4.2).

Figure 8.19 shows linear trends in forcing (anthropogenic, natural and total) over four different time periods. Three of the periods are the same as chosen in Chapter 9, Box 9.2 (1984–1998, 1998–2011, and 1951–2011) and the period 1970–2011 is shown in Chapter 13, Box 13.1. Monte Carlo simulations are performed to derive uncertainties in the forcing based on ranges given in Table 8.6 and the derived linear trends. Further, these uncertainties are combined with uncertainties derived from shifting time periods ± 2 years and the full 90% confidence range is shown in Figure 8.19 (in Box 9.2 only the total forcing is shown with uncertainties derived from the forcing uncertainty without sensitivity to time period). For the anthropogenic forcing sensitivity to the selection of time periods is very small with a maximum contribution to the uncertainties shown in Figure 8.19 of 2%. However, for the natural forcing the sensitivity to time periods is the dominant contributor to the overall uncertainty (see Supplementary Material Figure 8.SM.3) for the relatively short periods 1998–2011 and 1984–1998, whereas this is not the case for the longer periods. For the 1998–2011 period the natural forcing is negative and the offset of anthropogenic forcing by natural forcing over this period is *likely* substantial. For the 1998–2011 period both the volcanic and solar forcings contribute to this negative natural forcing, with the latter dominating. For the other periods shown in Figure 8.19 the best estimate of the natural is much smaller in magnitude than the anthropogenic forcing, but note that the natural forcing is very dependent on the selection of time period near the 1984–1998 interval. Over the period 1951–2011 the trend in anthropogenic forcing is almost 0.3 W m^{-2} per decade and thus anthropogenic forcing over this period is more than 1.5 W m^{-2} . The anthropogenic forcing for 1998–2011 is 30% higher and with smaller uncertainty than for the 1951–2011 period. Note, that due to large WMGHG forcing (Section 8.3.2)

the anthropogenic forcing was similar in the late 1970s and early 1980s to the 1998–2011 period. The reason for the reduced uncertainty in the 1998–2011 anthropogenic forcing is the larger domination of WMGHG forcing and smaller contribution from aerosol forcing compared to previous periods. Similar to the results for 1970–2011 in Figure 8.19, Box 13.1 shows that the global energy budget is dominated by anthropogenic forcing compared to the natural forcing, except for the two major volcanic eruption in this period as can be easily seen in Figure 8.18.

[INSERT FIGURE 8.18 HERE]

Figure 8.18: Time evolution of forcing for anthropogenic and natural forcing mechanisms. Bars with the forcing and uncertainty ranges (5–95% confidence range) at present are given in the right part of the figure. For aerosol the ERF due to aerosol-radiation interaction and total aerosol ERF are shown. The uncertainty ranges are for present (2011 versus 1750) and are given in Table 8.6. For aerosols, only the uncertainty in the total aerosol ERF is given. For several of the forcing agents the relative uncertainty may be larger for certain time periods compared to present. See Supplementary Material Table 8.SM.8 for further information on the forcing time evolutions. Forcing numbers provided in Annex II.

[INSERT FIGURE 8.19 HERE]

Figure 8.19: Linear trend in anthropogenic, natural and total forcing for the indicated time periods. The uncertainty ranges (5–95% confidence range) are combined from uncertainties in the forcing values (from Table 8.6) and the uncertainties in selection of time period. Monte Carlo simulations were performed to derive uncertainties in the forcing based on ranges given in Table 8.6 and linear trends in forcing. The sensitivity to time periods has been derived from changing the time periods by ± 2 years.

Figure 8.20 shows the forcing between 1980 and 2011. Compared to the whole industrial era the dominance of the CO₂ is larger for this recent period both with respect to other WMGHG and the total anthropogenic RF. The forcing due to aerosols is rather weak leading to a very strong net positive ERF for the 1980–2011 period. More than 40% of the total anthropogenic ERF has occurred over the 1980–2011 period with a value close to 1.0 W m⁻². The major contribution to the uncertainties in the time evolution of the anthropogenic forcing is associated with the aerosols (see Section 8.5.1). Despite this, anthropogenic ERF is *very likely* considerably more positive than the natural RF over the decadal time periods since 1950. This is in particular the case after 1980, where satellite data are available that provide important measurements to constrain the natural RF mechanisms (e.g., the volcanic RF change between 2007–2011 and 1978–1982 is 0.06 W m⁻² and the representative change in solar irradiance over the 1980–2011 period is -0.06 W m⁻²).

[INSERT FIGURE 8.20 HERE]

Figure 8.20: Bar chart for RF (hatched) and ERF (solid) for the period 1980–2011, where the total anthropogenic ERF are derived from Monte-Carlo simulations similar to Figure 8.16. Uncertainties (5–95% confidence range) are given for RF (dotted lines) and ERF (solid lines).

8.5.3 Future Radiative Forcing

Projections of global mean RF are assessed based on results from multiple sources examining the RF due to RCP emissions: the ACCMIP initiative (see Section 8.2) provides analysis of the RF or ERF due to aerosols and ozone (Shindell et al., 2013c), while WMGHG, land use and stratospheric water RFs are taken from the results of calculations with the reduced-complexity model MAGICC 6 driven by the RCP emissions and land use (Meinshausen et al., 2011a). While MAGICC 6 also estimated ozone and aerosol RF, those values differ substantially from the ACCMIP values and are considered less realistic. Additional discussion of biases in the MAGICC 6 results due to the simplified representations of atmospheric chemistry and the carbon cycle, along with further discussion on the representativeness of the RCP projections in context with the broader set of scenarios in the literature, is presented in Chapter 11, Section 11.3.5 and Chapter 12, Section 12.3 (also see Section 8.2). As the ACCMIP project provided projected forcings primarily at 2030 and 2100, we hereafter highlight those times. While understanding the relative contributions of various processes to the overall effect of aerosols on forcing is useful, we emphasize the total aerosol ERF, which includes all aerosol–radiation and aerosol–cloud interactions, as this is the most indicative of the aerosol forcing driving climate change. We also present traditional RF due to aerosol–radiation interaction (previously called aerosol direct forcing) but do not examine further the various components of aerosol ERF. Aerosol forcing estimates, both mean and uncertainty ranges, are derived from the 10 ACCMIP models, 8 of which are also CMIP5

models. We analyze forcing during the 21st century (relative to 2000), and hence the WMGHG forcing changes are in addition to persistent forcing from historical WMGHG increases.

Analysis of forcing at 2030 relative to 2000 shows that under RCP2.6, total ozone (tropospheric and stratospheric) forcing is near zero, RF due to aerosol-radiation interaction is positive but small, and hence WMGHG forcing dominates changes over this time period (Figure 8.21). WMGHG forcing is dominated by increasing CO₂, as declining methane and increasing N₂O have nearly offsetting small contributions to forcing. Aerosol ERF was not evaluated for this RCP under ACCMIP, and values cannot be readily inferred from RF due to aerosol-radiation interaction as these are not directly proportional. Under RCP8.5, RF due to aerosol-radiation interaction in 2030 is weakly negative, aerosol ERF is positive with a fairly small value and large uncertainty range, total ozone forcing is positive but small ($\sim 0.1 \text{ W m}^{-2}$), and thus WMGHG forcing again dominates with a value exceeding 1 W m^{-2} . As with RCP2.6, WMGHG forcing is dominated by CO₂, but under this scenario the other WMGHGs all contribute additional positive forcing. Going to 2100, ozone forcing diverges in sign between the two scenarios, consistent with changes in the tropospheric ozone burden (Figure 8.4) which are largely attributable to projected methane emissions, but is small in either case. Ozone RF is the net impact of a positive forcing from stratospheric ozone recovery owing to reductions in anthropogenic ozone-depleting halocarbon emissions in both scenarios and a larger impact from changes in tropospheric precursors (Shindell et al., 2013c) which have a negative forcing in RCP2.6 and a positive forcing in RCP8.5.

The two scenarios are fairly consistent in their trends in RF due to aerosol-radiation interaction by component (Figure 8.21). There is positive RF due to aerosol-radiation interaction due to reductions in sulfate aerosol. This is largely offset by negative RF due to aerosol-radiation interaction by primary carbonaceous aerosols and especially by nitrate (though nearly all CMIP5 models did not include nitrate), leaving net aerosol RF due to aerosol-radiation interaction values that are very small, 0.1 W m^{-2} or less in magnitude, in either scenario at 2030 and 2100. Nitrate aerosols continue to increase through 2100 as ammonia emissions rise steadily due to increased use of agricultural fertilizer even as all other aerosol precursor emissions decrease (Figure 8.2), including sulphur dioxide which drives the reduction in sulphate aerosol that also contributes to additional formation of nitrate aerosols in the future (Bauer et al., 2007; Bellouin et al., 2011). Aerosol ERF is likely similar at this time in all scenarios given that they all have greatly reduced emissions of all aerosols and aerosol precursors other than ammonia. Aerosol ERF shows a large positive value at 2100 relative to 2000, nearly returning to its 1850 levels (the 2100 versus 1850 ERF represents a decrease in ERF of 91% relative to the 2000 versus 1850 value), as is expected given the RCP emissions. Thus although some models project large increases in nitrate RF in the future, the reduction in overall aerosol loading appears to lead to such a strong reduction in aerosol ERF that the impact of aerosols becomes very small under these RCPs. Of course the projections of drastic reductions in primary aerosol as well as aerosol and ozone precursor emissions may be overly optimistic as they assume virtually all nations in the world become wealthy and that emissions reductions are exclusively dependent upon wealth. The RCPs also contain substantially lower projected growth in HFC emissions than in some studies (e.g., Velders et al., 2009).

While aerosol ERF becomes less negative by nearly 1 W m^{-2} from 2000 to 2100, this change is still small compared with the increased WMGHG forcing under RCP8.5, which is roughly 6 W m^{-2} during this time (Figure 8.21). Roughly 5 W m^{-2} of this WMGHG forcing comes from CO₂, with substantial additional forcing from increases in both methane and nitrous oxide and only a very small negative forcing from reductions in halocarbons. Under RCP2.6, the WMGHG forcing is only about 0.5 W m^{-2} during this time, as relatively strong decreases in methane and halocarbon forcing offset roughly 40% of the increased CO₂ forcing, which is itself far less than under RCP8.5. Hence under this scenario, the projected future forcing due to aerosol reductions is actually stronger than the WMGHG forcing. Viewing the timeseries of the various forcings, however, indicates that aerosol ERF is returning to its preindustrial levels, so that net forcing becomes increasingly dominated by WMGHGs regardless of scenario during the 21st century (Figure 8.22). As the forcing is so heavily dominated by WMGHGs at 2100, and the WMGHG concentrations (CO₂) or emissions (others) were chosen to match forcing targets, all the scenarios show net forcing values at that time that are fairly close to the scenarios' target values. The reduced aerosol forcing, with its large uncertainty, leads to a pronounced decrease in the uncertainty of the total net forcing by 2100. Based on the spread across ACCMIP models (using ERF for aerosols and converting to ERF for GHGs), the 90% confidence interval (CI) is about 20% for the 2100 net forcing, versus 26% for 2030 under RCP8.5 and

45–61% for 1980 and 2000 (Shindell et al., 2013c). The total ERF due to all causes has been independently estimated based on the transient response in the CMIP5 models and a linear forcing-response relationship derived through regression of the modelled response to an instantaneous increase in CO₂ (Forster et al., 2013). Uncertainties based on model spread behave similarly, with the 90% CI for net total ERF decreasing from 53% for 2003 to only 24–34% for 2100 (values are presumably larger than ACCMIP estimates due to use of ERF rather than RF for GHGs). Forcing due to land use (via albedo only) and stratospheric water vapor changes are not shown separately as their projected values under the four RCPs are quite small: 0.00 to –0.09 and 0.10 to –0.03 W m^{–2}, respectively.

The CMIP5 forcing estimates (Forster et al., 2013) for the total projected 2030 and 2100 ERF are slightly smaller than the results obtained from the ACCMIP models (or the RCP targets; see Chapter 12, Section 12.3.3). Examining the subset of models included in both this regression analysis and in ACCMIP shows that the ACCMIP subset show forcings on the low side of the mean value obtained from the full set of CMIP5 analyzed, indicating that the discrepancy between the methods is not related to analysis of a different set of models. Instead, it may reflect non-linearities in the response to forcing that are not represented by the regression analysis of the response to abrupt CO₂ increase experiments (Long and Collins, 2013) or differences in the response to other forcing agents relative to the response to CO₂ used in deriving the CMIP5 estimates (see also 12.3.3).

Natural forcings will also change in the future. The magnitudes cannot be reliably projected, but are likely to be small at multi-decadal scales (see Section 8.4). Brief episodic volcanic forcing could be large, however.

[INSERT FIGURE 8.21 HERE]

Figure 8.21: Radiative forcing relative to 2000 due to anthropogenic composition changes based on ACCMIP models for aerosols (with aerosol ERF scaled to match the best estimate of present-day forcing) and total ozone and RCP WMGHG forcings. Ranges are one standard deviation in the ACCMIP models and assessed relative uncertainty for WMGHGs and stratospheric water vapor. Carbonaceous aerosols refers to primary carbonaceous, while SOA are secondary organic aerosols. Note that 2030 ERF for RCP2.6 was not available, and hence the total shown for that scenario is not perfectly comparable to the other total values. RFari is RF due to aerosol-radiation interaction.

[INSERT FIGURE 8.22 HERE]

Figure 8.22: Global mean anthropogenic forcing with symbols indicating the times at which ACCMIP simulations were performed (solid lines with circles are net, long dashes with squares are ozone, short dashes with diamonds are aerosol, dash-dot are WMGHG, colors indicate the RCPs with red for RCP8.5, orange RCP6.0, light blue RCP4.5, and dark blue RCP2.6). RCPs 2.6, 4.5 and 6.0 net forcings at 2100 are approximate values using aerosol ERF projected for RCP8.5 (modified from Shindell et al., 2013c). Some individual components are omitted for some RCPs for visual clarity.

8.6 Geographic Distribution of Radiative Forcing

The forcing spatial pattern of the various RF mechanisms varies substantially in space and in time, especially for the NTCFs. The spatial pattern is of interest to the extent that it may influence climate response (Section 8.6.2.2) as is being particularly investigated in the ACCMIP simulations.

8.6.1 Spatial Distribution of Current Radiative Forcing

The WMGHGs such as CO₂ have largest forcing in the subtropics, decreasing toward the poles, with largest forcing in warm and dry regions and smaller values in moist regions and in high-altitude regions (Taylor et al., 2011). For the NTCFs (Box 8.2) their concentration spatial pattern and therefore their RF pattern are highly inhomogeneous, and again meteorological factors such as temperature, humidity, clouds, and surface albedo influence how concentration translates to RF.

Figure 8.23 shows the RF spatial distribution of the major NTCFs together with standard deviation among the ACCMIP models (Shindell et al., 2013c) the net anthropogenic composition (WMGHG+ozone+aerosol) forcing is also shown (lower left panel). These models used unified anthropogenic emissions of aerosol and ozone precursors (Supplementary Material Figure 8.SM.2), so that the model diversity in RF is due only to differences in model chemical and climate features and natural emissions, and would be larger if uncertainty

in the anthropogenic emissions were also included. In general, the confidence in geographical distribution is lower than for global mean, due to uncertainties in chemistry, transport and removal of species.

The negative RF due to aerosol-radiation interaction (first row; defined in Chapter 7, Figure 7.3) is greatest in the NH and near populated and biomass burning regions. The standard deviation for the net RF due to aerosol-radiation interaction is typically largest over regions where vegetation changes are largest (e.g., South Asia and central Africa), due to uncertainties in biomass burning aerosol optical properties and in treatment of secondary organic aerosols. Carbonaceous aerosol forcing (second row) is greatest in South and East Asia and can be negative in biomass burning regions due to large weakly absorbing organic components. Absorbing aerosols also have enhanced positive forcing when they overlie high albedo surfaces such as cryosphere, desert or clouds, with as much as 50% of BC RF resulting from BC above clouds (Zarzycki and Bond, 2010).

Figure 8.24 compares the aerosol RFs for ACCMIP (Shindell et al., 2013c), which are representative of the CMIP5 experiments, with those from the AeroCom model intercomparison (Myhre et al., 2013) which includes sixteen models that used unified meteorology and are more extensively compared to measurements (e.g., Koch et al., 2009b; Koffi et al., 2012). The forcing results are very similar, establishing the representativeness and validity of the ACCMIP aerosol simulations.

The net aerosol ERF (Figure 8.23; third row), includes both aerosol-radiation and aerosol-cloud interactions. The spatial pattern correlates with the RF (first row), except with stronger effect in the outflow regions over oceans. The flux change is larger in the NH than the SH (e.g., by nearly a factor of 3; Ming et al., 2007). Rapid adjustment associated with aerosol-radiation and aerosol-cloud interactions may enhance or reduce cloud cover depending on the region, cloud dynamics and aerosol loading (e.g., Randles and Ramaswamy, 2008; Koch and Del Genio, 2010; Persad et al., 2012). In general, the ocean-land forcing pattern differs from that reported in AR4, where the forcing due to aerosol-cloud interaction were larger over land than ocean (Forster et al., 2007), and this continues to be a source of uncertainty. Since AR4, Quaas et al. (2009) showed using satellite retrievals that the correlation between AOD changes and droplet number changes is stronger over oceans than over land and that models tend to overestimate the strength of the relation over land. Penner et al. (2011) showed that satellite retrievals, due to their dependence on present-day conditions, may underestimate the forcing due to aerosol-cloud interaction, especially over land, although this model analysis may overestimate the cloud condensation nucleus to AOD relation (Quaas et al., 2011). Wang and Penner (2009) also showed that if models include boundary layer nucleation and increase the fraction of sulphur emitted as a primary particle, the effect over land is increased relative to over ocean (see also Chapter 7, Section 7.5.3). The aerosol ERF standard deviation is large in biomass burning regions, as for the RF, and in regions where cloud effects differ among models (e.g., northern North America, northeast Asia, Amazonia). The spread in aerosol ERF is much larger than for the RF alone, although the relative standard deviation is no larger (Shindell et al., 2013c).

For components that primarily scatter radiation, the radiative effect at the surface is similar to the RF (according to the definition in Section 8.1.1). However for components that absorb radiation in the atmosphere the radiation reaching the surface is reduced (Forster et al., 2007; Ramanathan and Carmichael, 2008; Andrews et al., 2010). This absorption of incoming solar radiation alters the vertical temperature profile in the atmospheric column and can thus change atmospheric circulation and cloud formation. The aerosol atmospheric absorption (Figure 8.23, bottom right), or the difference between ERF and the analogous radiative flux reaching the surface including rapid adjustments, has a spatial pattern that to lowest order tracks the carbonaceous aerosol forcing, but is also affected by cloud changes, where e.g., cloud loss could enhance atmospheric absorption. Atmospheric aerosol absorption patterns thus mirror the ERF due to aerosol-cloud interaction pattern, with larger forcing over continents.

Ozone RF is calculated using the methodology described in Shindell et al. (2013c), but applied to the larger set of models in ACCMIP (Stevenson et al., 2013). The net ozone RF (Figure 8.23; fourth row) is largest in subtropical latitudes, and is more positive in the NH than the SH. Pollution in the NH accounts for positive tropospheric forcing; stratospheric ozone loss has caused negative SH polar forcing. Model standard deviation is largest in the polar regions where lower stratosphere/upper troposphere changes differ in the models (Young et al., 2013).

Overall, the *confidence* in aerosol and ozone RF spatial patterns is *medium* and lower than that for the global mean due to the large regional standard deviations (Figure 8.23), and is exacerbated in aerosol ERF patterns due to uncertainty in cloud responses.

[INSERT FIGURE 8.23 HERE]

Figure 8.23: Spatial pattern of ACCMIP models 1850 to 2000 forcings, mean values (left) and standard deviation (right) for aerosols and ozone (top 4 rows). Values above are the average of the area-weighted global means, with the area weighted mean of the standard deviation of models at each point provided in parenthesis. Shown are net aerosol RF due to aerosol-radiation interaction (top, 10 models), carbonaceous aerosol RF due to aerosol-radiation interaction (2nd row, 7 models), aerosol ERF (3rd row, 8 models), ozone (4th row, 11 models), total anthropogenic composition forcing (WMGHG+ozone+aerosols; bottom left), aerosol atmospheric absorption including rapid adjustment (bottom right, 6 models). Note that RF and ERF means are shown with different color scales, and standard deviation color scales vary among rows.

[INSERT FIGURE 8.24 HERE]

Figure 8.24: Spatial pattern of ACCMIP and 16 AeroCom models 1850 to 2000 RF due to aerosol-radiation interaction, mean values (left) and standard deviation (right). Note that different carbonaceous aerosol diagnostics are used here compared to Figure 8.23, due to available AeroCom fields. Values above are the average of the area-weighted global means, with the area weighted mean of the standard deviation of models at each point provided in parenthesis.

8.6.2 Spatial Evolution of Radiative Forcing and Response over the Industrial Era

8.6.2.1 Regional Forcing Changes During Industrial Era

The spatial distribution of the WMGHG RF has shifted only slightly over the industrial period; however the RF spatial distributions for NTCFs has shifted with emissions, due to the timing of regional development and implementation of pollution standards (Supplementary Material Figures 8.SM.1 and 8.SM.2 show regional trends and emissions maps; Lamarque et al., 2013). Figure 8.25 shows how the distributions of aerosol and ozone forcings are modelled to have changed up to 1930, 1980 and 2000. Substantial industrial coal-burning in the early part of the 20th century occurred in the northeastern United States and western Europe, leading to stronger sulphate and BC forcing near those regions (Figure 8.25, left). Between 1950 and 1970, coal burning for power generation increased while coal burning for other purposes was replaced by oil and natural gas and motor vehicle usage grew rapidly in these regions, leading to more sulphate and less BC. Peak aerosol forcing in North America and Europe occurred around 1970–1980 (Figure 8.25, second column), while Asian development led to increased biofuel and fossil fuel sources of aerosols and ozone precursors toward the end of the century. During the final decades of the century, desulphurization controls reduced sulphur emissions from North America and Europe, resulting in reduced negative forcing in these regions and positive Arctic aerosol forcing. The SH ozone hole developed during the final three decades, with negative forcing over high latitudes. Biomass burning generated ozone and carbonaceous aerosols in NH high-latitudes early in the century, with increased tropical burning from mid to late century.

Aerosol ERF grew rapidly from 1930 to 1980, as did RF due to aerosol-radiation interaction, with a spatial structure reflecting both the influence of aerosol-radiation and aerosol-cloud interactions that are especially strong over pollution outflow regions and over areas with high surface albedo. From 1980 to 2000, aerosol ERF continued to become more negative even as negative RF due to aerosol-radiation interaction grew weaker, with the spatial pattern showing strengthening of aerosol ERF over Asia and weakening of aerosol ERF over North America and Europe.

[INSERT FIGURE 8.25 HERE]

Figure 8.25: Multi-model mean RF due to aerosol-radiation interaction of all aerosols, carbonaceous aerosols, ozone, and aerosol ERF (W m^{-2}) for the indicated times based on the ACCMIP simulations. Global area-weighted means are given in the upper right.

Soil dust has changed since the pre-industrial due to land disturbance and resulting desertification (a forcing) and to changes in climate (a feedback). Mahowald et al. (2010) showed approximate doubling in dust loading over the 20th century (-0.1 W m^{-2} ; consistent with the best estimate in Chapter 7, Section 7.5.2; Chapter 8, Section 8.3.4.2), primarily from the Saharan and Middle Eastern deserts, with largest increase

from the 1950s to the 1980s (-0.3 W m^{-2}), followed by a leveling. The increased dustiness reduces model precipitation within the Saharan source region, improving agreement with observed precipitation.

Aerosol loading changes during the past century have impacted radiation at the surface (Chapter 2, Section 2.3.3), with peak radiation reductions in North America and Europe in the 1980s, and ongoing reduction in South and East Asia (Wild, 2009). The AR4 and CMIP5 models simulated these trends but underestimated their magnitude, the decadal temperature variations and the diurnal temperature range over land (Wild, 2009; see Chapter 9).

Changes in spatial patterns of species and their forcing over the century are difficult to validate due to sparse observations of short-lived species. Some constraint comes from limited historical observations in ice core records and from shorter trends beginning in late century from satellite and surface-based site measurements. The emissions estimates for historical species are very uncertain, especially for carbonaceous aerosols and dust. Therefore, the *confidence* in the historical forcing pattern changes is low for RF due to aerosol-radiation interaction and ozone, and very low for ERF, carbonaceous aerosols and dust.

8.6.2.2 *Relationship Between Regional Forcing Patterns and Climate Response During the Industrial Era*

An increasing body of research considers how spatial variations in radiative forcing affect climate response. Detection and attribution methods have had limited success in discerning statistically significant regional climate signals from regional forcing, due to large internal climate variability at regional scales, uncertainty in model processes and sparse regional observational records (Chapter 10). Meanwhile, research including model sensitivity studies for NTCF's, which vary strongly in space in time, explores climate response patterns.

In AR4 (Forster et al., 2007; Knutti et al., 2008) it was argued that the spatial pattern of forcing is not indicative of the pattern of climate response. Rather, the response is linked more closely to TOA flux resulting from the climate feedback spatial patterns (Boer and Yu, 2003; Taylor et al., 2011; Ming and Ramaswamy, 2012), with the lapse rate, surface albedo and cloud feedbacks explaining most of the temperature response. Yet Crook and Forster (2011) showed that both the spatial distribution of climate feedbacks and of heterogeneous forcing played important roles in the patterns of 20th century temperature changes. Other studies since AR4 have probed relationships between forcing patterns and climate responses.

Broad links between forcing and climate response have been identified. Shindell et al. (2010) used multiple models to show that surface temperature changes are much more sensitive to latitudinal than longitudinal variations in forcing. Shindell and Faluvegi (2009) used a model inverse approach to infer that NH aerosol reduction was associated with over 70% of Arctic warming from the 1970s to the 2000s, and that Arctic and much of the SH surface temperature changes are strongly affected by remote forcing changes (also Chapter 10, Section 10.3.1.1.4). Voulgarakis and Shindell (2010) defined a regional transient temperature sensitivity parameter, or temperature response per unit forcing for each four-degree latitude band. Using observed surface air temperature changes they showed that the parameter is best constrained from 50°S to 25°N , where the value is $0.35^{\circ}\text{C} (\text{W m}^{-2})^{-1}$, smaller than at northern higher latitudes, and 35% smaller than in AR4 models.

Some aerosol model studies have demonstrated highly localized climate response to regional forcing. Significant regional cooling and hydrological shifts in the Eastern U.S. and in Eastern Asia during the last half of the 20th century were modelled and attributed to local aerosols (Leibensperger et al., 2008; Chang et al., 2009; Leibensperger et al., 2012a, 2012b) and localized warming projected for aerosol reductions (Mickley et al., 2012). Observations have also linked historical trends in aerosols and temperature (Ruckstuhl et al., 2008; Philipona et al., 2009).

Since AR4, there has been new research on aerosol influences on the hydrologic cycle (also Chapter 10, Section 10.3.3.1; Chapter 11, Section 11.3.2.4.3, Chapter 7, Sections 7.4 and 7.6.4). Increased aerosol loading, with greater surface energy flux reduction in the NH, has been implicated in the observed southward shift of the intertropical convergence zone (ITCZ) towards the hemisphere with smaller surface energy reduction: southward up to the 1980s with a reversal since (e.g., Denman et al., 2007; Zhang et al., 2007). Several studies have modelled an associated reduction in NH precipitation and associated shifts in the

Hadley circulation (e.g., Rotstayn et al., 2000; Williams et al., 2001; Ming et al., 2011). The ITCZ shift may in turn be responsible for broad regional precipitation changes, including drying of the Sahel (e.g., Rotstayn and Lohmann, 2002; Biasutti and Giannini, 2006; Kawase et al., 2010; Ackerley et al., 2011) and northwestern Brazil (Cox et al., 2008), both of which peaked in the 1980s. These hemispheric asymmetric ITCZ effects are overlaid on thermodynamic aerosol effects which moisten subtropical regions, countering greenhouse gas induced drying of these regions (Ming et al., 2011). Studies indicate that aerosols are more effective than an equivalent WMGHG forcing for shifting precipitation, and that historical trends in several areas cannot be explained without including aerosol forcing (Bollasina et al., 2011; Booth et al., 2012; Shindell et al., 2012a; Shindell et al., 2012b). However, confidence in attribution of any human influence on zonal shifts in precipitation distribution is only *medium* (Chapter 10, Section 10.3.2.2).

There is increasing evidence but limited agreement that absorbing aerosols influence cloud distributions (Chapter 7, Section 7.3.4.2). Absorbing aerosols apparently have complex influences on precipitation in monsoon regions. Model studies of Stephens et al. (2004) and Miller et al. (2004) showed that dust absorption over Africa enhances low-level convergence, vertical velocities and therefore local monsoon circulation and precipitation. On the other hand, Kawase et al. (2010) showed that biomass burning black carbon may cause the decreasing precipitation trend seen in tropical Africa during austral summer, due to reduction in evaporation and enhanced subsidence. The aerosol effects on the Indian monsoon are similarly complex, and have been the subject of numerous studies (e.g., Ramanathan et al., 2005; Chung and Ramanathan, 2006; Lau et al., 2006; Wang et al., 2009; Bollasina et al., (2011), but a clear picture of how the regional aerosol forcing correlates with responses has not yet fully emerged. Attribution of changes in monsoon to human influence generally has *low confidence* (Chapter 10, Section 10.3).

Stratospheric ozone loss modelling has demonstrated an effect on the SH stratosphere similar to increased greenhouse gases, cooling stratospheric temperatures, strengthening the polar vortex and shifting the westerly jet poleward; however causing cooler Antarctic surface temperatures, with larger influence on austral summer conditions (Son et al., 2009; McLandress et al., 2011; Thompson et al., 2011; see also Chapter 10, Section 10.3.3, Chapter 11, Section 11.3.2.4.3.) In the troposphere, models indicate that increased tropospheric ozone has caused warming, proportionally more in the NH and notably to the Arctic during winter, mainly during the second half of the 20th century (Shindell et al., 2006a).

Albedo changes due to land use and land cover changes exert a heterogeneous climate forcing (Figure 8.9). The surface albedo brightened on the one hand due to a shift from forest to brighter croplands, causing local cooling (e.g., Eliseev and Mokhov, 2011; Lee et al., 2011), but also darkened due to the re-expansion of forests to higher latitudes (Esper and Schweingruber, 2004) and increased vegetation height in snowy regions (Bonfils et al., 2012; also Section 8.3.5). Model studies have shown cooling from land use and land cover changes, especially over NH continents, although without demonstrating a detectable signal in observations (Matthews et al., 2004).

In addition to land use and climate-induced vegetation changes, CO₂ affects vegetation forcing indirectly, reducing transpiration from plants as stomata open less with increasing CO₂, resulting in localized atmospheric drying and warming (Chapter 11, Section 11.3.2.3.1; Joshi and Gregory, 2008). These are not included in the standard RF (Section 8.1) and may be considered feedbacks (Section 8.3.2). This is modelled to be largest over the Amazon, the central African forest, and to some extent over boreal and temperate forests (Andrews et al., 2011). In the coupled climate modelling study of Lawrence and Chase (2010), the vegetation changes caused significant reduction in evapotranspiration, drying and warming in tropical and subtropical regions, with insignificant cooling at higher latitudes. Overall, vegetation changes may have caused modest cooling at high latitudes and warming at low latitudes, but the uncertainties are large and confidence is very low.

Deposition of black carbon on snow and ice, and loss of snow and ice darken the surface, reduces albedo, and enhances climate warming. Substantial snow-cover reduction of North America leads to warmer North American summertime temperature in models having a strong snow albedo feedback. These forcings can also have non-local impacts that result from enhanced land-ocean temperature contrast, increasing surface convergence over land and divergence over oceans. A poleward intensification of the high pressure patterns and subtropical jet may also result (Fletcher et al., 2009). BC contributions to snow darkening reduces snow cover, however the magnitude of the effect is very uncertain (Chapter 7, Section 7.5.2.3, Section 8.3.4.4). A

model study calculated BC-albedo reduction to cause about 20% Arctic snow/ice cover reduction and 20% of Arctic warming over the previous century (Koch et al., 2011). However, reductions in Arctic soot during the past two decades (e.g., Hegg et al., 2009) have likely reversed that trend (e.g., Koch et al., 2011; Skeie et al., 2011b; Lee et al., 2013). Cryospheric feedbacks and atmospheric dynamical responses in models have an associated poleward shift in the temperature response to aerosol-cloud interactions (Kristjansson et al., 2005; Koch et al., 2009a; Chen et al., 2010).

Solar spectral (UV) irradiance variations along the solar cycle induce ozone responses by modifying the ozone production rate through photolysis of molecular oxygen (Section 8.4.1.3.1), and the resulting differential heating can drive circulation anomalies which lead to regional temperature and precipitation changes (Haigh, 1999; Shindell et al., 2006b; Frame and Gray, 2010; Gray et al., 2010). Such solar forcing may influence natural modes of circulation such as the Northern Annular Mode (e.g., Shindell et al., 2001; de la Torre et al., 2006; Ineson et al., 2011), the South Asian Summer Monsoon (Fan et al., 2009), the Southern Annular Mode (Kuroda and Kodera, 2005; Roscoe and Haigh, 2007) or the ENSO (Mann et al., 2005). The pattern of temperature response is less uniform than the forcing, for example, warming in the NH, but little response in the SH due to temperature moderation by wind speed enhancement effects on ocean circulation (Swingedouw et al., 2011). Regional responses to solar forcing are mediated by the stratosphere, so that reproducing such change requires spectrally varying solar forcing rather than TSI forcing (Lee et al., 2009; Section 8.4.1.4).

Stratospheric aerosol clouds (also Section 8.4.2.2) from tropical eruptions spread poleward and can cover an entire hemisphere or the globe, depending on the initial latitudinal spread. The aerosol eruption cloud from the 1963 Agung was confined mainly to the SH; the 1982 El Chichón mainly to the NH; and the 1991 Pinatubo covered the globe, all with an *e*-folding lifetime of about 1 year (e.g., Antuña et al., 2003). High-latitude eruptions typically stay confined to the high-latitude regions with shorter lifetimes of 2–4 months (Kravitz and Robock, 2011). Volcanic aerosols primarily scatter solar radiation back to space, but also absorb longwave radiation with the former larger by an order of magnitude. Stratospheric aerosol absorption heats the layer where they reside and produces distinct vertical and horizontal distributions of the heating rate. The temperature and chemical effects of the aerosols also enhance ozone destruction, which somewhat counteracts the radiative heating (Stenchikov et al., 2002). For tropical eruptions, this may affect atmospheric dynamics, with a stronger polar vortex, a positive mode of the Arctic Oscillation, and winter warming over NH continents (Robock, 2000). Climate responses to solar and volcanic forcings are further discussed in the context of detection and attribution of millennial climate change (Chapter 10, Section 10.7).

The study of how climate responds to regionally varying patterns of forcing is critical for understanding how local activities impact regional climate, however the studies are exploratory and generally evoke very low *confidence*. However there is *medium to high confidence* in some qualitative but robust features, such as the damped warming of the NH and shifting of the ITCZ from aerosols, and positive feedbacks from high-latitude snow and ice albedo changes.

8.6.3 Spatial Evolution of Radiative Forcing and Response for the Future

Most components of aerosols and ozone precursors are estimated to decrease toward the end of this century in the RCPs except CH₄ in RCP8.5 (Figure 8.2) and nitrate aerosols, though some species reach the maximum amounts of emissions around the mid-21st century (Figure 8.2). The RCPs therefore contrast with the emission scenarios for TAR and AR4, which were based on Special Report on Emissions Scenarios (SRES) and have future projections of larger increase in the near-term climate forcers (NTCFs). It has been questioned whether such low emission of NTCF is possible in the future given the current policies (Pozzer et al., 2012). This section surveys spatial differences in the radiative forcing of aerosols and ozone for the future based on the RCPs.

Figure 8.26 shows the global distributions of changes in aerosol and ozone forcings in 2030 and 2100 relative to 2000 for RCP2.6 and 8.5 (Shindell et al., 2013c). Both scenarios indicate reduced aerosol loading, and thus positive forcing over Europe, North America and Asia by 2100 where RF is above +0.5 W m⁻² because of substantial reduction of scattering aerosols. The global mean RF due to aerosol-radiation interaction is estimated to be +0.12 and +0.08 W m⁻² for RCP2.6 and 8.5, respectively, in 2100. Though the RF by total anthropogenic aerosols is positive, reduced BC contributes substantial negative forcing

especially over the similar regions. The global mean carbonaceous RF including both the effects of BC and OC is estimated to be -0.20 and -0.11 W m^{-2} for RCP2.6 and 8.5, respectively, in 2100. Early in the century, on the other hand, both scenarios indicate increased negative aerosol forcing over South Asia, with reversal between 2030 and 2100. Emissions of BC, OC, and SO_2 will reach their maximums early and middle in the century for RCP2.6 and 8.5, respectively in India. In RCP6, high emission levels of SO_2 in China persist until the mid-21st century (Supplementary Material Figure 8.SM.1), and then it is predicted to keep a high negative RF due to aerosol-radiation interaction over East Asia. The RF due to aerosol-radiation interaction for carbonaceous aerosol is positive over East and South Asia in 2030 relative to 2000 for RCP8.5 because BC emission is also larger in 2030. Over central and southern Africa, a change in the future RF due to aerosol-radiation interaction based on RCPs is not clear mainly because of uncertainties in the wildfires emissions (see Chapter 7, Section 7.3.5.3). The global mean total RF due to aerosol-radiation interaction in the future is rather small due to offsetting effects, with reductions in BC, increases in nitrate aerosols, and reductions in scattering aerosols each causing substantially more forcing than the net.

Emissions and atmospheric loadings of natural aerosols are affected by climate change. There is, however, no consensus among studies on future trends of their changes for major natural aerosols, mineral dust and sea salt, as indicated in Chapter 7, Section 7.3.5.1. The spatial pattern of the aerosol forcing may be influenced by natural aerosols due to reduction in sea ice cover leading to increased emission of high latitude sea salt (Struthers et al., 2011; Takemura, 2012) and SOA from vegetation changes (Tsigaridis and Kanakidou, 2007).

The simulations applying the RCPs indicate that the latitude of maximum emission of NTCFs, and therefore of maximum RF, is projected to shift somewhat southward for the next few decades (in 2030 of Figure 8.26). The shift of peak aerosol loading southward is expected to cause the ITCZ to continue to shift northward. This, in combination with warming and drying over tropical land, has been modelled to lead to greatly enhanced drought conditions in the Amazon (Cox et al., 2008). On the other hand, if the low-latitude aerosol is sufficiently absorbing, broadening of the ITCZ convergence region and enhanced cloud cover could result, as modelled for dust (Perlwitz and Miller, 2010).

Reductions in high-latitude BC are expected to contribute to reducing Arctic forcing (e.g., Koch et al., 2011), due to reduction in BC deposition on snow as well as in absorption of sunlight over bright surface. On the other hand, reduction in mid-high-latitude scattering aerosols may offset all or part of the impact of the local Arctic forcing change (Shindell et al., 2010; Koch et al., 2011).

Figure 8.26 also shows the ozone RF in 2030 and 2100 relative to 2000, which includes both changes in tropospheric and stratospheric ozone. Recovery of ozone in the stratosphere in the 21st century will result in positive forcing in the southern high-latitudes in comparison with the year 2000 for both the pathways. This is because of the reduced emissions of ozone-depleting substances controlled under the Montreal Protocol, with a small additional effect from a feedback of changes in temperature and in the vertical circulation due to changes in stratospheric compositions (Kawase et al., 2011; Lamarque et al., 2011). In the troposphere, on the other hand, a large difference in the methane emissions between RCP8.5 and the other pathways shown in Figure 8.2 leads to a different RF trend outside the southern high-latitudes. Ozone recovery in the stratosphere and ozone increase in the troposphere leads to a positive RF all over the globe in RCP8.5 with a mean of $+0.26$ W m^{-2} in 2100. The cancellation between positive RF due to ozone increase in the stratosphere and negative RF due to ozone decrease in the troposphere results in a global mean RF of -0.12 W m^{-2} in RCP2.6.

Figure 8.26 also shows the global distributions of changes in ERF due to both aerosol-radiation and aerosol-cloud-interactions in 2030 and 2100 relative to 2000 for RCP8.5. Although the ERF includes rapid adjustments and therefore its magnitude is much larger than that of RF due to aerosol-radiation interaction, the spatial pattern is generally similar to RF. The ERF in 2100 shows positive values relative to 2000 in North America, Europe, and Asia even with RCP8.5, which indicates the aerosol forcing is projected to approach to the preindustrial level.

[INSERT FIGURE 8.26 HERE]

Figure 8.26: Multi-model mean RF (W m^{-2}) due to aerosol-radiation interaction of all anthropogenic aerosols (first and second rows) and anthropogenic carbonaceous (BC+OC) aerosols (third and fourth rows), and total ozone (fifth and

sixth rows) in 2030 (left) and 2100 (right) relative to 2000 for RCP2.6 (top each) and RCP8.5 (bottom each) based on the ACCMIP simulations. The seventh row shows multi-model mean ERF (W m^{-2}) by all anthropogenic aerosols in 2030 (left) and 2100 (right) relative to 2000 for RCP8.5. Global area-weighted means are given in the upper right of each panel.

8.7 Emission Metrics

8.7.1 Metric Concepts

8.7.1.1 Introduction

To quantify and compare the climate impacts of various emissions, it is necessary to choose a climate parameter by which to measure the effects; i.e., radiative forcing, temperature response, etc. Thus, various choices are needed for the steps down the cause-effect chain from emissions to climate change and impacts (Figure 8.27 and Box 8.4). Each step in the cause effect chain requires a modelling framework. For assessments and evaluation one may — as an alternative to models that explicitly include physical processes resulting in forcing and responses — apply simpler measures or *metrics* that are based on results from complex models. Metrics are used to quantify the contributions to climate change of emissions of different substances and can thus act as ‘exchange rates’ in multi-component policies or comparisons of emissions from regions/countries or sources/sectors. Metrics are also used in areas such as Life Cycle Assessments and Integrated Assessment Modelling (e.g., by IPCC WGIII).

[INSERT FIGURE 8.27 HERE]

Figure 8.27: The cause-effect chain from emissions to climate change and impacts showing how metrics can be defined to estimate responses to emissions (left side) and for development of multi-component mitigation (right side). The relevance of the various effects increases downwards but at the same time the uncertainty also increases. The dotted line on the left indicates that effects and impacts can be estimated directly from emissions, while the arrows on the right side indicate how these estimates can be used in development of strategies for reducing emissions. Adapted from Fuglestvedt et al. (2003) and Plattner et al. (2009).

Metrics can be given in *absolute* terms (e.g., K/kg) or in *relative* terms by normalizing to a reference gas — usually CO_2 . To transform the effects of different emissions to a common scale — often called ‘ CO_2 equivalent emissions’ — the emission (E_i) of component i can be multiplied with the adopted normalized metric (M_i): $M_i \times E_i = \text{CO}_2\text{-eq}_i$. Ideally, the climate effects of the calculated CO_2 equivalent emissions should be the same regardless of the mix of components emitted. However, different components have different physical properties, and a metric that establishes equivalence with regard to one effect cannot guarantee equivalence with regard to other effects and over extended time periods, e.g., Lauder et al. (2013); O’Neill (2000); Smith and Wigley (2000), Fuglestvedt et al. (2003).

Metrics do not define goals and policy — they are tools that enable evaluation and implementation of multi-component policies (i.e., which emissions to abate). The most appropriate metric will depend on which aspects of climate change are most important to a particular application, and different climate policy goals may lead to different conclusions about what is the most suitable metric with which to implement that policy, e.g., Plattner et al. (2009); Tol et al. (2012). Metrics that have been proposed include physical metrics as well as more comprehensive metrics that account for both physical and economic dimensions (see 8.7.1.5 and WGIII, Chapter 3).

This section provides an assessment that focuses on the scientific aspects and utility of emission metrics. Extending such an assessment to include more policy-oriented aspects of their performance and usage such as simplicity, transparency, continuity, economic implications of usage of one metric over another, etc., is not given here as this is beyond the scope of WGI. However, consideration of such aspects is vital for user-assessments. In the following, the focus is on the more well-known Global Warming Potential (GWP) and Global Temperature change Potential (GTP), whilst other concepts are also briefly discussed.

[START BOX 8.4 HERE]

Box 8.4: Choices Required When Using Emission Metrics

Time frames: One can apply a *backward-looking* (i.e., historical) or a *forward-looking* perspective on the responses to emissions. In the forward looking case one may use pulses of emissions, sustained emissions or emission scenarios. All choices of emission perturbations are somewhat artificial and idealized, and different choices serve different purposes. One may use the *level* (e.g., degrees Celsius) or *rate* of change (e.g., degrees Celsius per decade). Furthermore, the effects of emissions may be estimated at a particular time or be integrated over time up to a chosen time horizon. Alternatively, discounting of future effects may be introduced (i.e., a weighting of effects over time).

Type of effect or end-point: Radiative forcing, temperature change, or sea level change, for example, could be examined (Figure 8.27). Metrics may also include eco/biological or socioeconomic damages. The choice of climate impact parameters is related to which aspects of climate change are considered relevant for interpretation of ‘dangerous anthropogenic interference with the climate system’ (UNFCCC Article 2).

Spatial dimension for emission and response: Equal-mass emissions of NTCFs from different regions can induce varying global-mean climate responses, and the climate response also has a regional component irrespective of the regional variation in emissions. Thus, metrics may be given for region of *emission* as well as region of *response*.

Some of the choices involved in metrics are scientific (e.g., type of model, and how processes are included or parameterized in the models). Choices of time frames and climate impact are policy-related and cannot be based on science alone, but scientific studies can be used to analyse different approaches and policy choices.

[END BOX 8.4 HERE]

8.7.1.2 The GWP Concept

The Global Warming Potential (GWP) is defined as the time-integrated RF due to a pulse emission of a given component, relative to a pulse emission of an equal mass of CO₂ (Figure 8.28a and formula). The GWP was presented in The First IPCC Assessment (Houghton et al., 1990) stating ‘*It must be stressed that there is no universally accepted methodology for combining all the relevant factors into a single global warming potential for greenhouse gas emissions. A simple approach has been adopted here to illustrate the difficulties inherent in the concept, ...*’. Further, the First IPCC Assessment gave no clear physical interpretation of the GWP.

[INSERT FIGURE 8.28 HERE]

Figure 8.28: (a) The Absolute Global Warming Potential (AGWP) is calculated by integrating the RF due to emission pulses over a chosen time horizon; e.g., 20 and 100 years (vertical lines). The GWP is the ratio of AGWP for component *i* over AGWP for the reference gas CO₂. The blue hatched field represents the integrated RF from a pulse of CO₂, while the green and red fields represent example gases with 1.5 and 13 years lifetimes, respectively. (b) The Global Temperature change Potential (GTP) is based on the temperature response at a selected year after pulse emission of the same gases; e.g., 20 or 100 years (vertical lines). See Supplementary Material Section 8.SM.11 for equations for calculations of GWP and GTP.

A direct interpretation is that the GWP is an index of the total energy added to the climate system by a component in question relative to that added by CO₂. However, the GWP does not lead to equivalence with temperature or other climate variables (Fuglestedt et al., 2000; Fuglestedt et al., 2003; O’Neill, 2000; Daniel et al., 2012; Smith and Wigley, 2000; Tanaka et al., 2009). Thus, the name ‘Global Warming Potential’ may be somewhat misleading, and ‘relative cumulative forcing index’ would be more appropriate. It can be shown that the GWP is approximately equal to the ratio (normalizing by the similar expression for CO₂) of the *equilibrium temperature response due to a sustained emission* of the species or to the *integrated temperature response for a pulse emission* (assuming efficacies are equal for the gases that are compared; O’Neill, 2000; Prather, 2002; Shine et al., 2005a; Peters et al., 2011a; Azar and Johansson, 2012).

The GWP has become the default metric for transferring emissions of different gases to a common scale; often called ‘CO₂ equivalent emissions’ (e.g., Shine, 2009). It has usually been integrated over 20, 100 or 500 years consistent with Houghton et al. (1990). Note, however that Houghton et al. presented these time horizons as ‘*candidates for discussion [that] should not be considered as having any special significance*’. The GWP for a time horizon of 100 years was later adopted as a metric to implement the multi-gas approach

embedded in the UNFCCC and made operational in the 1997 Kyoto Protocol. The choice of time horizon has a strong effect on the GWP values — and thus also on the calculated contributions of CO₂ equivalent emissions by component, sector or nation. There is no scientific argument for selecting 100 years compared with other choices (Fuglestvedt et al., 2003; Shine, 2009). The choice of time horizon is a value judgement since it depends on the relative weight assigned to effects at different times. Other important choices include the background atmosphere on which the GWP calculations are superimposed, and the way indirect effects and feedbacks are included (see Section 8.7.1.4).

For some gases the variation in GWP with time horizon mainly reflects properties of the reference gas, not the gas for which the GWP is calculated. The GWP for NTCF decreases with increasing time horizon, since GWP is defined with the integrated RF of CO₂ in the denominator. As shown in Figure 8.29, after ca 5 decades the development in the GWP for CH₄ is almost entirely determined by CO₂. However, for long-lived gases (e.g., SF₆) the development in GWP is controlled by both the increasing integrals of RF from the long-lived gas and CO₂.

[INSERT FIGURE 8.29 HERE]

Figure 8.29: Development of AGWP-CO₂, AGWP-CH₄ and GWP-CH₄ with time horizon. The yellow and blue curves show how the AGWPs changes with increasing time horizon. Due to the integrative nature the AGWP for CH₄ (yellow curve) reaches a constant level after ca 5 decades. The AGWP for CO₂ continues to increase for centuries. Thus the ratio which is the GWP (black curve) falls with increasing time horizon.

8.7.1.3 The GTP Concept

Compared to the GWP, the Global Temperature change Potential (GTP; Shine et al., 2005a) goes one step further down the cause-effect chain (Figure 8.27) and is defined as the *change in global mean surface temperature at a chosen point in time* in response to an emission pulse — relative to that of CO₂. While GWP is integrated in time (Figure 8.28a), GTP is an end-point metric which is based on temperature change for a selected year, t , (see Figure 8.28b with formula). Like for the GWP, the impact from CO₂ is normally used as reference, hence, for a component i , $GTP(t)_i = AGTP(t)_i / AGTP(t)_{CO_2} = \Delta T(t)_i / \Delta T(t)_{CO_2}$, where AGTP is the absolute GTP giving temperature change per unit emission (see Supplementary Material Section 8.SM.11 for equations and parameter values). Shine et al. (2005a) presented the GTP for both pulse and sustained emission changes based on an energy balance model as well as analytical equations. A modification was later introduced (Shine et al., 2007) in which the time horizon is determined by the proximity to a target year as calculated by using scenarios and climate models (see Section 8.7.1.5).

Like GWP, the GTP values can be used for weighting the emissions to obtain “CO₂ equivalents” (see 8.7.1.1). This gives the temperature effects of emissions relative to that of CO₂ for the chosen time horizon. As for GWP, the choice of time horizon has a strong effect on the metric values and the calculated contributions to warming.

In addition, the AGTP can be used to calculate the global mean temperature change due to any given emission scenario (assuming linearity) using a convolution of the emission scenarios and AGTP _{i} :

$$\Delta T(t) = \sum_i \int_0^t E_i(s) AGTP_i(t-s) ds \quad (8.1)$$

where i is component, t is time, and s is time of emission (Berntsen and Fuglestvedt, 2008; Peters et al., 2011b; Shindell et al., 2011).

By accounting for the climate sensitivity and the exchange of heat between the atmosphere and the ocean, the GTP includes physical processes that the GWP does not. The GTP accounts for the slow response of the (deep) ocean, thereby prolonging the response to emissions beyond what is controlled by the decay time of the atmospheric concentration. Thus the GTP includes both the atmospheric adjustment timescale of the component considered and the response timescale of the climate system.

The GWP and GTP are fundamentally different by construction and different numerical values can be expected. In particular, the GWPs for NTCF, over the same time frames, are higher than GTPs due to the integrative nature of the metric. The GTP values can be significantly affected by assumptions about the

climate sensitivity and heat-uptake by the ocean. Thus, the relative uncertainty ranges are wider for the GTP compared to GWP (see next section). The additional uncertainty is a typical trade-off when moving along the cause-effect chain to an effect of greater societal relevance (Figure 8.27). The formulation of the ocean response in the GTP has a substantial effect on the values, thus its characterization also represents a trade-off between simplicity and accuracy. As for GWP, the GTP is also influenced by the background atmosphere, and the way indirect effects and feedbacks are included (see Section 8.7.1.4).

8.7.1.4 Uncertainties and Limitations related to GWP and GTP

The uncertainty in the numerator of GWP; i.e., the $AGWP_1$ (see formula in Figure 8.28a) is determined by uncertainties in lifetimes (or perturbation lifetimes) and radiative efficiency. Inclusion of indirect effects increases uncertainties (see below). For the reference gas CO_2 , the uncertainty is dominated by uncertainties in the *impulse response function* (IRF) that describes the development in atmospheric concentration that follows from an emission pulse (Joos et al., 2013); see Chapter 6, Box 6.2 and Supplementary Material Section 8.SM.12. The IRF is sensitive to model representation of the carbon cycle, pulse size and background CO_2 concentrations and climate.

Based on a multi-model study, Joos et al. (2013) estimate uncertainty ranges for the time-integrated IRF for CO_2 to be $\pm 15\%$ and $\pm 25\%$ (5–95% uncertainty range) for 20 and 100 year time horizons, respectively. Assuming quadratic error propagation, and $\pm 10\%$ uncertainty in radiative efficiency, the uncertainty ranges in $AGWP$ for CO_2 were estimated to be $\pm 18\%$ and $\pm 26\%$ for 20 and 100 years. These uncertainties affect all metrics that use CO_2 as reference. Reisinger et al. (2010) and Joos et al. (2013) show that these uncertainties increase with time horizon.

The same factors contribute to uncertainties in the GTP, with an additional contribution from the parameters describing the ocean heat uptake and climate sensitivity. In the first presentation of the GTP, Shine et al. (2005a) used one time-constant for the climate response in their analytical expression. Improved approaches were used by Boucher and Reddy (2008), Collins et al. (2010), and Berntsen and Fuglestedt (2008) that include more explicit representations of the deep ocean which increased the long-term response to a pulse forcing. Over the range of climate sensitivities from AR4, GTP_{50} for BC was found to vary by a factor of 2, the methane GTP_{50} varied by $\sim 50\%$, while for N_2O essentially no dependence was found (Fuglestedt et al., 2010). $AGTPs$ for CO_2 were also calculated in the multi-model study by Joos et al. (2013). They found uncertainty ranges in $AGTP$ that are much larger than for $AGWP$; $\pm 45\%$ and $\pm 90\%$ for 20 and 100 years (5–95% uncertainty range). These uncertainty ranges also reflect the signal-to-noise ratio, and not only uncertainty in the physical mechanisms.

There are studies combining uncertainties in various input parameters. Reisinger et al. (2011) estimated the uncertainty in the GWP for CH_4 and found an uncertainty of -30 to $+40\%$ for the GWP_{100} and -50 to $+75\%$ for GTP_{100} of CH_4 (for 5–95% of the range). Boucher (2012) performed a Monte Carlo analysis with uncertainties in perturbation lifetime and radiative efficiency, and for GWP_{100} for CH_4 (assuming a constant background atmosphere) he found $\pm 20\%$, and -40 to $+65$ for GTP_{100} (for 5–95% uncertainty range).

Here we estimate uncertainties in GWP values based on the uncertainties given for radiative efficiencies (Section 8.3.1), perturbation lifetimes, indirect effects and in the $AGWP$ for the reference gas CO_2 (see Supplementary Material Section 8.SM.12). For CH_4 GWP we estimate an uncertainty of $\pm 30\%$ and $\pm 40\%$ for 20 and 100 year time horizons, respectively (for 5–95% uncertainty range). The uncertainty is dominated by $AGWP$ for CO_2 and indirect effects. For gases with lifetimes of a century or more the uncertainties are of the order of $\pm 20\%$ and $\pm 30\%$ for 20 and 100 years horizons. The uncertainty in GWPs for gases with lifetimes of a few decades is estimated to be of the order of $\pm 25\%$ and $\pm 35\%$ for 20 and 100 years. For shorter-lived gases, the uncertainties in GWPs will be larger (see Supplementary Material Section 8.SM.12 for a discussion of contributions to the total uncertainty.) For GTP, few uncertainty estimates are available in the literature. Based on the results from Joos et al. (2013), Reisinger et al. (2010), and Boucher (2012) we assess the uncertainty to be of the order of $\pm 75\%$ for the methane GTP_{100} .

The metric values are also strongly dependent on which processes are included in the definition of a metric. Ideally all indirect effects (Sections 8.2 and 8.3) should be taken into account in the calculation of metrics. The indirect effects of CH_4 on its own lifetime, tropospheric ozone and stratospheric water have been

traditionally included in its GWP. Boucher et al. (2009) have quantified an indirect effect on CO₂ when fossil fuel methane is oxidised in the atmosphere. Shindell et al. (2009) estimated the impact of reactive species emissions on both gaseous and aerosol forcing species and found that ozone precursors, including methane, had an additional substantial climate effect because they increased or decreased the rate of oxidation of SO₂ to sulphate aerosol. Studies with different sulphur cycle formulations have found lower sensitivity (Collins et al., 2010; Fry et al., 2012). Collins et al. (2010) postulated an additional component to their GWPs and GTPs for ozone precursors due to the decreased productivity of plants under higher levels of surface ozone. This was estimated to have the same magnitude as the O₃ and CH₄ effects. This effect, however, has so far only been examined with one model. In a complex and interconnected system, feedbacks can become increasingly complex, and uncertainty of the magnitude and even direction of feedback increases the further one departs from the primary perturbation, resulting in a trade-off between completeness and robustness, and hence utility for decision-making.

Gillett and Matthews (2010) included climate-carbon feedbacks in calculations of GWP for CH₄ and N₂O and found that this increased the values by ~20% for 100 years. For GTP they found an increase of ~80%. They used numerical models for their studies and suggest that climate-carbon feedbacks should be considered and parameterized when used in simple models to derive metrics. Collins et al. (2013) parameterize the carbon-climate feedback based on Friedlingstein et al. (2006) and Arora et al. (2013) and find that this more than doubles the GTP₁₀₀ for methane. Enhancement of methane's GTP due to carbon-climate feedbacks may also explain the higher GTP values found by Reisinger et al. (2010).

The inclusion of indirect effects and feedbacks in metric values has been inconsistent in the IPCC reports. In SAR and TAR, a carbon model without a coupling to a climate model was used for calculation of IRF for CO₂ (Joos et al., 1996), while in AR4 carbon-climate feedbacks were included for the CO₂ IRF (Plattner et al., 2008). For the time horizons 20 and 100 years, the AGWP_{CO₂} calculated with the Bern3D-LPJ model is, depending on the pulse size, 4–5% and 13–15% lower, respectively, when carbon cycle-climate feedbacks are not included (Joos et al., 2013). While the AGWP for the reference gas CO₂ included climate-carbon feedbacks, this is not the case for the non-CO₂ gas in the numerator of GWP, as recognized by Gillett and Matthews (2010), Joos et al. (2013), Collins et al. (2013) and Sarofim (2012). This means that the GWPs presented in AR4 may underestimate the relative impacts of non-CO₂ gases. The different inclusions of feedbacks partially represent the current-state of knowledge, but also reflect inconsistent and ambiguous definitions. In calculations of AGWP for CO₂ in AR5 we use the IRF for CO₂ from Joos et al. (2013) which includes climate-carbon feedbacks. Metric values in AR5 are presented both with and without including climate-carbon feedbacks for non-CO₂ gases. This feedback is based on the carbon-cycle response in a similar set of models (Arora et al., 2013) as used for the reference gas (Collins et al., 2013).

Table 8.7: GWP and GTP with and without inclusion of climate-carbon feedbacks (cc fb) in response to emissions of the indicated non-CO₂ gases (climate-carbon feedbacks in response to the reference gas CO₂ are always included).

	Lifetime (year)		GWP ₂₀	GWP ₁₀₀	GTP ₂₀	GTP ₁₀₀
CH ₄	12.4 ^a	No cc fb	84	28	67	4.3
		With cc fb	86	34	70	11
HFC-134a	13.4	No cc fb	3710	1300	3050	201
		With cc fb	3790	1550	3170	530
CFC-11	45.0	No cc fb	6900	4660	6890	2340
		With cc fb	7020	5350	7080	3490
N ₂ O	121.0 ^a	No cc fb	264	265	277	234
		With cc fb	268	298	284	297
CF ₄	50000.0	No cc fb	4880	6630	5270	8040
		With cc fb	4950	7350	5400	9570

Note:

Uncertainties related to the climate-carbon feedback are large, comparable in magnitude to the strength of the feedback for a single gas.

(a) Perturbation lifetime is used in calculation of metrics.

The effect of including this feedback for the non-reference gas increases with time horizon due to the long-lived nature of the initiated CO₂ perturbation (Table 8.7). The relative importance also increases with decreasing lifetime of the component, and is larger for GTP than GWP due to the integrative nature of GWP. We calculate an increase in the methane GWP₁₀₀ of 20%. For GTP₁₀₀, however, the changes are much larger; of the order of 160%. For the shorter time horizons (e.g., 20 years) the effect of including this feedback is small (<5%) for both GWP and GTP. For the more long-lived gases the GWP₁₀₀ values increase by 10–12%, while for GTP₁₀₀ the increase is 20–30%. Table 8.A.1 gives metric values including the climate-carbon feedback for CO₂ only, while Supplementary Material Table 8.SM.16 gives values for all halocarbons that include the climate-carbon feedback. Though uncertainties in the carbon-cycle are substantial, it is *likely* that including the climate-carbon feedback for non-CO₂ gases as well as for CO₂ provides a better estimate of the metric value than including it only for CO₂.

Emission metrics can be estimated based on a constant or variable background climate and this influences both the adjustment times and the concentration-forcing-temperature relationships. Thus, all metric values will need updating due to changing atmospheric conditions as well as improved input data. In AR5 we define the metric values with respect to a constant present day condition of concentrations and climate. However, under non-constant background, Joos et al. (2013) found decreasing CO₂ AGWP₁₀₀ for increasing background levels (up to 23% for RCP8.5). This means that GWP for all non-CO₂ gases (except CH₄ and N₂O) would increase by roughly the same magnitude. Reisinger et al. (2011) found a reduction in AGWP for CO₂ of 36% for RCP8.5 from 2000 to 2100 and that the methane radiative efficiency and AGWP also decrease with increasing CH₄ concentration. Accounting for both effects, the GWP₁₀₀ for CH₄ would increase by 10–20% under low and mid-range RCPs by 2100, but would decrease by up to 10% by mid-century under the highest RCP. While these studies have focused on the background levels of GHGs, the same issues apply for temperature. Olivié et al. (2012) find different temperature IRFs depending on the background climate (and experimental set up).

User related choices (see Box 8.4) such as the time horizon can greatly affect the numerical values obtained for CO₂ equivalents. For a change in time horizon from 20 to 100 years, the GWP for methane decreases by a factor of ~3 and its GTP by more than a factor of 10. Short-lived species are most sensitive to this choice. Some approaches have removed the time horizon from the metrics (e.g., Boucher, 2012), but discounting is usually introduced which means that a discount rate r (for the weighting function e^{-rt}) must be chosen instead. The choice of discount rate is also value based (see WGIII, Chapter 3).

For NTCF the metric values also depend on the location and timing of emission and whether regional or global metrics are used for these gases is also a choice for the users. Metrics are usually calculated for pulses, but some studies also give metric values that assume constant emissions over the full time horizon (e.g., Shine et al., 2005a; Jacobson, 2010). It is important to be aware of the idealized assumption about constant future emissions (or change in emissions) of the compound being considered if metrics for sustained emissions are used.

8.7.1.5 *New Metric Concepts*

New metric concepts have been developed both to modify physical metrics to address shortcomings as well as to replace them with metrics that account for economic dimensions of problems to which metrics are applied. Modifications to physical metrics have been proposed to better represent CO₂ emissions from bioenergy, regional patterns of response, and for peak temperature limits.

Emissions of CO₂ from the combustion of biomass for energy in national emission inventories are currently assumed to have no net RF, based on the assumption that these emissions are compensated by biomass regrowth (IPCC, 1996). However, there is a time-lag between combustion and regrowth, and while the CO₂ is resident in the atmosphere it leads to an additional RF. Modifications of the GWP and GTP for bioenergy (GWP_{bio}, GTP_{bio}) have been developed (Cherubini et al., 2011; Cherubini et al., 2012). The GWP_{bio} give values generally between zero (current default for bioenergy) and one (current for fossil fuel emissions) (Cherubini et al., 2011), and negative values are possible for GTP_{bio} due to the fast time scale of atmospheric-ocean CO₂ exchange relative to the growth cycle of biomass (Cherubini et al., 2012). GWP_{bio} and GTP_{bio} have only been used in a few applications, and more research is needed to assess their robustness and applicability. Metrics for biogeophysical effects, such as albedo changes, have been proposed (Betts,

2000; Rotenberg and Yakir, 2010), but as for NTCFs regional variations are important (Claussen et al., 2001) and the radiative forcing concept may not be adequate (Davin et al., 2007).

New concepts have also been developed to capture information about regional patterns of responses and cancelling effects that are lost when global mean metrics are used. The use of non-linear damage functions to capture information on the spatial pattern of responses has been explored (Shine et al., 2005b; Lund et al., 2012). In addition, the Absolute Regional Temperature Potential (ARTP) (Shindell, 2012; Collins et al., 2013) has been developed to provide estimates of impacts at a sub-global scale. ARTP gives the time-dependent temperature response in four latitude bands as a function of the regional forcing imposed in all bands. These metrics, as well as new regional precipitation metrics (Shindell et al., 2012b), require additional studies to determine their robustness.

Alternatives to the single basket approach adopted by the Kyoto Protocol are a component-by-component approach or a multi-basket approach (Rypdal et al., 2005; Daniel et al., 2012, Sarofim, 2012; Jackson, 2009). Smith et al. (2012) show how peak temperature change is constrained by *cumulative emissions* (see 12.5.4) for gases with long lifetimes and *emissions rates* for shorter-lived gases (including CH₄). Thus, they divide gases into two baskets and present two metrics that can be used for estimating peak temperature for various emission scenarios. This division of gases into the two baskets is sensitive to the time of peak temperature in the different scenarios. The approach uses time invariant metrics that do not account for the timing of emissions relative to the target year. The choice of time horizon is implicit in the scenario assumed and this approach only works for a peak scenario.

A number of new metrics have been developed to add economic dimensions to purely physically based metrics such as the GWP and GTP. The use of physical metrics in policy contexts has been criticized by economists (Reilly and Richards, 1993; Schmalensee, 1993; Hammitt et al., 1996; Reilly et al., 1999; Bradford, 2001; De Cara et al., 2008). A prominent use of metrics is to set relative prices of gases when implementing a multi-gas policy. Once a particular policy has been agreed on, economic metrics can address policy goals more directly than physical metrics by accounting not only for physical dimensions but also for economic dimensions such as mitigation costs, damage costs, and discount rates (see WGIII, Chapter 3; Deuber et al., 2013).

For example, if mitigation policy is set within a *cost-effectiveness* framework with the aim of making the least cost mix of emissions reductions across components to meet a global temperature target, the 'price ratio' (Manne and Richels, 2001), also called the Global Cost Potential (GCP) (Tol et al., 2012), most directly addresses the goal. The choice of target is a policy decision; metric values can then be calculated based on an agreed upon target. Similarly, if policy is set within a *cost-benefit* framework, the metric that directly addresses the policy goal is the ratio of the marginal damages from the emission of a gas (i.e., the damage costs to society resulting from an incremental increase in emissions) relative to the marginal damages of an emission of CO₂, known as the Global Damage Potential (GDP) (Kandlikar, 1995). Both types of metrics are typically determined within an integrated climate-economy model, since they are affected both by the response of the climate system as well as by economic factors.

If other indexes, such as the GWP, are used instead of an economic cost-minimizing index, costs to society will increase. Cost implications at the project or country level could be substantial under some circumstances (Godal and Fuglestedt, 2002; Shine, 2009; Reisinger et al., 2012). However, under idealized conditions of full participation in mitigation policy, the increase is relatively small at the global level, particularly when compared to the cost savings resulting from a multi- (as opposed to single-) gas mitigation strategy even when based on an imperfect metric (O'Neill, 2003; Aaheim et al., 2006; Johansson et al., 2006; Johansson, 2012; Reisinger et al., 2012; Smith et al., 2013).

Purely physical metrics continue to be used in many contexts due at least in part to the added uncertainties in mitigation and damage costs, and therefore in the values of economic metrics (Boucher, 2012). Efforts have been made to view purely physical metrics such as GWPs and GTPs as approximations of economic indexes. GTPs, for example, can be interpreted as an approximation of a Global Cost Potential designed for use in a cost-effectiveness setting (Shine et al., 2007; Tol et al., 2012). Quantitative values for time-dependent GTPs reproduce in broad terms several features of the Global Cost Potential such as the rising value of metrics for short-lived gases as a climate policy target is approached (Tanaka et al., 2013). Figure 8.30 shows how

contributions of N₂O, CH₄ and BC to warming in the target year changes over time. The contributions are given relative to CO₂ and show the effects of emission occurring at various times. Similarly, GWPs can be interpreted as approximations of the Global Damage Potential designed for a cost-benefit framework (Tol et al., 2012). These interpretations of the GTP and GWP imply that using even a purely physical metric in an economic policy context involves an implicit economic valuation.

In both cases, a number of simplifying assumptions must be made for these approximations to hold (Tol et al., 2012). For example, in the case of the GWP, the influence of emissions on RF, and therefore implicitly on costs to society, beyond the time horizon is not taken into account, and there are substantial numerical differences between GWP and GDP values (Marten and Newbold, 2012). In the case of the GTP, the influence of emissions on temperature change (and costs) is included only at the time the target is reached, but not before nor after. Other metrics have been developed to more closely approximate GCPs or GDPs. The Cost Effective Temperature Potential (CETP) reproduces values of the GCP more closely than does the GTP (Johansson, 2012). It is similar to the GTP but accounts for post-target temperature effects based on an assumption about how to value costs beyond the time the target is reached. Metrics have also been proposed that take into account forcing or temperature effects that result from emissions trajectories over broad time spans, and that behave similarly to GCP and GTP (Tanaka et al., 2009; Manning and Reisinger, 2011) or to GWP (e.g., O'Neill, 2000; Peters et al., 2011a; Gillett and Matthews, 2010; Azar and Johansson, 2012).

[INSERT FIGURE 8.30 HERE]

Figure 8.30: Global temperature change potential (GTP(t)) for methane, nitrous oxide and BC for each year from year of emission to the time at which the temperature change target is reached. The (time-invariant) GWP₁₀₀ is also shown for N₂O and CH₄ for comparison.

8.7.1.6 Synthesis

In the application and evaluation of metrics, it is important to distinguish between two main sources of variation in metric values. While scientific choices of input data have to be made, there are also choices involving value judgements. For some metrics such choices are not always explicit and transparent. The choice of metric type and time horizon will for many components have a much larger effect than improved estimates of input parameters and can have strong effects on perceived impacts of emissions and abatement strategies.

In addition to progress in understanding of GWP, new concepts have been introduced or further explored since AR4. Time variant metrics introduce more dynamical views of the temporal contributions that accounts for the proximity to a prescribed target (in contrast to the traditional static GWP). Time variant metrics can be presented in a format that makes changing metric values over time predictable.

As metrics use parameters further down the cause effect chain the metrics become in general more policy relevant, but at the same time the uncertainties increase. Furthermore, metrics that account for regional variations in sensitivity to emissions or regional variation in response could give a very different emphasis to various emissions. Many species, especially NTFCF, produce distinctly regionally heterogeneous RF and climate response patterns. These aspects are not accounted for in the commonly used global scale metrics. The GWPs and GTPs have had inconsistent treatment of indirect effects and feedbacks. The GWPs reported in AR4 include climate-carbon feedbacks for the reference gas CO₂ but not for the non-CO₂ gases. Such feedbacks may have significant impacts on metrics and should be treated consistently. More studies are needed to assess the importance of consistent treatment of indirect effects/feedbacks in metrics.

The weighting of effects over time – choice of time horizon in the case of GWP and GTP – is value based. Discounting is an alternative, which also includes value judgements and is equally controversial. The weighting used in the GWP is a weight equal to one up to the time horizon and zero thereafter, which is not in line with common approaches for evaluation of future effects in economics (e.g., as in WGIII, Chapter 3). Adoption of a fixed horizon of e.g., 20, 100 or 500 years will inevitably put no weight on the long-term effect of CO₂ beyond the time horizon (Figure 8.28 and Chapter 6, Box 6.2). While GWP integrates the effects up to a chosen time horizon the GTP gives the temperature just for one chosen year with no weight on years before or after. The most appropriate metric depends on the particular application and which aspect of climate change is considered relevant in a given context. The GWP is not directly related to a temperature

limit such as the 2°C target (Manne and Richels, 2001; Shine et al., 2007; Manning and Reisinger, 2011; Smith et al., 2012; Tol et al., 2012; Tanaka et al., 2013), whereas some economic metrics and physical end-point metrics like the GTP may be more suitable for this purpose.

To provide metrics that can be useful to the users and policymakers a more effective dialog and discussion on three topics is needed: 1) which applications particular metrics are meant to serve; 2) how comprehensive metrics need to be in terms of indirect effects and feedbacks, and economic dimensions; and – related to this; 3) how important it is to have simple and transparent metrics (given by analytical formulations) versus more complex model-based and thus model-dependent metrics. These issues are also important to consider in a wider disciplinary context (e.g., across the IPCC Working Groups). Finally, it is important to be aware that all metric choices, even 'traditional' or 'widely-used' metrics, contain implicit value judgements as well as large uncertainties.

8.7.2 Application of Metrics

8.7.2.1 Metrics for CO₂, CH₄, N₂O, Halocarbons and Related Compounds

Updated (A)GWP and (A)GTP values for CO₂, CH₄, N₂O, CFCs, HCFCs, bromofluorocarbons, halons, HFCs, PFCs, SF₆, NF₃, and related halogen containing compounds are given for some illustrative and tentative time horizons in Tables 8.7, 8.A.1 and Supplementary Material Table 8.SM.16. The input data and methods for calculations of GWPs and GTPs are documented in the Supplementary Material Section 8.SM.13. Indirect GWPs that account for the RF caused by depletion of stratospheric ozone (consistent with Section 8.3.3) are given for selected gases in Table 8.A.2.

The confidence in the ability to provide useful metrics at timescales of several centuries is *very low* due to non-linear effects, large uncertainties for multi-century processes and strong assumptions of constant background conditions. Thus, we do not give metric values for longer timescales than 100 years (see discussion in Supplementary Material Section 8.SM.11). However, these timescales are important to consider for gases such as CO₂, SF₆ and PFCs. For CO₂, as much as 20–40% of the initial increase in concentration remains after 500 years. For PFC-14, 99% of an emission is still in the atmosphere after 500 years. The effects of emissions on these timescales are discussed in Chapter 12.

The GWP values have changed from previous assessments due to new estimates of lifetimes, impulse response functions and radiative efficiencies. These are updated due to improved knowledge and/or changed background levels. Since CO₂ is used as reference, any changes for this gas will affect all metric values via AGWP changes. Figure 8.31 shows how the values of radiative efficiency (RE), integrated impulse response function (IRF) and consequentially AGWP for CO₂ have changed from earlier assessments relative to AR5 values. The net effect of change in RE and IRF is an increase of approximately 1% and 6% from AR4 to AR5 in AGWP for CO₂ for 20 and 100 years, respectively (see Supplementary Material Section 8.SM.12). These increases in the AGWP of the reference gas lead to corresponding decreases in the GWPs for all non-CO₂ gases. Continued increases in the atmospheric levels of CO₂ will lead to further changes in GWPs (and GTPs) in the future.

[INSERT FIGURE 8.31 HERE]

Figure 8.31: Changes in the radiative efficiency (RE), integrated IRF and AGWP for CO₂ for 100 years from earlier IPCC Assessment Reports normalised relative to the values given in AR5. The 'original' values are calculated based on the methods explained or value reported in each IPCC Assessment Report. The 'updated' values are calculated based on the methods used in AR5, but the input values from each Assessment Report. The difference is primarily in the formula for the RE, which was updated in TAR. The different integrated IRF in TAR relates to a different parameterisation of the same IRF (WMO, 1999). Changes represent both changes in scientific understanding and a changing background atmospheric CO₂ concentration (note that y-axis starts from 0.8). The lines connecting individual points are meant as a visual guide and not to represent the values between different Assessment Reports.

To understand the factors contributing to changes relative to AR4, comparisons are made here using the AR5 values that include climate-carbon feedbacks for CO₂ only. Relative to AR4 the methane AGWP has changed due to changes in perturbation lifetime, a minor change in RE due to an increase in background concentration, and changes in the estimates of indirect effects. The indirect effects on O₃ and stratospheric H₂O are accounted for by increasing the effect of methane by 50% and 15%, respectively (see

Supplementary Material Table 8.SM.12). The ozone effect has doubled since AR4 taking into account more recent studies as detailed in Sections 8.3.3 and 8.5.1. Together with the changes in AGWP for CO₂ the net effect is increased GWP values of methane.

The GWPs for N₂O are lower here compared to AR4. A longer perturbation lifetime is used in AR5, while the radiative efficiency is lower due to increased abundances of CH₄ and N₂O. In addition, the reduction in CH₄ via stratospheric O₃, UV fluxes and OH levels due to increased N₂O abundance is included in GWPs and GTP. Due to large uncertainties related to altitude of changes, we do not include the RF from stratospheric ozone changes as an indirect effect of N₂O.

Lifetimes for most of the halocarbons are taken from WMO (2011) and many of these have changed from AR4. The lifetimes of CFC-114, CFC-115 and HCF-161 are reduced by approximately 40%, while HFC-152 is reduced by one third. Among the hydrofluoroethers (HFE) there are also several large changes in lifetimes. In addition, substantial updates of radiative efficiencies are made for several important gases; CFC-11, CFC-115, HCFC-124, HCFC-225cb, HFC-143a, HFC-245fa, CCl₄, CHCl₃, and SF₆. The radiative efficiency for carbon tetrachloride (CCl₄) is higher now and the GWP₁₀₀ has increased by almost 25% from AR4. Uncertainties in metric values are given in Section 8.7.1.4. See also Supplementary Material Section 8.SM.12 and footnote to Table 8.A.1. As can be seen from Table 8.A.2, some ODS have strong indirect effects through stratospheric ozone forcing, which for some of the gases reduce their net GWP₁₀₀ values substantially (and for the Halons, to large negative values). Note that, consistent with Section 8.3.3, the uncertainties are large; ±100% for this indirect effect.

When climate-carbon feedbacks are included for both the non-CO₂ and reference gases, all metric values increase relative to the methodology used in AR4, sometimes greatly (Table 8.7, Supplementary Material Table 8.SM.16). Though the uncertainties range for these metric values is greater, as uncertainties in climate-carbon feedbacks are substantial, these calculations provide a more consistent methodology.

8.7.2.2 Metrics for Near Term Climate Forcers (NTCF)

The GWP concept was initially used for the WMGHGs, but later for NTCF as well. There are, however, substantial challenges related to calculations of GWP (and GTP) values for these components, which is reflected in the large ranges of values in the literature. Below we present and assess the current status of knowledge and quantification of metrics for various NTCF.

8.7.2.2.1 Nitrogen oxides (NO_x)

Metric values for NO_x usually include the short-lived O₃ effect, CH₄ changes and the CH₄-controlled O₃ response. NO_x also causes RF through nitrate formation, and via methane it affects stratospheric H₂O and through ozone it influences CO₂. In addition, NO_x affects CO₂ through nitrogen deposition (fertilization effect). Due to high reactivity and the many non-linear chemical interactions operating on different timescales, as well as heterogeneous emission patterns, calculation of *net* climate effects of NO_x is difficult. The net effect is a balance of large opposing effects with very different temporal behaviours. There is also a large spread in values among the regions due to variations in chemical and physical characteristics of the atmosphere.

As shown in Table 8.A.3 the GTP and GWP values are very different. This is due to the fundamentally different nature of these two metrics (see Figure 8.28) and the way they capture the temporal behaviour of responses to NO_x emissions. Time variation of GTP for NO_x is complex, which is not directly seen by the somewhat arbitrary choices of time horizon, and the net GTP is a fine balance between the contributing terms. The general pattern for NO_x is that the short-lived ozone forcing is always positive, while the methane-induced ozone forcing and methane forcing are always negative (see Section 8.5.1). Nitrate aerosols from NO_x emission are not included in Table 8.A.3. For the GTP, all estimates for NO_x from surface sources give a negative net effect. As discussed in Section 8.7.1.4 Collins et al. (2010) and Shindell et al. (2009) implemented further indirect effects, but these are not included in Table 8.A.3 due to large uncertainties. The metric estimates for NO_x reflect the level of knowledge, but they also depend on experimental design, treatment of transport processes, and modelling of background levels. The multi-model study by Fry et al. (2012) shows the gaseous chemistry response to NO_x is relatively robust for European

emissions, but that the uncertainty is so large that for some regions of emissions it is not possible to conclude whether NO_x causes cooling or warming.

8.7.2.2.2 *Carbon monoxide (CO) and volatile organic compounds (VOC)*

Emissions of carbon monoxide (CO) and volatile organic compounds (VOC) lead to production of ozone on short timescales. By affecting OH and thereby the levels of methane they also initiate a positive long-term O_3 effect. With its lifetime of 2–3 months, the effect of CO emissions is less dependent on location than is the case for NO_x (see Table 8.A.4). There is also less variation across models. However, Collins et al. (2010) found that inclusion of vegetation effects of O_3 increased the GTP values for CO by 20–50%. By including aerosol responses Shindell et al. (2009) found an increase in GWP_{100} by a factor of ~ 2.5 . CO of fossil origin will also have a forcing effect by contributing to CO_2 levels. This effect adds 1.4–1.6 to the GWP_{100} for CO (Daniel and Solomon, 1998; Derwent et al., 2001). (The vegetation and aerosol effects are not included in the numbers in Table 8.A.4)

VOC is not a well-defined group of hydrocarbons. This group of gases with different lifetimes is treated differently across models by lumping or using representative key species. However, the spread in metric values in Table 8.A.5 is moderate across regions, with highest values for emissions in South-Asia (of the four regions studied). The effects via O_3 and CH_4 cause warming, and the additional effects via interactions with aerosols and via the O_3 - CO_2 link increase the warming effect further. Thus, the net effects of CO and VOC are less uncertain than for NO_x for which the net is a residual between larger terms of opposite sign. However, the formation of SOA is usually not included in metric calculations for VOC, which introduces a cooling effect and increased uncertainty.

8.7.2.2.3 *Black carbon (BC) and organic carbon (OC)*

Most of the metric values for BC in the literature include the aerosol-radiation interaction and the snow/ice albedo effect of BC, though whether external or internal mixing is used varies between the studies. Bond et al. (2011) calculate GWPs and find that when albedo effect is included the values increase by 5–15%. Studies have shown, however, that the climate response per unit forcing to this mechanisms is stronger than for WMGHG (Chapter 7, Section 7.5).

Bond et al. (2013) assessed the current understanding of BC effects and calculated GWP and GTP for BC that includes aerosol-radiation interaction, aerosol-cloud interactions and albedo. As shown in Table 8.A.6 the uncertainties are wide for both metrics (for 90% uncertainty range) reflecting the current challenges related to understanding and quantifying the various effects (see Chapter 7, Section 7.5, Sections 8.3.4 and 8.5.1). Their aerosol-radiation interaction effect is $\sim 65\%$ of the total effect while the albedo effect is approximately 20% of the aerosol-radiation interaction effect. Based on two studies (Rypdal et al., 2009; Bond et al., 2011), the GWP and GTP metrics were found to vary with the region where BC is emitted by about $\pm 30\%$. For larger regions of emissions, Collins et al. (2013) calculated GWPs and GTPs for the direct effect of BC and found somewhat lower variations among the regions.

Several studies have focused on the effects of emissions of BC and OC from different regions (Bauer et al., 2007; Koch et al., 2007; Naik et al., 2007; Reddy and Boucher, 2007; Rypdal et al., 2009). However, examination of results from these models (Fuglestvedt et al., 2010) reveals that there is not a robust relationship between the region of emission and the metric value — hence, regions that yield the highest metric value in one study, do not, in general, do so in the other studies.

The metric values for OC are quite consistent across studies, but fewer studies are available (see Table 8.A.6). A brief overview of metric values for other components is given in the Supplementary Material Section 8.SM.14.

8.7.2.2.4 *Summary of status of metrics for NTCF*

The metrics provide a format for comparing the magnitudes of the various emissions as well as for comparing effects of emissions from different regions. They can also be used for comparing results from different studies. Much of the spread in results is due to differences in experimental design and how the models treat physical and chemical processes. Unlike most of the WMGHGs, many of the NTCF are tightly coupled to the hydrologic cycle and atmospheric chemistry, leading to a much larger spread in results as these are highly complex processes that are difficult to validate on the requisite small spatial and short

temporal scales. The confidence level is lower for many of the NTCF compared to WMGHG and much lower where aerosol-cloud interactions are important (see Section 8.5.1). There are particular difficulties for NO_x , because the net impact is a small residual of opposing effects with quite different spatial distributions and temporal behaviour. While climate-carbon feedbacks for non- CO_2 emissions have not been included in the NTCF metrics (other than methane) presented here, they can greatly increase those values (Collins et al., 2013) and likely provide more realistic results.

8.7.2.3 *Impact by Emitted Component*

We now use the metrics evaluated here to estimate climate impacts of various components (in a forward looking perspective). Figure 8.32 shows global anthropogenic emissions of some selected components weighted by the GWP and GTP. The time horizons are chosen as examples and illustrate how the perceived impacts of components — relative to the impact of the reference gas — vary strongly as function of impact parameter (integrated RF in GWP or end-point temperature in GTP) and with time horizon.

We may also calculate the temporal development of the temperature responses to pulse or sustained emissions using the AGTP metric. Figure 8.33 shows that for a one-year pulse the impacts of NTCF decay quickly due to their atmospheric adjustment times even if effects are prolonged due to climate response time (in the case of constant emissions the effects reach approximately constant levels since the emissions are replenished each year, except for CO_2 which has a fraction remaining in the atmosphere on timescales of centuries). Figure 8.33 also shows how some components have strong short-lived effects of both signs while CO_2 has a weaker initial effect but one that persists to create a long-lived warming effect. Note that there are large uncertainties related to the metric values (as discussed in 8.7.1.4); especially for the NTCF.

These examples show that the outcome of comparisons of effects of emissions depends strongly on choice of time horizon and metric type. Such end-user choices will have a strong influence on the calculated contributions from NTCF vs WMGHG or non- CO_2 vs CO_2 emissions. Thus, each specific analysis should use a design chosen in light of the context and questions being asked.

[INSERT FIGURE 8.32 HERE]

Figure 8.32: Global anthropogenic emissions weighted by GWP and GTP for chosen time horizons (aerosol-cloud interactions are not included). Emission data for 2008 are taken from the EDGAR database. For BC and OC emissions for 2005 are from Shindell et al. (2012a). The units are “ CO_2 equivalents” which reflects equivalence only in the impact parameter of the chosen metric (integrated RF over the chosen time horizon for GWP; temperature change at the chosen point in time for GTP), given as $\text{Pg}(\text{CO}_2)_{\text{eq}}$ (left axis) and given as PgC_{eq} (right axis). There are large uncertainties related to the metric values and consequentially also to the calculated CO_2 equivalents (see text).

[INSERT FIGURE 8.33 HERE]

Figure 8.33: Temperature response by component for total anthropogenic emissions for a one-year pulse. Emission data for 2008 are taken from the EDGAR database and for BC and OC for 2005 from Shindell et al. (2012a). There are large uncertainties related to the AGTP values and consequentially also to the calculated temperature responses (see text).

8.7.2.4 *Metrics and Impacts by Sector*

While the emissions of WMGHGs vary strongly between sectors, the climate impacts of these gases are independent of sector. The latter is not the case for chemically active and short-lived components, due to the dependence of their impact on the emission location. Since most sectors have multiple co-emissions, and for NTCFs some of these are warming while others are cooling, the net impact of a given sector requires explicit calculations. Since AR4 there has been significant progress in the understanding and quantification of climate impacts of NTCF from sectors such as transportation, power production, and biomass burning (Berntsen and Fuglestedt, 2008; Skeie et al., 2009; Stevenson and Derwent, 2009; Lee et al., 2010; Unger et al., 2010; Dahlmann et al., 2011). Supplementary Material Table 8.SM.18 gives an overview of recent published metric values for various components by sector.

The impact from sectors depends on choice of metric, time horizon, pulse versus sustained emissions, and forward versus backward looking perspective (see Section 8.7.1 and Box 8.4). Unger et al. (2010) calculated RF for a set of components emitted from each sector. RF at chosen points in time (20 and 100 years) for

sustained emissions was used by Unger et al. (2010) as the metric for comparison. This is comparable to using integrated RF up to the chosen times for *pulse* emissions (as in GWPs). Such studies are relevant for policymaking that focuses on regulating the *total activity* of a sector or for understanding the contribution from a sector to climate change. On the other hand, the fixed mix of emissions makes it less general and relevant for emission scenarios. Alternatively, one may adopt a component-by-component view which is relevant for policies directed towards specific components (or sets of components, as controlling an individual pollutant in isolation is usually not practical). But this view will not capture interactions and non-linearities within the suite of components emitted by most sectors. The effects of specific emission control technologies or policies or projected societal changes on the mix of emissions is probably the most relevant type of analysis, but there are an enormous number of possible actions and regional details that could be investigated. Henze et al. (2012) demonstrate a method for providing highly spatially resolved estimates of forcing per component, and caution that RF aggregated over regions or sectors may not represent the impacts of emissions changes on finer scales.

Metrics for individual land-based sectors are often similar to the global mean metric values (Shindell et al., 2008). In contrast, metrics for emissions from aviation and shipping usually show large differences from global mean metric values (Table 8.A.3 vs Table 8.A.7). Though there can sometimes be substantial variation in the impact of land-based sectors across regions, and for a particular region even from one sector to another, variability between different land-based sources is generally smaller than between land, sea and air emissions.

NO_x from aviation is one example where the metric type is especially important. GWP₂₀ values are positive due to the strong response of short-lived O₃. Reported GWP₁₀₀ and GTP₁₀₀ values are of either sign, however, due to the differences in balance between the individual effects modelled. Even if the models agree on the net effect of NO_x, the individual contributions can differ significantly, with large uncertainties stemming from the relative magnitudes of the methane and O₃ responses (Myhre et al., 2011) and the background tropospheric concentrations of NO_x (Holmes et al., 2011; Stevenson and Derwent, 2009). Köhler et al. (2013), find strong regional sensitivity of O₃ and CH₄ to NO_x particularly at cruise altitude. Generally, they find the strongest effects at low latitudes. For the aviation sector contrails and contrail induced cirrus are also important. Based on detailed studies in the literature, Fuglestvedt et al. (2010) produced GWP and GTP for contrails, water vapor, and contrail induced cirrus.

The GWP and GTPs for NO_x from shipping are strongly negative for all time horizons. The strong positive effect via O₃ due to the low-NO_x environment into which ships generally emit NO_x is outweighed by the stronger effect on methane destruction due to the relatively lower latitudes of these emissions compared to land-based sources.

In addition to having large emissions of NO_x the shipping sector has large emission of SO₂. The direct GWP₁₀₀ for shipping ranges from -11 to -43 (see Supplementary Material Table 8.SM.18). Lauer et al. (2007) reported detailed calculations of the indirect forcing specifically for this sector and found a wide spread of values depending on the emission inventory. Righi et al. (2011) and Peters et al. (2012) calculate indirect effects that are 30–50% lower than the indirect forcing reported by Lauer et al. (2007). The values from Shindell and Faluvegi (2010) for SO₂ from power generation are similar to those for shipping.

While the various land transport sectors often are treated as one aggregate (e.g., road transport) there are important subdivisions. For instance, Bond et al. (2013) points out that among the BC-rich sectors they examined, diesel vehicles have the most clearly positive net impact on forcing. Studies delving even further have shown substantial differences between trucks and cars, gasoline and diesel vehicles, and low-sulfur versus high-sulfur fuels. Similarly, for power production there are important differences depending on fuel type (coal, oil, gas; e.g., Shindell and Faluvegi, 2010).

In the assessment of climate impacts of current emissions by sectors we give examples and apply a forward looking perspective on effects in terms of temperature change. The AGTP concept can be used to study the effects of the various components for chosen time horizons. A single year's worth of current global emissions from the energy and industrial sectors have the largest contributions to warming after 100 years (see Figure 8.34a). Household fossil fuel and biofuel, biomass burning and on-road transportation are also relatively large contributors to warming over 100 year timescales. Those same sectors, along with sectors

that emit large amounts of methane (animal husbandry, waste/landfills and agriculture), are most important over shorter time horizons (~20 years; see Figure 8.34b).

Analysing climate change impacts by using the net effect of particular activities or sectors may — compared to other perspectives — provide more insight into how societal actions influence climate. Due to large variations in mix of short- and long-lived components, as well as cooling and warming effects, the results will also in these cases depend strongly on choice of time horizon and climate impact parameter. Improved understanding of aerosol-cloud interactions and how those are attributed to individual components is clearly necessary to refine estimates of sectoral or emitted component impacts.

[INSERT FIGURE 8.34 HERE]

Figure 8.34: Net global mean temperature change by source sector after (a) 100 and (b) 20 years (for one year pulse emissions). Emission data for 2008 are taken from the EDGAR database. For BC and OC anthropogenic emissions are from Shindell et al. (2012a) and biomass burning emissions are from Lamarque et al. (2010), see Supplementary Material Section 8.SM.17. There are large uncertainties related to the AGTP values and consequentially also to the calculated temperature responses (see text).

[START FAQ 8.1 HERE]

FAQ 8.1: How Important Is Water Vapour to Climate Change?

As the largest contributor to the natural greenhouse effect, water vapour plays an essential role in the Earth's climate. However, the amount of water vapour in the atmosphere is mostly controlled by air temperature, rather than by emissions. For that reason, scientists consider it a feedback agent, rather than a forcing to climate change. Anthropogenic emissions of water vapour through irrigation or power plant cooling have a negligible impact on the global climate.

Water vapour is the primary greenhouse gas in the Earth's atmosphere. The contribution of water vapour to the natural greenhouse effect relative to that of carbon dioxide depends on the accounting method, but can be considered to be approximately two to three times greater. Additional water vapour is injected into the atmosphere from anthropogenic activities, mostly through increased evaporation from irrigated crops, but also through power plant cooling, and marginally through the combustion of fossil fuel. One may therefore question why there is so much focus on carbon dioxide, and not on water vapour, as a forcing to climate change.

Water vapour behaves differently from carbon dioxide in one fundamental way: it can condense and precipitate. When air with high humidity cools, some of the vapour condenses into water droplets or ice particles and precipitates. The typical residence time of water vapour in the atmosphere is ten days. The flux of water vapour into the atmosphere from anthropogenic sources is considerably less than from 'natural' evaporation. Therefore, it has a negligible impact on overall concentrations, and does not contribute significantly to the long-term greenhouse effect. This is the main reason why tropospheric water vapour (typically below 10 km altitude) is not considered to be an anthropogenic gas contributing to radiative forcing.

Anthropogenic emissions do have a significant impact on water vapour in the stratosphere, which is the part of the atmosphere above about 10 km. Increased concentrations of methane due to human activities lead to an additional source of water, through oxidation, which partly explains the observed changes in that atmospheric layer. That stratospheric water change has a radiative impact, is considered a forcing, and can be evaluated. Stratospheric concentrations of water have varied significantly in past decades. The full extent of these variations is not well understood and is probably less a forcing than a feedback process added to natural variability. The contribution of stratospheric water vapour to warming, both forcing and feedback, is much smaller than from methane or carbon dioxide.

The maximum amount of water vapour in the air is controlled by temperature. A typical column of air extending from the surface to the stratosphere in polar regions may contain only a few kilograms of water vapour per square meter, while a similar column of air in the tropics may contain up to 70 kilograms. With every extra degree of air temperature, the atmosphere can retain around 7% more water vapour (see upper-left insert in the FAQ 8.1, Figure 1). This increase in concentration amplifies the greenhouse effect, and

therefore leads to more warming. This process, referred to as the water vapour feedback, is well understood and quantified. It occurs in all models used to estimate climate change, where its strength is consistent with observations. Although an increase in atmospheric water vapour has been observed, this change is recognised as a climate feedback (from increased atmospheric temperature) and should not be interpreted as a radiative forcing from anthropogenic emissions.

Currently, water vapour has the largest greenhouse effect in Earth's atmosphere. However, other greenhouse gases, and primarily carbon dioxide, are necessary to sustain the presence of water vapour in the atmosphere. Indeed, if these other gases were removed from the atmosphere, its temperature would drop sufficiently to induce a decrease of water vapour, leading to a runaway drop of the greenhouse effect that would plunge the Earth into a frozen state. So greenhouse gases other than water vapour provide the temperature structure that sustains current levels of atmospheric water vapour. Therefore, although carbon dioxide is the main anthropogenic control knob on climate, water vapour is a strong and fast feedback that amplifies any initial forcing by a typical factor between two and three. Water vapour is not a significant initial forcing, but is nevertheless a fundamental agent of climate change.

[INSERT FAQ 8.1, FIGURE 1 HERE]

FAQ 8.1, Figure 1: Illustration of the water cycle and its interaction with the greenhouse effect. The upper-left insert indicates the relative increase of potential water vapour content in the air with an increase of temperature (roughly 7% per degree). The white curls illustrate evaporation, which is compensated by precipitation to close the water budget. The red arrows illustrate the outgoing infrared radiation that is partly absorbed by water vapour and other gases, a process that is one component of the greenhouse effect. The Stratospheric processes are not included in this Figure.

[END FAQ 8.1 HERE]

[START FAQ 8.2 HERE]

FAQ 8.2: Do Improvements in Air Quality Have an Effect on Climate Change?

Yes they do, but depending on which pollutant(s) they limit, they can either cool, or warm, the climate. For example, while a reduction in sulphur dioxide emissions leads to more warming, nitrogen oxide emission control has both a cooling (through reducing of tropospheric ozone) and a warming effect (due to its impact on methane lifetime and aerosol production). Air pollution can also affect precipitation patterns.

Air quality is nominally a measure of airborne surface pollutants, such as ozone, carbon monoxide, nitrogen oxides, and aerosols (solid or liquid particulate matter). Exposure to such pollutants exacerbates respiratory and cardiovascular diseases, harms plants and damages buildings. For these reasons, most major urban centres try to control discharges of airborne pollutants.

Unlike carbon dioxide and other WMGHG, tropospheric ozone and aerosols may only last in the atmosphere for a few days to a few weeks, though indirect couplings within the Earth system can prolong their impact. These pollutants are usually most potent near their area of emission or formation, where they can force local or regional perturbations to climate, even if their globally averaged effect is small.

Air pollutants affect climate differently according to their physical and chemical characteristics. Pollution-generated greenhouse gases will primarily impact climate through shortwave and longwave radiation, while aerosols can in addition affect climate through cloud-aerosol interactions.

Controls on anthropogenic emissions of methane (FAQ 8.2, Figure 1) to lower surface ozone have been identified as “win-win” situations. Consequences of controlling other ozone precursors are not always as clear. Nitrogen oxide emission controls, for instance, might be expected to have a cooling effect as they reduce tropospheric ozone, but their impact on methane lifetime and aerosol formation is more likely instead to cause overall warming.

Satellite observations have identified increasing atmospheric concentrations of sulphur dioxide (the primary precursor to scattering sulphate aerosols) from coal-burning power plants over eastern Asia during the last few decades. The most recent power plants use scrubbers to reduce such emissions (albeit not the concurrent carbon dioxide emissions and associated long-term climate warming). This improves air quality, but also

reduces the cooling effect of sulphate aerosols and therefore exacerbates warming. Aerosol cooling occurs through aerosol-radiation and aerosol-cloud interactions and is estimated at -0.9 W m^{-2} (all aerosols combined, Section 8.3.4.3) since pre-industrial, having grown especially during the second half of the 20th century when anthropogenic emissions rose sharply.

Black carbon or soot, on the other hand, absorbs heat in the atmosphere (leading to a 0.4 W m^{-2} radiative forcing from anthropogenic fossil and biofuel emissions) and, when deposited on snow, reduces its albedo, or ability to reflect sunlight. Reductions of black carbon emissions can therefore have a cooling effect, but the additional interaction of black carbon with clouds is uncertain and could lead to some counteracting warming.

Air quality controls might also target a specific anthropogenic activity sector, such as transportation or energy production. In that case, co-emitted species within the targeted sector lead to a complex mix of chemistry and climate perturbations. For example, smoke from biofuel combustion contains a mixture of both absorbing and scattering particles as well as ozone precursors, for which the combined climate impact can be difficult to ascertain.

Thus, surface air quality controls will have some consequences on climate. Some couplings between the targeted emissions and climate are still poorly understood or identified, including the effects of air pollutants on precipitation patterns, making it difficult to fully quantify these consequences. There is an important twist, too, in the potential effect of climate change on air quality. In particular, an observed correlation between surface ozone and temperature in polluted regions indicates that higher temperatures from climate change alone could worsen summertime pollution, suggesting a “climate penalty”. This penalty implies stricter surface ozone controls will be required to achieve a specific target. In addition, projected changes in the frequency and duration of stagnation events could impact air quality conditions. These features will be regionally variable and difficult to assess, but better understanding, quantification and modelling of these processes will clarify the overall interaction between air pollutants and climate.
